Preface

We celebrate the new millenium with the fourth edition of *Primary Care Medicine*. In the twenty years since publication of the first edition, the primary care agenda has expanded from the modernization of generalism to reform of health care delivery. Propelled by its emphasis on comprehensive care and coordination, primary care has moved from the periphery of medicine to center stage. With this move comes ever-increasing pressure to ensure that care is not only personalized and high-quality, but also cost-effective. Such responsibilities and expectations pose both the challenge and promise of modern primary care, which the fourth edition is designed to help learners master and practitioners fulfill.

Those who have used the book in the past will recognize our continued commitment to a terse yet thoughtful, problem-based style. A comprehensive index plus well-marked chapter sections, subsections, and chapter cross-references facilitate quick, easy location of desired information. Emphasis is placed on key clinical data essential to decision-making and on critical use of tests and therapies that truly add value to overall management. Practical recommendations that incorporate the best available evidence, expert consensus guidelines, clinical judgment, and everyday common sense are put forward at the end of every chapter (often in bulleted form). Each chapter includes an annotated bibliography that highlights and encourages the reading of the best available studies and analyses; over 2,000 new references have been added for this edition.

Like previous editions, this edition represents a major rewriting. Every chapter has been revised and many extensively rewritten to incorporate the important advances in medicine that have taken place over the last 5 years. Major changes in the approach to such conditions as HIV infection, diabetes, syncope, coronary disease, heart failure, peptic ulcer disease, osteoporosis, menopause, hepatitis, rheumatoid arthritis, inflammatory bowel disease, and asthma are covered in depth. New sections on chronic pain, domestic violence, ethical challenges of managed care, adolescent medicine, and alternative/complementary medicine have been added, reflecting further expansion of the primary care role and new treatment modalities. The best evidence on safety and efficacy of alternative/complementary therapies is provided to facilitate patient education and rational choice of therapy. Moreover, the chapters on estimating and communicating risk and prognosis and on interpreting evidence of therapeutic efficacy are designed to help provide the thoughtful advise and effective counsel patients expect and appreciate from their primary care physician, even in this era of "surfing the net."

We continue to be deeply moved and humbled by the enthusiastic responses to each new edition of *Primary Care Medicine*. The editors and our colleagues have worked hard to make this edition the best one yet and hope it will prove useful for learning and patient care. In keeping with its pioneering tradition (e.g., first textbook in the field), *Primary Care Medicine* is about to become the first "living" textbook of primary care, to be continuously updated and made available on the internet as new advances emerge from the scientific literature. See you on the Web!

Acknowledgments

PART 1 PRINCIPLES OF PRIMARY CARE

CHAPTER 1 THE PRACTICE OF PRIMARY CARE

Part 1: The Tasks of Primary Care

JOHN D. STOECKLE

DEFINITION OF PRIMARY CARE

Primary care is coordinated, comprehensive, and personal care, available on both a first-contact and a continuous basis. It incorporates several tasks: medical diagnosis and treatment, psychological assessment and management, personal support, communication of information about illness, prevention, and health maintenance.

This book addresses the clinical problems encountered by primary care physicians in the office practice of adult medicine. In this setting, the physician's responsibilities and tasks extend beyond the narrow technologic confines of medical diagnosis and treatment. Although a great deal of effort must be focused on accurate diagnosis and technically sound therapy, the other clinical tasks that complete the very definition of primary care also assume major importance.

Alongside this clinical definition of primary care stands a plethora of other definitions; these derive from organizational, functional, professional, and academic perspectives. For example, policy planners have defined primary care as a *level of medical services*, one that is provided outside the hospital. Presumably, primary care (community-based services) is, then, a less technical practice in comparison with secondary care (consultant or specialty services) and tertiary care (hospital services). This organizational definition provides a scheme for the allocation of public resources among these health services, each of which has a distinct professional, economic, institutional, and political structure. For another definition, Alpert and Charney have looked at important *patient care functions* of doctors—namely, to provide access, continuity, and integration. Although this view is useful in describing the functions performed by practitioners for their patients within organized health services, it does not define the content of their clinical work. From the standpoint of professionalism, primary care has been defined as a *specialty* concentrating on general medicine practiced outside the hospital but devoid of the special procedures and technology that typically characterize specialization. This definition has been useful in organizing general internal medicine, general pediatrics, and family practice and in designing a new curriculum for the education and training of doctors. From the university comes still another definition of primary care as an *academic discipline* concerned with the expansion of knowledge unique to primary practice and personal care, a definition that contains the promise of a departmental position for primary care in the medical school.

Although each of these definitions presents a particular perspective about primary care and serves some special purpose, none explains the primary care physician's day-to-day work with patients.

From the perspective of the doctor's practice, primary care can be defined by several tasks: (a) medical diagnosis and treatment; (b) psychological diagnosis and treatment; (c) personal support of patients of all backgrounds, in all stages of illness; (d) communication of information about diagnosis, treatment, prevention, and prognosis; (e) maintenance of patients with chronic illness; and (f) prevention of disability and disease through detection, education, behavioral change, and preventive treatment. These tasks comprise the clinical work of doctors providing primary care. They not only restate medicine's central mandate of patient care but also constitute a clinical definition of primary care to which the information in this text is applied.

TASKS AND THEIR RATIONALE

Except for medical diagnosis and treatment, the tasks that define primary care may seem merely vocational—that is, practical but not scientifically based. However, social science research has provided a logical and rational basis for the clinical work of primary care. Attention to the skillful conduct of these tasks appears to improve outcomes and reduce the risk that patients will file malpractice claims. The data derived from these studies concern the patient's *illness* rather than the doctor's definition of *disease*; they are contained in the cognitive, communicative, and behavioral processes by which the patient defines being ill; and they are found in the clinical and social science literature on such topics as the patient's emotional reactions, personality, expectations, requests, attributions, views of treatment, and social networks, to mention but a few. Knowledge concerning such aspects of care in conjunction with statistical thinking contributes a rational framework for the tasks of primary care.

Medical Diagnosis and Treatment Medical diagnosis and treatment remain central tasks, although they are by no means the end point of care. As the patient's first contact with medical services, the primary doctor not only must be knowledgeable about disease but also must exercise critical judgment in determining the scope, site, and pace of the medical workup and management. In organizing diagnosis and management, the physician needs to know the clinical presentation and natural history of illness, the uses and limits of the laboratory, and the indications for and shortcomings of invasive tests and therapeutic measures. In continuing care, the issues are the same. The doctor's critical attitude toward the use of technology and the referral of patients for special therapies or diagnostic techniques remains essential. Methods developed in clinical epidemiology and decision analysis that help the clinician rationally choose among a sometimes bewildering array of diagnostic and therapeutic options are discussed in Chapter 2 and Chapter 5.

Psychological Diagnosis and Treatment and Personal Support. Physical diiagnosis and treatment and personal support complement the medical components of care. Studies documenting the relationship between emotional reactions and illness, coupled with surveys showing a high frequency of such reactions in office practice, underscore their importance in patients seeking medical help. The recognition of anxiety, depression, sexual dysfunction, personality disturbance, and psychosis is necessary for the interpretation of bodily complaints, the communication of personal feelings, and the joint decision of doctor and patient regarding acceptable and effective treatment plans. The recognition of emotional reactions alone is insufficient. The doctor's response to the normal patient's psychological defenses is essential to securing cooperation and relieving anxiety. Understanding the patient's defenses and personality style allows the clinician to provide meaningful support and respond appropriately to the patient's emotional needs. The care rendered is then likely to be perceived as personal and psychologically acceptable. Much of this analysis of the psychological aspects of clinical practice derives from classic case studies by Kahana and Bibring, Lipsett, Balaint, and Zaborenko et al. on the emotional reactions and personality traits of patients with medical disorders. More recent qualitative surveys of medical practice populations document the importance of emotional states, especially depression, in the outcome of treatment. Written exercises involving emotional expression have been shown in randomized trials to increase subjective well-being, decrease care-seeking behavior, and improve outcomes of some chronic conditions.

Eliciting and Addressing Patient Expectations and Requests. Eliciting and addressing patient expectations and requests are also important. *Expectations* often play a major part in seeking help, complying with treatment, and feeling satisfied with care. In their studies of illness behavior and patients' use of doctors, Zola and Mechanic viewed expectations as explanations of patients' decisions to see a doctor. In health centers in Israel, Shuval et al. found specific expectations of visits to doctors: status enhancement in seeing socially important professionals; catharsis of grief, anger, and despair; sanctioning of failure to cope; and understanding and control of illness through medical "scientific" explanations. This brief list is by no means complete, for along with these so-called latent expectations are traditional or "real" medical ones—for example, that the doctor is a healer of disease and possesses techniques for its control, relief, or cure. Such expectations not only explain the decision to seek medical care but also are, in fact, elements of the clinical tasks of personal support and communication of information about illness.

Newer clinical studies by Lazare and colleagues have separated *requests* from expectations. Requests are specific and concrete helping actions and behaviors

identified by patients. These studies identified some 14 requests and demonstrated that their prompt recognition and negotiation benefited both patient and doctor. The doctor's interest in ascertaining what treatment the patient wants indicates a reciprocity that is associated with greater satisfaction and adherence to medical advice. These efforts are part of the task of personal support and management. Still other elements of the management task, such as decisions about continued care, referral, and discharge, are also realized through an understanding of requests; thus, physicians need both to elicit and to respond to them.

Communication of Information about Illness. The need to inform, explain, reassure, and advise patients is essential to primary care. This task often depends on a knowledge of the patient's attributions (i.e., what the patient thinks is the cause of illness). If the patient's *attributions* differ from the doctor's and are not uncovered, the patient's anxieties may not be relieved, nor will the doctor's explanation be accepted. Knowing how and what to tell the patient about an illness is often difficult, especially if the patient's interpretation of the illness has not been elicited.

Mechanic, for example, suggests that patients with bodily complaints may go to the primary care doctor not for relief of physical discomfort but rather to learn what is causing their complaints and sometimes to obtain reassurance that the causes of their complaints are less serious than they may have thought. Such confirmation or correction of the patient's attributions is a kind of "attribution therapy." From a broader perspective, Kleinman assigns to attributions a major function in all medical care systems—namely, the control of illness through the explanation of its cause. In effect, the doctor's clinical or scientific explanations of illness provide labels, names, and models so that the patient feels the illness can be understood and controlled, regardless of its technical treatment. In essence, the patient's beliefs about illness need to be elicited so that they can be used in explanation, education, and reassurance (see Appendix).

Maintenance of the Chronically Ill. Maintenance of the chronically ill requires continuous, long-term treatment and is a distinct task of primary care. Here, obtaining patient compliance is essential because most long-term treatment now takes place without daily medical supervision, and most of that treatment requires the self-administration of drugs. To improve adherence to therapy, it has become increasingly important to learn about the *patient's views of treatment* and actual self-treatment. So far, the record on adherence to treatment has not been good. A wide discrepancy between what is prescribed and what is done typifies the literature of "following the doctor's orders," and the problem seems to be as much the doctor's as the patient's.

Knowledge about patients' views and behaviors can be used to design more effective therapeutic regimens and to alter therapeutic directions. Moreover, the act of eliciting information may improve communication between doctor and patient, thus strengthening their relationship and further promoting therapeutic efforts. More studies of patient views of treatment and of the dynamics of the doctor–patient relationship should provide new knowledge that can be used to enhance compliance.

Prevention of Disease and Disability. Prevention of disease and disability, an essential task of primary care, emphasizes screening and the assessment of risk and function. With early intervention through health education, behavioral change, and preventive treatment, some of the expected morbidity, disability, and mortality may be delayed—if not prevented—and costly technologic interventions and therapies avoided. The primary physician needs to know which conditions and risk factors are worth screening for and how best to detect and effectively manage them (see Chapter 3).

A less commonly considered but no less important aspect of prevention involves attention to the patient's *social network* because illness is often precipitated by a disruption of interpersonal relationships. For example, Parkes and others have noted an increased mortality and morbidity among recent widows, and Zola has reported that interpersonal crises are among the most frequent of five common circumstances that motivate patients to seek medical attention. Knowledge of patients' social situations can help in the prevention of illness and visits to the doctor by focusing attention on stresses that might be precipitants. Attention to social networks is important for personal treatment. If significant loss or separation occurs, a major part of treatment can involve helping the patient reestablish a social network, thus lessening dependence on professional help from the doctor, nurse, or social worker. Patient illness narratives and doctors' clinical experiences illustrate that much of the work of care is done by patients themselves, their families, and their informal networks. Helping patients to share the preventive work with others can be of major benefit.

THE PROMISE OF PRIMARY CARE MEDICINE

So far, the clinical tasks of primary care have been proposed as a perspective from which readers can view the information in this text. In addition, the tasks also promise changes in our ideas about standards of treatment, doctor–patient relations, professional relations, organization, prevention, clinical excellence, and clinical effectiveness.

Treatment. The ideal of personal treatment is revived and reemphasized. Although it is not entirely dead, the increasing size, specialization, and organization of practice often make personal, patient-oriented treatment a luxury rather than a medical care necessity. Patient-centered treatment also means that specific therapeutic regimens must be not only technically correct but also designed to be acceptable to patients, especially because more patients than ever are being cared for on an outpatient basis.

Doctor–Patient Relationship. Patient-centered treatment in primary care practice implies a doctor–patient relationship in which the doctor acts out several behaviors that will enhance the patient's participation in care and treatment:

1. Making the relationship more democratic by eliciting and responding to patients' preferences in decisions regarding the scope of diagnosis and alternatives of treatment.
2. Developing patient participation by transmitting appropriate information so that patients can make intelligent choices.
3. Attending to patients' feelings about illness and treatment with regard, genuine concern, and empathy.
4. Providing helping actions that are person-centered by eliciting, acknowledging, and responding to patients' own perspectives of their illness and care.
5. Responding by negotiation to patients' choices, decisions, and requests; similarly, acknowledging and negotiating conflict, even if in the relationship itself.
6. Promoting health education, self-help, and preventive behaviors by communicating information about diagnosis, treatment, and prevention.
7. Conveying respect for the person of the patient without regard to the patient's gender, race, ethnicity, age, or social class.

Social Change and the Doctor–Patient Relationship. Changes in our patient population, practice organization, and information technologies require changes in the uses of the relationship to continue the improvement of care. Interpreters for the interview, assessments of the aged, advocacy for patients' treatment, and skill in the use of information technologies for patient education are needed.

Today, our patient population is older and more multicultural, trends that are predicted to continue as the United States remains an open society and longevity increases with better control of chronic disease. Patient care now requires understanding varied cultural backgrounds and performing functional assessments of older patients. The doctor in the clinical interview often needs the skills of a trained interpreter, not just the help of a family member. With older patients, there is the need to assess visual, auditory, vocal, and cognitive functions to help overcome or cope with communication barriers.

In a market economy of health care, practice organizations are becoming larger, incorporated, managed, and often commercialized. In incorporated practices, more physicians are employees. The doctor's shared decision making with the patient is often monitored and sometimes restricted, depending on health care plans and insurers. In the managed care setting, patients look upon the doctor to be their advocate and protect their interests.

With modern information technologies (especially through the Internet and Worldwide Web), patients can access and receive more information and instruction on disease management and obtain more mutual support and personal advice than ever before. Such improved access to information, if facilitated and guided by the primary care physician, can promote better patient understanding, compliance, and self-care.

Recent data suggest that patients more often than not fail to share their Internet search findings with their primary care physician. The reasons are not well described, but the result is a potential information divide in the doctor-patient relationship. To prevent or overcome such a division, several steps are recommended: (a) Ask patients about Internet use when reviewing their condition and its treatment. (b) Review with them the information they have obtained; help put it in context. (c) Avoid being defensive or pejorative about their searches; build on their desire for accurate medical information by providing suggestions for further reading. (d) Help patients to obtain reliable information; direct them to authoritative websites and teach them how to differentiate reliable sites from those that should be avoided.   **Updated: 4/29/02**

Organization. The ambulatory practice organizations outside the hospital (offices, health centers, group practices, health maintenance organizations) have become essential sites for the delivery of primary care services. Because the goals of primary care include not only cure but also prevention and health maintenance, the ambulatory setting emerges as the major organizational locus for the delivery of primary care services. The move to outpatient care has been greatly facilitated by the

direct availability to the primary physician of the major technologies for screening, diagnosis, and treatment. Even the management of chronic illness, one of society's major health problems, is now largely conducted in the outpatient setting.

Prevention. The ideal of prevention in practice has been to deal with the individual patient seeking help. Primary care medicine also examines the epidemiology of the entire practice, and even its community base, to institute a program of effective preventive intervention.

Clinical Excellence and Ethics. Skills in medical diagnosis and treatment have often been the only measure of clinical excellence. The ideal of excellence is now expanded to include all the tasks of primary care, the communicative as well as the technical. In making decisions about the use of technologies, new ethical considerations are also required. For the public accountability of medical practice, the primary physician must support professional group efforts that scientifically examine the appropriate use of medical technologies. These are now being conducted as outcome, clinical effectiveness, technology, and evidence-based assessments. In the care of individual patients, the primary physician must continue to elicit preferences and exercise discretionary decisions regarding the personal needs and benefit of each patient.

Clinical Effectiveness. The usual objective criteria for efficacy of diagnosis and treatment have been derived from the standards of clinical science. Consideration of subjective parameters, such as patient acceptance and a sense of well-being, is mandatory in the primary care setting and must be added to the assessment of clinical efficacy.

These themes on the clinical tasks and promises of primary care run through the chapters that follow, sometimes explicitly, sometimes latently; however, they are always central to providing personalized care to patients.

Part 2: Approaches to Common Ethical and Legal Issues in Primary Care Practice

LINDA L. EMANUEL

Being a patient's primary physician necessitates the skillful management of several key ethical and legal issues. These include maintenance of confidentiality, provision of informed consent, assistance in developing a health care proxy and living will, and determination of patient incompetence. The advent of managed care and new incentive schemes raise a host of ethical problems that need to be addressed. Timely and skillful attention to the basics in these areas can greatly facilitate care and minimize problems later on for both patient and physician.

CONFIDENTIALITY

Trust—the *sine qua non* of the patient–doctor relationship—requires that patients' confidences be kept by the physician. This precept is well articulated in the Hippocratic Oath. It is also honored in the law as part of the constitutional right to privacy. Physicians should be able to reassure the patient who is concerned about confidentiality of the primacy and privacy of the patient–doctor relationship. However, there are some limits to this confidentiality, and these should be clarified and discussed with the patient at the earliest relevant moment.

Limits to Confidentiality. Confidentiality is limited by the imperative *to protect third parties from harm*, as may occur, for example, when a patient reveals to a psychiatrist a plan to murder someone. In everyday primary care practice, balancing obligations to the patient with obligations to a third party depends on an assessment of relative harms. This can be a difficult judgment. One such example is the reporting of a venereal disease or AIDS to the patient's sexual contact(s). State requirements vary. Persuading the patient to reveal the information directly to the third party often allows the discharge of all obligations to the third party with minimal damage to the patient–doctor alliance. Occasionally, confidentiality must be breached when it is *in the best interests of the patient*, although this rule should be used sparingly. The physician should reveal the minimum that is necessary in such situations.

Sometimes, the *physician's role* or *responsibility* limits the ability to keep a patient's confidence. A physician employed by a company, school, military unit, or court has split allegiances, which the patient must be made aware of at the outset. Medical information must be reported to insurance companies in many cases, but not all, and the consent of the patient is always required before this can occur. More subtle constraints on confidentiality can arise when *medical records* are readily accessed by other employees, such as those in a billing office. Policies and procedures for affording extra protection to patients who may be known to employees are indicated. Physicians may receive *court subpoenas*, in response to which they must appear in court with the appropriate information. A patient's privilege to bar the physician from testifying may be invoked but certainly can be overruled by the court.

Sharing of Information within the Limits of Confidentiality. Sharing of information about a patient among members of the health care team is rarely problematic. However, the risk of losing sight of the confidential nature of the relationship with the patient rises as the number of persons included in the health care team increases; this is a problem that needs to be guarded against. Patient information used for teaching rounds or publication should be carefully edited to remove any identifying features.

Involving family or friends in a patient's care is often in the best interests of the patient, but sharing patient information with them must be preceded by the patient's explicit permission. When family members reveal information relevant to the patient that they ask the physician to withhold from the patient, the request cannot be honored, and the family should be made aware of this obligation ahead of time if possible. The conflict may be resolved by persuading the family of the inadvisability of such secrecy.

Patient Data in Large Electronic Systems. With the use of computer-based records and central support systems has arisen the issue of how to maintain the proper confidentiality of patient records in large electronic systems. Among other concerns, protective measures must still allow the desirable use of information—for example, for systematic quality improvement or approved research activities. The issue is largely an institutional policy matter, and quality improvement and research information in many cases can be pursued without a breach of patient confidentiality by the use of only de-identified, aggregate data. However, individual physicians should be sure that the institution in which they work provides suitable confidentiality protection in the electronic medium, and that physicians and others abide by the protective measures. These should include the use of personal identification codes for access to computers that hold patient information. If a physician has concerns about the inappropriate use of information, even after working to improve the system, possibly separate personal computers (with user codes and frequent backup to prevent loss of data) or paper-only files may be an appropriate option.

Improperly Motivated Requests for Confidentiality. Such requests may be encountered from patients with seductive, suicidal, hostile, or criminal intentions. The physician should immediately involve another colleague, either as chaperone or consultant, and document the encounter. These steps will serve to protect the physician from such charges as sexual misconduct, harboring a fugitive, or facilitating a suicide. They also help to preserve good judgment and justified levels of confidentiality, and they free the physician from the intimidating nature of the secret.

FINANCIAL INCENTIVES

Medicine is a profession with its own standards for handling financial matters. Major medical ethics codes all note the need to avoid financial exploitation of patients, many of whom are in situations such that they would spend unfair amounts of money in the hope of securing their health.

Reasonable and Honest Charges. Physicians should charge or help ensure that their institutions charge fees that are not exorbitant. In addition, physicians should avoid charging for services, such as referral, that involve minimal work and for services provided by other colleagues, as the other colleague will bill for these services. Reimbursement claims should honestly describe the service rendered and should avoid claiming for subcomponents of the service for the purpose of securing a higher reimbursement rate. If the physician feels unable to secure needed services for patients within a set of billing or reimbursement standards, attempts should be made openly and honestly to bring changes to the system.

Fee-splitting Arrangements. Self-employed and group practice physicians working within fee-for-service systems need to avoid arrangements such as "self-referrals" and "kickbacks." Such arrangements include those in which physicians refer patients to facilities in which the physician has a financial interest or to other physicians who pay the referring physician a referral fee, and those in which physicians receive payment from a drug company for each prescription written for a specified drug. These arrangements can influence a physician to recommend actions that are not so much in the patient's interest as in the physician's financial interest.

Incentives. Physicians employed in a managed care environment often face incentives that are in place to influence their treatment decisions. Although some argue that physician incentives are a good thing if they are aligned with patient interests, others note that they encourage physicians to follow their personal interests when instead professionalism requires that physicians be altruistic and serve patient needs. Either way, individual physicians working in a system that uses incentives should be sure that the incentives are (a) a relatively small proportion of a physician's income, (b) paid relatively infrequently, (c) shared by a group of physicians rather than applied to individuals, and (d) designed in such a way that they foster good patient care. A useful rule of thumb may be to ask the following question:

Would the physician be embarrassed to disclose the incentive arrangement to the patient? These standards may minimize the inappropriate influence of incentives. If incentive systems deviate from professional standards, physicians can work within the institution to effect change and if necessary can also decline to receive inappropriate incentives.

INFORMED CONSENT

Informed consent is much more than a legal document. In fact, a signed document in the absence of a valid discussion with the physician is unlikely to be of legal benefit. Informed consent is a continuing part of the patient–physician relationship and involves the giving and interpretation of information, deliberation, and joint decision making. As such, informed consent represents an integral part of the continuing therapeutic alliance.

Informed consent is required for most nonemergent decisions, whether routine or major.

Required Components of Information Giving and Consent. Laws and legal opinions have defined the following required components of information giving: The patient must receive a description of the *nature of the treatment*, the associated risks (both major and frequent), and their expected time of occurrence. It is neither reasonable nor appropriate for the physician to furnish an exhaustive catalogue of risks; the physician's role here is to provide relevant information and judgment. The *expected benefits* and *alternative treatments* should also be reviewed relative to the recommended action.

Each component of informed consent can be pursued to varying levels of intensity. The courts initially adopted a "*standard of practice*" criterion in which the physician was expected to provide information according to the standards of current practice in the community. Later, the criterion shifted toward providing what a hypothetically "*reasonable person*" would want to know. Presently, a mixed standard is in general use. In practice, valid consent is most likely to be given when information giving is tailored to suit the needs of the individual patient.

Consent also has required components. First, there must be an *understanding of the information* by the patient. A practical means of assessing understanding is to ask the patient about concerns and expectations; the responses can guide further information giving. Second, the decision must be *voluntary*. However, persuasion is fully appropriate, and physicians need not feel constrained from expressing their best medical judgment.

Consent to Research. Consent by a patient to participate in a research protocol requires that particular attention be paid to the patient's sense of volunteerism and understanding. The design of the study protocol must be fully understood. Randomized, controlled trials require patients to take the chance of receiving the standard treatment instead of what may be the desired treatment. In some trials, patients also take the chance of receiving placebo treatment, and in double-blind studies, the patient's physician will not know which treatment the patient is receiving. The benefit to patients in the control arm may be limited to improved monitoring.

Patients must understand that the physician may have conflicting interests. For example, there may be a gain in collegiality, career advancement, or even material benefit. Many of these interests are inevitable and acceptable, but they must be fully disclosed and discussed with the patient. Reassurance of a true primary commitment by the physician to the patient should be possible. If such a primary commitment to the patient is lacking, the patient should be transferred to another physician for care or should not participate in the research protocol.

ADVANCE DIRECTIVES FOR HEALTH CARE: LIVING WILLS, PROXY DECISION MAKERS, AND COMPREHENSIVE DIRECTIVES

The term *advance directives* refers to provisions made by patients to direct their health care in case of future incompetence. Advance directives are written statements and can include a living will and the designation of a proxy decision maker (sometimes referred to as *durable power of attorney for health care*). Ideally, advance directives combine both modalities. They are inactive until such time as incompetence occurs.

The Office Discussion. For the sake of clear communication, advance directives should be completed in the context of a discussion with the patient and witnessed by the person who will be the designated proxy decision maker. Outpatients have been found to be very receptive to advance planning, often expecting physicians to take the initiative. When structured around the completion of an advance directive document, the core discussion can be expected to take about 15 to 30 minutes. Interval follow-up discussions are appropriate and particularly relevant at times of a significant change in the patient's health or personal circumstances. Although it is common to undertake advance planning for the elderly and seriously ill, planning for the young and healthy can be quite worthwhile. Planning discussions can be regarded as a good investment of time in that they can make subsequent difficult decisions more efficient. Moreover, they help build a quality relationship of shared decision making around the patient's goals and the physician's expertise and efforts at health promotion.

As important as any other components of advance care planning are the education and sense of readiness provided to the patient, proxy, and physician. These discussions foster a sense of participation and consensus and consign documents and legalities to their proper role as necessary but peripheral components.

Choosing the Document. Using a standardized, worksheet-type document or the outline of a document can be very helpful. A well-designed worksheet facilitates discussion. Many facilities have recommended documents available, and some generic documents have been designed to be binding in all states. Usually, there are separate documents for a written statement of preferences and for the designation of a proxy, although more efficient documents combining the two exist. If a patient has a document already drawn up, the physician should review it with the patient. It is helpful to include scenarios in the document, and they should cover a range of prognoses, disabilities, and treatment choices, so that the patient's threshold for withholding or withdrawing treatment can be ascertained. Patients should be advised that advance directives can elect for intervention as well as withdrawal or withholding of treatment, depending on the situation. Treatment decisions should be as specific as possible and linked to statements regarding the goals of intervention and general values of health care.

Legal Considerations. Federal law requires that patients be informed of hospital policy regarding living wills at the time of admission and be asked whether they have any advance directives already drawn up. This information must be entered into the medical record. Advance directives must be honored under constitutional law as a statement of the patient's autonomous wishes. Rarely, there may be a conflict between a patient's wishes and local statutes. For example, some states restrict the withdrawal of nutrition and hydration to terminally ill patients, which potentially prevents withdrawal from hopelessly but not terminally ill patients, such as those in a persistent vegetative state. The patient should be informed if conflict exists. Conflicts related to differences in values between the patient and physician should be discussed fully so that they can be resolved before problematic decisions arise. An inability to resolve the conflict is cause for asking the patient to agree to transfer of care should the circumstances in question arise.

PATIENTS WHO ARE CONFUSED OR REFUSE CARE

Many treatment refusals arise from fear, perceived loss of control, distrust, or anger. Discussing patient concerns in a receptive, respectful manner that also offers the patient some choices and a sense of control often suffices to reverse the refusal. Treatment refusal may be a result of patient incompetence, but other refusals may be well reasoned and valid.

Right to Refuse Treatment. The right to refuse medical care is strongly endorsed by the law as part of a constitutional right to privacy. The Supreme Court has affirmed that this right exists for competent patients, incompetent patients with explicit preferences, and even incompetent patients without explicit preferences (although the right is more difficult to implement in this circumstance). Treatments that have been determined in case law to be terminable range from mechanical respiration to artificial nutrition and hydration. The Patient Self-determination Act of 1990 requires that patients be reminded on enrollment in or admission to a health care facility of their right to accept or refuse medical treatment.

However, the right to refuse care is *not absolute*. It can be limited by opposing interests. Some states invoke their interest in preserving life to restrict withholding or withdrawing of life-sustaining treatments from incompetent patients unless they are terminally ill or, in some states, in a hopeless or persistent vegetative state. The protection of minors may limit a competent patient's right to refuse treatment.

Declaring and Determining Incompetence. If a patient's refusal of care appears related to mental or psychological incompetence(s), the patient can be declared incompetent and the refusal can be overridden. Incompetence is commonly declared by the physician, sometimes with the help of a consulting psychiatrist. Review by an institutional ethics committee or even the judiciary should be considered if (a) a question arises about who should be the surrogate decision maker for the patient; (b) legal action is current or anticipated; or (c) the case involves the termination of life-sustaining treatment in the absence of a valid advance directive to that effect.

Determining incompetence involves assessing inability to make the individual decision at hand. Competence is not an all-or-nothing state. A patient may be competent for some decisions but incompetent for others. There are four minimum standards of competence: The patient must (a) be able to *communicate a choice*; (b) have an adequate *factual understanding* of information relevant to the decision (e.g., be able to paraphrase the information); (c) *appreciate the implications* of the decision; and (d) be able to *manipulate relevant information rationally*. Rational manipulation refers to the ability to understand, for example, not only that nontreatment of a gangrenous limb may result in death, but also that death means the end of life.

If incompetence is determined, a proxy decision maker should be appointed promptly. Generally, this person should be someone other than the physician and will be responsible for speaking with the physician on behalf of the patient.

SEXUAL BOUNDARIES AND THE PATIENT–PHYSICIAN RELATIONSHIP

The intimacy of the patient–physician encounter and the trust required for the therapeutic encounter together require that personal boundaries be clear and well maintained. One such boundary concerns sexual behavior. A unanimous standard throughout major traditions in medicine is that physicians should not engage in sexual relations with their patients. Variations in opinion tend to relate to matters of definition—what exactly constitutes a sexual touch, for instance—and to questions such as whether or not the prohibition applies to former patients.

In general, physicians should stay well away from sexual behavior in the professional context and avoid behavior that tests any fine distinctions. One allegation of sexual misconduct can end an entire medical career. If any concerns arise—for instance, if the physician's instincts suggest that such feelings exist on either side and certainly if a patient makes sexual overtures—some of the following steps may help. Involve a chaperone, especially during the physical examination of any sexual region of the anatomy. Ask a colleague on your team for additional insight; a nurse may be able to provide important feedback about patient perceptions. Consult a physician colleague; apart from receiving helpful advice, shared information is less likely to become a coercive secret. Spend enough quality time with friends and family to be secure in your personal life. Consider displaying evidence of personal commitment, such as photographs of loved ones on your desk, a code of ethics on the wall, and so forth.

CHAPTER 2 SELECTION AND INTERPRETATION OF DIAGNOSTIC TESTS

Laboratory investigations are often essential to patient care. Although the history and physical examination remain the foundation of a clinical database and sometimes suffice, the limits to what we can know about a patient are continually expanding with the addition of new diagnostic tests. These tests have many uses: to make a diagnosis in a patient known to be sick; to provide prognostic information for a patient with known disease; to identify a person with subclinical disease or at risk for subsequent development of disease; and to monitor ongoing therapy. The ultimate objective is to reduce morbidity and mortality and increase satisfaction and the sense of well-being. If the physician and patient are to reach these objectives, they must avoid some pitfalls along the way that can result from misuse or misinterpretation of laboratory tests.

Pitfalls are more likely to be avoided if the physician appreciates the inherent uncertainty and probabilistic nature of the diagnostic process and understands the relationship between the characteristics of a diagnostic test and those of the patient(s) being tested. Sometimes, a diagnosis is evident when a patient presents with a pathognomonic constellation of signs and symptoms. In most cases, however, presenting signs or symptoms are not specific. Rather, they can be explained by a number of diagnoses, each with distinctly different implications for the patient's health. On completion of the history and physical examination, the clinician considers a list of conditions, referred to as the *differential diagnosis*, that might explain the findings. The diagnoses can then be ranked to reflect an implicit assignment of probabilities to each. Such a ranking can be thought of as the physician's index of suspicion for each condition, based on knowledge and past experience with similar patients. The purpose of subsequent laboratory testing is to refine the initial probability estimates and, in the process, to revise the differential diagnosis. The probability of any particular disease on the revised list will depend on its probability of being present before testing and the validity of the information provided by test results.

VOCABULARY OF DIAGNOSTIC TEST INTERPRETATION

Terminology is important in diagnostic test interpretation. Clinical pathologists often focus on a test's accuracy and precision. *Accuracy* is the degree of closeness of the measurement made to the true value, measured by some alternative "gold standard" or definitive test. *Precision* is a test's ability to give nearly the same result in repeated determinations. Clinicians are more concerned with the ability of a test result to discriminate between persons with and persons without a given disease or condition; this discriminating ability can be characterized by a test's sensitivity and specificity. *Sensitivity* is the probability that a test result will be positive when the test is applied to a person who actually has the disease. *Specificity* is the probability that a test result will be negative when the test is applied to a person who actually does not have the disease. A perfectly sensitive test can rule out disease if the result is negative. A perfectly specific test can rule in disease if the result is positive. Because most tests are neither perfectly sensitive nor perfectly specific, the result must be interpreted probabilistically rather than categorically.

Although sensitivity and specificity are important considerations in selecting a test, the probabilities they measure are not in themselves what ordinarily concern the physician and the patient after the test result has returned. Both are concerned with the following questions: If the result is positive, what is the probability that disease is present? If the result is negative, what is the probability that the patient is indeed disease-free? These probabilities are known respectively as the *predictive value positive* and the *predictive value negative*. They are determined not only by the sensitivity and specificity of the test, but also by the probability of the disease being present before the test was ordered.

Relationships between sensitivity and specificity and positive and negative predictive values can be better understood by referring to a two-by-two table (Fig. 2.1). The two columns indicate the presence or absence of disease (note that a gold standard of diagnosis is assumed), and the two rows indicate positive or negative test results. Any given patient with a test result could be included in one of the four cells labeled *a, b, c*, or *d*. Definitions of sensitivity, specificity, predictive value positive, and predictive value negative can be restated by using these labels. It is important to note that each of these four ratios has a complement. The complement of sensitivity (1 − sensitivity) is referred to as the *false-negative rate*, whereas the complement of specificity (1 − specificity) is referred to as the *false-positive rate*. These terms are often used ambiguously in the medical literature; the false-negative rate is confused with the complement of the predictive value negative, which is *best* termed the *false-reassurance rate*; the false-positive rate is confused with the complement of the predictive value positive, which is *best* termed the *false-alarm rate*.

		Disease		
		Present	Absent	
Test	Positive	a	b	$a + b$
	Negative	c	d	$c + d$
		$a + c$	$b + d$	$a + b + c + d$

Definitions

Sensitivity:	$\dfrac{a}{a+c}$	False negative rate:	$\dfrac{c}{a+c}$
Specificity:	$\dfrac{d}{b+d}$	False positive rate:	$\dfrac{b}{b+d}$
Predictive value positive:	$\dfrac{a}{a+b}$	False alarm rate:	$\dfrac{b}{a+b}$
Predictive value negative:	$\dfrac{d}{c+d}$	False reassurance rate:	$\dfrac{c}{c+d}$

FIG. 2.1. The two-by-two table clarifies relationships between test characteristics (sensitivity and specificity) and the predictive values of positive and negative test results. Clinicians, interpreting a diagnostic test, can fill in the table if they are aware of the sensitivity and specificity of the test and a patient's (population's) pretest probability (prevalence) of disease. The pretest probability is (*a + c*) and (1 − the pretest probability) is (*b + d*). Multiplying (*a + c*) by the sensitivity provides the value for *a*, and multiplying (*b + d*) by the specificity provides the value for *d*. Values for cell *c* and cell *b* can be determined by simple subtraction. With the cells filled in, the predictive value of a negative or positive test result can be calculated easily. It is worth noting that this calculation method is precisely equivalent to Bayes' theorem of conditional probability.

INTERPRETING TEST RESULTS: REVISING DIAGNOSTIC PROBABILITIES

When clinicians interpret test results, they usually process the information informally. Rarely is a pad and pencil or calculator used to revise probability estimates explicitly. However, sometimes the revision of diagnostic probabilities is counterintuitive; for instance, it has been shown that most clinicians rely too heavily on positive test results when the pretest probability or disease prevalence is low.

Attention to the two-by-two table indicates why predictive values are crucially dependent on disease prevalence. This is particularly true when one is using a test to screen for a rare disease. If a disease is rare, even a very small false-positive rate (which is, remember, the complement of specificity) is multiplied by a very large relative number—that is, (*b + d*) × (*a + c*). Therefore, *b* will be surprisingly large relative to a, and the predictive value positive will be counterintuitively low. Examples of this effect are evident in Table 2.1.

PRIOR PROBABILITY (PREVALENCE) (%)	PREDICTIVE VALUE OF POSITIVE TEST RESULT (%)		
	SENSITIVITY 80% SPECIFICITY 80%	SENSITIVITY 95% SPECIFICITY 95%	SENSITIVITY 99% SPECIFICITY 99%
0.1	0.9	1.9	9.0
1	8.3	16.1	50.0
2	15.5	27.9	66.9
5	32.1	50.0	83.9
50	90.0	95.0	99.0

Table 2.1. Effect of Prior Probability (Prevalence) on Predictive Value of Positive Test Results

Consider the example of a noninvasive test to detect coronary disease applied to a 40-year-old man with a history of atypical chest pain. Based on test evaluations reported in the literature, the sensitivity and specificity of the test can be estimated at 80% and 90%, respectively. Based on symptoms and risk factors, the clinician estimates that the patient's pretest probability of coronary disease is 0.20. (This is the same as saying that the prevalence of coronary disease in a population of similar patients would be 20%.)

According to Fig. 2.1, with a pretest probability of 0.20, $a + c$ = 0.20 and $b + d$ = 0.80. Multiplying 0.20 by 0.8 (the sensitivity) gives us a value of 0.16 for a (subtraction gives us a value of 0.04 for c). Multiplying 0.80 by 0.9 (the specificity) gives us a value of 0.72 for d (again, subtraction gives us 0.08 for b). The predictive value positive, then, is 0.16/0.24, or 0.67. The predictive value negative is 0.72/0.76, or 0.95.

Clinicians can use another method to revise probabilities quickly to test their intuition. It requires an understanding of *odds* as well as probability. If p is the probability that a particular disease is present, the ratio of p to $(1 − p)$, or $p/(1 − p)$, is called the *odds favoring that disease*. The *odds against that disease* being present are represented by $(1 − p)/p$. Just as one can estimate the pretest probability of disease before diagnostic tests are performed, one can express that estimate as the pretest odds.

Pretest odds can be revised simply by multiplying a ratio called the *likelihood ratio*, which is the relative occurrence of the test result among persons with and without disease—that is, the probability of the result (either positive or negative or a particular range of values) given the presence of disease divided by the probability of that result given the absence of disease. Note that the positive likelihood ratio is nothing more (or less) than the ratio of sensitivity to the false-positive rate (i.e., 1 − specificity).The negative likelihood ratio is the ratio of the false-negative rate (i.e., 1 − sensitivity) to the specificity. Likelihood ratios therefore include all the information contained in estimates of sensitivity and specificity. When the pretest odds of a disease are multiplied by the likelihood ratio, the result—sometimes termed the *posttest odds*—represents the odds favoring disease given the test result.

Returning to the example, the patient with atypical chest pain could have his chances of having coronary disease expressed as odds rather than a probability. A probability of 0.20 is equivalent to odds of 1/4 (0.20/0.80). The likelihood ratio for a test with a sensitivity of 0.8 and a specificity of 0.9 is 8 [0.8/(1 − 0.9)]. The pretest odds can be converted to posttest odds following a positive test result simply by multiplying by the positive likelihood ratio: 1/4 × 8 = 2. Note that the posttest odds ratio of 2:1 is equivalent to the posttest probability of 0.66.

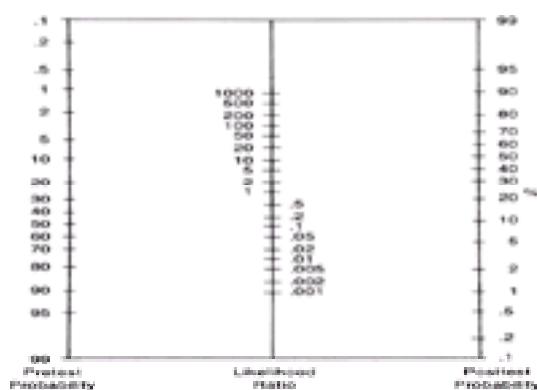
For some, it is easier to revise probabilities in the clinical setting by using likelihood ratios. A nomogram can be helpful until one gets used to converting from probabilities to odds and back again (Fig. 2.2). Likelihood ratios also have the advantage of capturing more clinical data from the patient's particular test results. Whereas estimates of sensitivity and specificity usually rely on a dichotomous positive–negative result threshold, different likelihood ratios can be determined for different ranges of test results. For example, a very high creatine phosphokinase (CPK) level will have a higher positive likelihood ratio than a moderate elevation. The degree of elevation will then be reflected in the revised probability of myocardial infarction.


FIG. 2.2. A nomogram for applying likelihood ratios. [Adapted from Fagan TJ. Nomogram for Bayes' theorem [Letter]. N Engl J Med 1975;293:257, with permission. (Sackett DL, Haynes RB, Tugwell P. Clinical epidemiology, 1985.)]

WHERE DOES THE INFORMATION COME FROM?

One of the reasons clinicians are reluctant to take a quantitative approach to diagnostic test interpretation is that such an approach suggests a precision that belies our uncertainty about pretest probabilities and about sensitivity and specificity of even commonly used tests. The estimation of pretest probability hinges on epidemiologic information about the incidence and prevalence of various diseases, modified on the basis of patient characteristics and presenting symptoms. This kind of information is all too rarely presented in the medical literature. Estimates are necessarily uncertain.

There is also uncertainty about the sensitivity and specificity of tests. Rarely are these values presented in medical texts, and test evaluations in the medical literature can sometimes be misleading. The clinician should be familiar with some of the reasons why a test rarely performs as well in general use as it does during the evaluation study that appears in the medical journal.

False-positive Rate and Pretest Probability: Overestimating Predictive Values

The importance of the pretest probability of disease in an individual patient (or the prevalence of disease in a population of such patients) for determining the predictive values of a test is often not fully appreciated and may lead to disappointment in the clinical performance of the test. Consider how, during its evaluation, the sensitivity and specificity of a test are estimated. Two groups of patients are assembled. One consists of patients known to have the disease in question as defined by some gold standard (represented by $a + c$ in Fig. 2.1). The other consists of persons without disease based on the same gold standard (represented by $b + d$). The test being evaluated is then applied to both populations. The proportion of those with disease who have a positive result [$a/(a + c)$] provides us with an estimate of the test's sensitivity. The proportion of those without the disease who have a negative result [$d/(b + d)$] gives us an estimate of the test's specificity. Our confidence that these estimates of sensitivity and specificity are accurate increases with the number of people in each group tested. The investigator can most efficiently maximize confidence in the estimates of both sensitivity and specificity by applying the test to disease and nondisease groups of equal size. It is not surprising, therefore, that tests are often evaluated by applying them to populations in which disease and nondisease occur with equal frequency, or nearly so.

If sensitivity, specificity, and predictive values are sufficiently high in such an evaluation study, the test is proposed for general use. What happens when the test is adopted and applied in a general population in which the disease is much less likely to be present than nondisease? The sensitivity and specificity should remain the

same, but the predictive value positive will necessarily fall, and its complement, the false-alarm rate, will necessarily increase. This phenomenon is most important when the disease in question is rare, as is evident in Table 2.1.

Defining Disease for Diagnostic Test Evaluation: The Gold Standard Problem

To evaluate a diagnostic test, an investigator must be able to distinguish between persons with and without disease by some alternative method. Often, this gold standard test is more invasive or more expensive than the newer, proposed test being evaluated. (The newer test would not be worth evaluating if it did not confer some advantage for patient or clinician.) Sometimes, a gold standard is not readily available. If the disease is one with a short, predictable, natural history (e.g., pancreatic cancer), an investigator may resort to follow-up, defining the absence of disease by morbidity-free survival during a specified period. But if the disease has a highly variable natural history (e.g., coronary disease and most rheumatologic disorders), the follow-up approach becomes impractical. Instead, the investigator must rely on more arbitrary and often more subjective criteria to define disease, including combinations of tests, signs, and symptoms. Herein lies a potential pitfall that can affect the accuracy of the estimates of sensitivity and specificity. If the diagnostic criteria are not assessed independently of the test being evaluated, the sensitivity, specificity, or both will be overestimated.

The problem occurs in its most obvious form when a positive test result leads the investigator to a more extensive search for disease than was applied to those with a negative test result. A related problem occurs when the test and the diagnostic criteria are very similar biologic measures. This will result in overly optimistic estimates of sensitivity and specificity. For example, to the extent that false-negative isoenzyme results are correlated with false-negative enzyme results, the sensitivity of the test will be overestimated. To the extent that false-positive results are correlated with false-positive results, the specificity of the new test will be overestimated.

The Narrow Spectrum Problem: Overestimating Sensitivity When the "Disease" Group Is Too Sick

When investigators assemble a group known to have the disease in question by means of some gold standard, they may choose patients with unequivocal diagnostic (gold standard) findings. In doing so, they may select a severely ill group that is not representative of the disease in the general population—that is, they will focus on too narrow a spectrum of disease.

Consider a group of investigators evaluating a noninvasive test for coronary artery disease, such as an electrocardiographically monitored exercise tolerance test. To be sure that they are dealing with true coronary disease, the investigators include only people with unequivocal prior myocardial infarction or with classic angina symptoms. By using their chosen criteria for a positive test result, they determine that the sensitivity of the test is 90%. What they (and the readers of their report) may not realize is that the test is more sensitive when coronary disease is extensive (two- or three-vessel disease rather than single-vessel disease) or severe (99% stenosis rather than 80% stenosis) and that their gold standard criteria have selected for patients with extensive or severe disease. When the test is used to detect less extensive disease producing more equivocal symptoms in the general population, its sensitivity will prove disappointing. Recognize that the sensitivity estimate provided by the evaluation is accurate for the narrow spectrum of disease severity found in the test population. The disappointment comes when that estimate is generalized inappropriately to include those with less severe disease.

The Comorbidity Problem: Overestimating Specificity When the "No Disease" Group Is Too Well

In the same way that investigators can assemble a "disease" group that is sicker than the population to which the test will eventually be applied, they can assemble a "no disease" group that is too healthy. Many tests will perform better when used to discriminate between "disease A" and "no disease" than when used to discriminate between disease A, on the one hand, and diseases B through Z, on the other. Consider the fledgling investigator who wishes to estimate the sensitivity and specificity of guaiac testing as a screening test for colonic cancer. The investigator knows about the spectrum problem and has included in the "disease" group people with early cancers. For the "no disease" group, medical school students have been selected. It should be clear that this choice of controls will provide an estimate of specificity that is higher than could be expected when the test is generally applied to a population including older individuals more likely to have a nonmalignant source of occult bleeding. Obviously, the controls should not have the target disease (i.e., colon cancer). However, if all comorbid conditions that the test might confuse with the disease (e.g., peptic ulcer disease, diverticular disease) are also excluded from the control population, the investigator's estimate of specificity will be too optimistic.

Investigators can guard against such disappointments by drawing their "disease" and "no disease" populations from the target population in which the test will eventually be used. The spectrum of disease that should be detected in the target population should be represented in the "disease" group. Comorbid conditions that might be confused with that disease should be included in the "no disease" control group. Such an effectiveness evaluation of a diagnostic test might be preceded by a simpler study comparing very sick with completely well persons. If the test cannot discriminate between the very sick and the very well in such an efficacy study, the more difficult effectiveness trial need not be undertaken. The clinician can guard against being misled by reports of a test's efficacy by carefully considering the populations in which a test has been evaluated and not generalizing the results inappropriately to larger, more heterogeneous groups.

How Does the Test Compare with Others?

A final reason for disappointment with the application of apparently promising tests is failure to consider adequately a test's potential role in the constellation of tests that is already available. Does the new test provide new information? Does it obviate the need for more invasive or more expensive tests? If the answer to these questions is no, the worth of the test and its evaluation are in obvious doubt.

WHICH TESTS SHOULD WE USE?

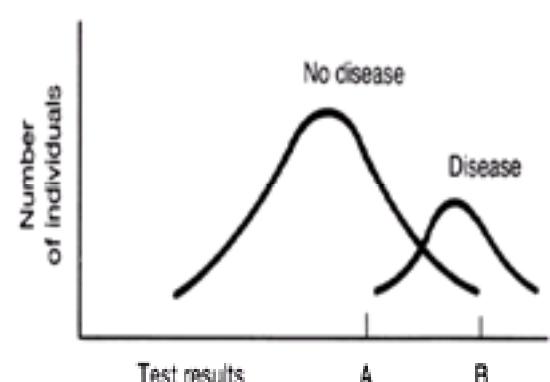
Perfect tests are rare. Clinicians must choose among tests with imperfect sensitivity and specificity. The physician frequently has some choice about the sensitivity and specificity of a test. Obviously, alternative tests—usually those that are more costly or invasive—may be more sensitive and more specific. A new technology or an improved skill in interpretation may improve both measures. Often, however, the physician can increase specificity only by accepting a decrease in sensitivity. The most graphic examples of this principle involve tests that provide quantitative results, such as the measurement of serum prostate-specific antigen when the diagnosis of prostate cancer is being considered. The general case is illustrated in Fig. 2.3. Note that the "normal" values for the test results are all too often derived from frequency distributions of results among apparently well persons; the potential trade-off between sensitivity and specificity is not considered.


FIG. 2.3. Hypothetical distribution of test results among patients with and without disease. Because the distributions overlap, the test is far from perfect. If all patients with values to the right of *A* are said to have "positive" results, the test will be 100% sensitive but will have a low specificity. If only those patients with values to the right of *B* are said to have "positive" results, the test will be 100% specific but will have a low sensitivity. The choice of a cutoff value between *A* and *B* should depend on the relative importance of true- and false-positive and true- and false-negative results.

Which is more important, sensitivity or specificity? In general, the answer depends on the cost—which includes patient inconvenience, morbidity, and mortality as well as dollars—of false-negative results compared with that of false-positive results, and the benefits of true-negative and true-positive results. Sensitive tests or less stringent criteria for disease and the resulting low false-negative rate should be favored when effective treatment for the condition exists and the cost of lost opportunity is great. High specificity or more stringent criteria for disease and the resulting low false-positive rate are most important when a positive diagnostic result

does not significantly influence therapy or outcome and may be a burden for the patient.

Clinicians who are mindful of the purpose of making a particular diagnosis, who consider the natural history of a disease in addition to the prognostic and therapeutic implications of the diagnosis, are likely to make efficient use of the laboratory while maximizing health benefits for their patients.

CHAPTER 3 HEALTH MAINTENANCE AND THE ROLE OF SCREENING

ALBERT G. MULLEY, JR.

INTRODUCTION

Public interest in health maintenance or, more positively, health enhancement has grown dramatically in recent years. Many Americans have demonstrated their interest in exercise, good dietary habits, maintenance of appropriate body weight, and stress reduction. Increased enthusiasm stems from the growing awareness of associations between elements of life-style and health. Despite reliable evidence and public acceptance of these associations, however, many people continue to indulge in self-destructive habits such as smoking, overeating, and alcohol abuse. Efforts to alter such behavior are often frustratingly ineffective. Patients who seek reassurance from physician visits that include routine screening procedures often persist in behavior that greatly increases their risk of morbidity.

Physicians must acknowledge their primary role in prevention as that of educators. Accurate information regarding risk factors is most likely to reinforce health-enhancing behavior and alter self-destructive behavior. Physicians must appreciate the potential for behavior modification and familiarize themselves with local resources. Routine screening for specific diseases, the health maintenance activity most closely identified with the physician, should be performed selectively. The limits of screening tests as well as their potential health benefits should be clearly understood by every primary care physician.

Specific risk factors and screening tests are discussed in subsequent chapters. This chapter focuses on the question, What makes a disease or risk factor worth screening for? The relationship between prevalence and the predictive value of a test is particularly important in the screening situation (see Chapter 2). Because the physician is more interested in improving health outcomes for patients than in simply providing them with diagnoses, elements of the natural history of the disease and of the effectiveness of therapy are critically important.

CRITERIA FOR SCREENING

Whether or not a screening policy results in improved health outcomes depends on the characteristics of the disease(s), the test(s), and the patient population. These are summarized in Table 3-1.

Characteristics of the disease
Significant effect on quality or length of life
Prevalence sufficiently high to justify costs
Acceptable methods of treatment available
Asymptomatic period during which detection and treatment significantly reduce morbidity and mortality
Treatment in the asymptomatic phase yields a better therapeutic result than treatment delayed until symptoms appear
Characteristics of the test
Sufficiently sensitive to detect disease during the asymptomatic period
Sufficiently specific to provide acceptable predictive value positive
Acceptable to patients
Characteristics of the population screened
Sufficiently high disease prevalence
Accessibility
Compliance with subsequent diagnostic tests and necessary therapy

Table 3-1. Criteria for Screening

NATURAL HISTORY OF THE DISEASE AND EFFECTIVENESS OF THERAPY

Screening tests are performed to identify asymptomatic disease. The alternative is to wait until the patient presents with symptoms and then make a diagnosis. The question then is, What makes a disease worth diagnosing early? The practical objective of screening is prevention of morbidity and mortality—not simply early diagnosis. There is little benefit to the patient, and perhaps considerable harm, in advancing the time of diagnosis of a disease for which earlier treatment does not influence outcome.

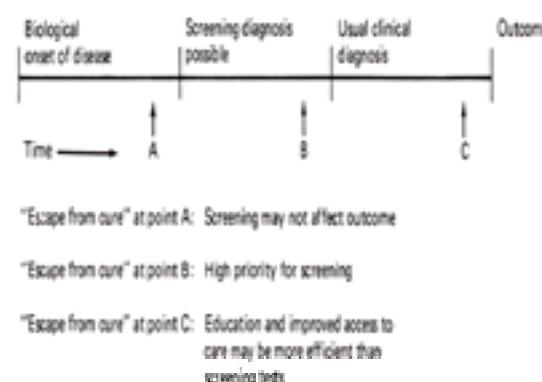
The importance of the natural history of the disease and the effectiveness of therapy can be illustrated by considering Fig. 3-1. As it shows schematically, some variable time after the biologic onset of a disease, a diagnosis is possible with the use of a screening test. This is followed by another variable time period, during which the patient has no symptoms. Usually, a short time after symptoms appear, the clinical diagnosis is made. Eventually, after the course of therapy has been selected and completed, there is an identifiable clinical outcome that can range from cure and complete health to death.


Figure 3-1. Relationships between screening and natural history of disease.

Often, outcome depends somewhat on the point during the natural history of the disease at which therapy is initiated. This is clearest in the case of localized versus metastatic cancer. Many tumors can be readily excised, and the patient cured of the disease, during early stages. The opportunity for cure is often lost when tumor spread makes excision or other local therapy impractical. The "escape from cure" may not be as dramatic as the point of tumor metastasis; a disease may simply become more refractory to therapy, which increases the likelihood of morbid complications. The practical purpose of screening is to advance the time of the diagnosis to a point in the natural history of the disease when a relative or absolute "escape from cure" is less likely to have occurred.

Although the natural history of any disease varies a great deal among persons afflicted, some generalizations are worthwhile. If an "escape from cure" generally occurs at point A in Fig. 3-1 or at any point before available screening tests can detect the disease in question, the value of screening must be questioned. The most common result will be bad news sooner for the patient but no difference in outcome. If "escape from cure" routinely occurs after symptoms appear (e.g., at point C),

screening may be valuable but can likely be supplanted by patient and professional education programs aimed at ensuring early presentation and prompt diagnosis. Diseases in which "escape from cure" generally occurs after the disease is detectable but while it remains asymptomatic (e.g., at point B) are the most appropriate targets of screening efforts.

Several points about the evaluation of screening programs can also be made with reference to Fig. 3-1. Critics of indiscriminate screening point out that the benefits of a screening program can easily be overestimated if the relationship between time of diagnosis and natural history is not understood. One fallacy results from neglecting the importance of *lead time* when evaluating the effect of screening on subsequent survival. Because screening has the potential to advance the time of diagnosis from one point in the natural history to another and because survival is, by necessity, measured from the time of diagnosis rather than from the time of onset, the survival of patients whose diseases are detected by screening should be expected to be longer than that of patients who present symptomatically. Extensive follow-up data on many patients allow approximation of the average length of time by which the diagnosis is advanced by screening. This illusory gain in survival, the lead time, can then be subtracted from any measured difference in survival duration to learn the true benefits of the screening program.

The second fallacy that can lead to overestimation of screening benefits depends on the variability in natural history among individual cases of the same disease. Patients who have less aggressive disease and so spend more time in a detectable but asymptomatic stage are, other things being equal, more likely to have their disease detected by a screening test than are patients with more aggressive disease. If patients with indolent, asymptomatic disease are more likely to have an indolent clinical course after diagnosis, patients with disease diagnosed by screening should be expected to have longer survival rates than patients who present symptomatically. Arguments about the impact of such biologic determinism versus that of advancing the time of diagnosis have most frequently been raised with regard to breast and prostate cancers, but they apply generally to all screening. This potential bias toward prolonged survival among patients with disease detected by screening tests has been called *time-linked bias sampling*.

Neither of these arguments is meant to deny the value of screening for treatable disease. They simply advise caution in interpreting apparently favorable results based on unsophisticated measures of effectiveness.

VALIDITY OF AVAILABLE SCREENING TESTS AND POPULATIONS SCREENED

Diseases worth identifying usually have a relatively low prevalence in the asymptomatic population. As a result, the specificity of the diagnostic test used is the principal determinant of the predictive value positive of the test. Tests that may be very useful in diagnosis when the prior probability of disease is 10% or 20% may produce an unacceptable number of false-positive results when used in a screening situation. Such nonspecificity has been referred to as the *cost of a screening test*. The costs, including morbidity and patient concern, of diagnostic evaluations among patients with false-positive screening results can far outweigh other costs of a screening program. The sensitivity and specificity of the screening test, costs, and patient acceptability are critical considerations in the decision to screen for disease.

The importance of disease prevalence in determining the predictive value positive is one basis for the use of risk factors in screening policy. By limiting screening to a high-risk population, the physician in effect increases the prevalence of the disease in the population tested (and alternatively increases the prior probability of the disease in any individual patient), thereby increasing the predictive value positive and decreasing the false-alarm rate and the number of false-positive results.

HEALTH MAINTENANCE—WHAT IS APPROPRIATE?

Periodic health evaluation has been recommended with varying degrees of enthusiasm throughout the 20th century. Many patients believe in its value; the majority of Americans feel that more health resources should be expended on preventive efforts. However, the value of periodic examinations and specific preventive measures has been questioned. Evidence regarding the effectiveness of periodic examinations, measured in terms of decreased morbidity and mortality, is fragmentary. Supporters of periodic evaluation argue that the additional benefits of regular physician contact result in a greater sense of well-being. Such contact provides opportunities for appropriate patient education.

Routine examinations should be tailored to the individual patient. Although the importance of the characteristics of the patient, the diseases, and the test in determining appropriate prevention strategies must be recognized, summary recommendations can be useful. A number of reviews, each applying the criteria discussed in this chapter, have offered recommendations for preventive health care. The recommendations of the American Cancer Society, the American College of Physicians, the Canadian Task Force on the Periodic Health Examination, and the U.S. Preventive Services Task Force have received the most attention. Relatively few conditions have received general endorsement as targets for screening among *asymptomatic* persons *without* specific *risk factors*. These are summarized in Table 3-2. The rationales for these recommendations are presented in the subsequent chapters noted in the table.

Table 3-2. Conditions that Warrant Periodic Evaluation in All Patients of Appropriate Age and Gender

Disease	Comments
Hypertension	See Chapter 14, Chapter 19, and Chapter 26.
Hyperlipidemia	See Chapter 5 and Chapter 27.
Smoking	See Chapter 54.
Colon cancer	See Chapter 56.
Breast cancer	See Chapter 106.
Cervical cancer	See Chapter 107.
Alcoholism	See Chapter 228.

Table 3-3 provides a summary of recommendations that have been made for other preventive services that are warranted in selected patients. Again, the rationales for these recommendations are presented in subsequent chapters. It should be noted that uncertainty about both the natural history and the effectiveness of therapy, the importance of specific risk factors, and the sensitivity and specificity of potential screening tests rarely, if ever, allow proof of the effectiveness of a screening procedure. Some conclusions and recommendations, necessarily based on speculative data, remain controversial. The clinician must also be mindful of the potential to help patients avoid preventable morbidity and early death by taking the time to provide advice and counsel about behavior and life-style. Patients often need specific advice, not only about the use of alcohol, tobacco, and harmful substances, but also about diet, exercise, sexual practices, and injury prevention. Such discussions have the potential to produce a far greater effect on health and longevity than do specific screening tests and procedures.

Table 3-3. Conditions that Warrant Periodic Evaluation in Selected Patients

Comments	Condition	Risk Factors
Rubella susceptibility	Anticipated pregnancy and risk-group membership; occupation health care worker)	See Chapter 6.
Human immunodeficiency virus infection	Anticipated pregnancy and risk-group membership; blood transfusion 1978-1985	See Chapter 7.
Endocarditis susceptibility	Valvular heart disease	See Chapter 16.
Rheumatic fever susceptibility	Rheumatic fever history	See Chapter 17.
Tuberculosis (PPD reactivity)	Occupational exposure	See Chapter 38 and Chapter 49.
Occupational lung disease	Occupational exposure	See Chapter 39.
Susceptibility to hepatitis B virus	Male homosexual Exposure Occupation (health care worker)	See Chapter 57.
Anemia	Pregnancy	See Chapter 77.

Sickle cell trait	African-American of childbearing age	Genetic counseling must be acceptabe; see [Chapter 78]().
Thyroid cancer	Radiation of head and neck	See [Chapter 94]().
Diabetes	Pregnancy; family history of diabetes; obesity; or history of gestational diabetes	See [Chapter 93]().
Endometrial cancer	Exogenous estrogens	See [Chapter 109]().
Vaginal cancer	*In utero* diethylstillbestrol exposure	See [Chapter 110]().
Syphilis	Male homosexual Pregnancy Other sexually transmitted diseases	See [Chapter 124]().
Chlamydial genitourinary infection	Other sexually transmitted diseases Women of childbearing age	See [Chapter 125]().
Bacteriuria	Pregnancy Kidney stones	See [Chapter 127]().
Lower urinary tract cancer	Occupational exposure to aromatic amines (e.g., dyestuffs, leather tanning, rubber)	See [Chapter 128]().
Testicular cancer	Cryptorchidism	See [Chapter 131]() and [Chapter 143]().
Osteoporosis	Early menopause	See [Chapter 144]().
Cerebrovascular disease	Advanced age, TIA history	See [Chapter 171]().
Skin cancer	Fair skin, sun exposure Family history	See [Chapter 177]().
Glaucoma	Family history Advanced age	See [Chapter 198]().
Oral cancer	Alcohol Tobacco	See [Chapter 211]().
Decreased hearing	Advanced age, excssive noise	See [Chapter 212]().

PPD, purified protein derivative; TIA, transient ischemic attack.

MAXIMIZING USE OF IMMUNIZATIONS AND SCREENING SERVICES

The efforts of the individual primary physician, while important, are insufficient to ensure that patients take maximal advantage of available effective preventive services. Meta-analysis of controlled trials examining strategies for optimizing use of preventive services has identified systematic organizational measures as central to the effort. The most effective of these measures include establishment of separate clinics devoted to prevention, a planned prevention care visit, and assignment of nonphysicians to perform specific prevention activities. Next-best approaches involve removal of financial barriers and patient reminders. Less benefit has been observed from education of patients and health care professionals and from feedback to providers. The take-home message: It takes a "systems" approach.

CHAPTER 4 ESTIMATING AND COMMUNICATING RISK AND PROGNOSIS

Diagnosis is a process of classification. A constellation of symptoms, signs, and test results is given a label, and the patient who presents with those characteristics is implicitly grouped with other patients who have presented with similar findings. What makes the classification process and the resulting label so significant for both patient and clinician is what it implies about the future. Will symptoms persist, get worse, or resolve spontaneously? What other health outcomes can be expected? Will therapeutic interventions improve chances for a good outcome?

Similar questions arise when a patient is found to have a risk factor that increases the likelihood of future disease. How great is the risk? What are the chances of avoiding the anticipated bad outcome, either because of efforts to lower risk or by good fortune? To answer such questions, the primary care physician must understand the methods by which valid information about prognosis and risk is derived from the experience of previous patients. Doctor–patient dialogues about the future implications of an illness or risk factor are often momentous for patients. Information about an uncertain future must be communicated with clarity, compassion, and an appreciation for the uniqueness of each patient's needs.

RISK AND PROGNOSIS: PREDICTING THE PATIENT'S FUTURE

The source for information about the future of any particular patient is the collective experience of previous patients with the same condition. The accuracy of the information so derived depends on the manner in which that experience is collected and recorded and on the degree of similarity between the patient at hand and past patients who have been followed over time.

Theoretically, the best mechanism for studying prognosis would be to characterize patients carefully at the time of diagnosis (or when a risk factor is identified) with regard to disease stage and severity, presence or absence of any comorbid conditions, and other factors that could be expected to have an impact on outcome. Because such factors are often systematically influenced by the pattern of patient referral, the setting in which patients are seen and the manner in which they happened to be there would be described. All patients would be examined with the same level of scrutiny at the time they entered the *cohort* and during subsequent follow-up examinations. Relevant outcomes, and criteria by which they would be measured, would be specified in advance. Those conducting follow-up examinations would be unaware of baseline differences among patients so as not to be influenced by expected associations betweenthese variables and outcomes. All patients would be followed, and their status with regard to outcomes would be known at the time the experience was analyzed. The impact of different baseline characteristics on relevant outcomes would be examined by reporting experience for different subgroups or developing statistical models. The predictive validity of these models would be tested in separate samples of patients.

Rarely, if ever, is it possible to meet all these methodologic objectives. As a result, much of the research that clinicians rely on for information about risk and prognosis is potentially misleading. To avoid being misled and misleading patients, clinicians must understand the biases that can be introduced when suboptimal methods are used to gather information to help predict the future.

When the outcomes of interest are rare events, it may not be feasible to assemble a cohort large enough, and follow it long enough, to accumulate sufficient experience to provide useful estimates of prognosis or risk. Alternatively, patients who have already experienced the outcome can be identified as cases and their past histories examined to identify events or *exposures* that may have conferred risk and may be of prognostic value. *Control* patients without the outcome of interest can also be questioned about the same exposures. Comparison of the rates of exposure among cases and controls can produce an estimate of the degree of risk associated with the exposure. The *odds ratio* is an estimate of the *relative risk* that is very accurate when the disease or outcome in question is rare. This retrospective case–control approach places a heavy burden on the investigator and sources of information to ensure that similar degrees of scrutiny are applied to the histories of cases and controls. Selective recollection of the past, often with greater vigilance stimulated by the outcome of interest, can produce misleading estimates of risk and prognosis.

Even if patients with a particular risk factor or diagnosis are identified prospectively and followed forward in time, biases that can lead to faulty conclusions may be introduced. Perhaps the most important bias for primary care physicians to recognize has been termed *referral filter bias*. It occurs frequently as a result of the fact that patients in many published reports have been described because they have been referred to academic centers. Such patients often have complicating characteristics and exhibit a worse prognosis than do patients who are drawn from an entire population or a representative sample of a population. Similar problems arise when patients are selected for study based on particular test results. Patients with more worrisome signs and symptoms may be more likely to be tested and more likely to fare poorly over time. Alternatively, patients who are tested may have better access to medical care and fare better than average as a result.

Differences in the ways patients are followed over time can also introduce important biases. Patients lost to follow-up may be different from those who remain in the cohort. A conservative approach to estimating prognosis when some patients are lost to follow-up before the relevant outcome has occurred is to assume that all lost patients experienced the outcome, and then to assume that no lost patients experienced it. The first assumption produces an *upper bound estimate*, with lost patients included in both numerator and denominator; the second produces a *lower bound estimate*, with lost patients included only in the denominator.

Even when patients are successfully followed over time, biases can be introduced by the selective use of tests and other outcome measures or by the expectations of clinicians who are aware of patient characteristics that may or may not have real prognostic significance. Statistical models that have not been validated on independent samples may mistake random variations among characteristics and outcomes for important prognostic associations.

DESCRIBING THE RISK OF FUTURE DISEASE

People are generally very interested in the risk of untoward events and ways to reduce risks. Despite the high level of interest, there is a great deal of confusion about the meaning of quantitative expressions of risk. This confusion often carries over to conversations between doctors and patients. An important source of confusion is the distinction between *relative* and *absolute* risk. The effect of risk factors is usually expressed as a relative risk or risk ratio—that is, the incidence of disease among people with the risk factor divided by the incidence among people without the factor (often estimated as the odds ratio from a case–control study). However, for the individual patient with the risk factor, the incidence of disease, the absolute risk of the outcome, may be more useful. For example, a patient may have a 20- or 30-fold increased risk for a rare disease but still face less than a 1% absolute risk for development of that disease in his or her lifetime. Another way of conveying the implications of a risk factor is to cite the attributable risk, which is the difference between the incidence among exposed people and the incidence among those who are not exposed.

Such distinctions are also important in weighing the harms and benefits of interventions designed to reduce risk. Treating hypertension may well reduce the risk of stroke by 40% (the relative risk reduction). However, doctor and patient should also understand that the baseline risk of stroke during the next 10 years may be as low as 1% for some patients with mild hypertension. This means that the benefit of risk reduction, or the risk difference attributable to the untreated mild hypertension, is the difference between 1.0% and 0.6%, or 0.4%. Another approach to summarizing this kind of data is to cite the number of patients one would need to treat to have the desired effect in a single patient. Returning to the hypertension example, treating 1,000 patients would reduce the number of strokes from 10 to 6, so 250 people with mild hypertension would have to be treated to avoid one stroke.

DESCRIBING OUTCOMES DURING AN UNCERTAIN FUTURE

The diagnosis of a particular condition is generally much more predictive of future outcomes than the identification of risk factors. Outcomes are more frequent and are often described as simple rates. The proportion of people with a particular condition who eventually die of that disease is the *case fatality rate*. Some indication of the duration of survival may be included by describing survival at a point in time after diagnosis (e.g., the 5-year survival rate). Simple rates have the advantage of being easy to remember and communicate. However, valuable information is lost when prognosis, the distribution of uncertain events over time, is summarized by a single rate. The more complete picture of prognosis is captured in a *survival curve*. Survival curves are often used to display the proportion of a cohort surviving over

time, but the same technique can beused to display the occurrence, or lack thereof, of other events, such as onset of symptoms or recurrence of disease. Survival curves are constructed by plotting sequentially calculated probabilities of survival (or freedom from events) over time. The decrease in the height of the curve at any time period depends on the proportion of the remaining cohort who experience the event during that period, with patients lost to follow-up excluded from the denominator. Sometimes, the proportion of people who experience events, rather than the proportion who are event-free, is plotted on the vertical axis. Such *cumulative incidence curves* convey the same information.

It is important to remember that survival curves display serial estimates that are based on the experience of fewer and fewer people as events and loss to follow-up deplete the denominator. Therefore, the clinician can be more confident in the estimates displayed on the left part of the curve than on the right. The distant future is more uncertain than the near term. However, when a new diagnosis of serious disease is made, it is often the near term that is of greatest interest to the patient. A cumulative recurrence risk of 30% may be frightening to the woman with early-stage breast cancer, and this may be a case in which use of the simple rate to express prognosis is a disservice. The more complete picture presented by a survival curve, including attention to the low annual incidence of recurrence in the near term, may be more helpful to the patient.

THE UNIQUENESS OF EACH PATIENT

Descriptions of risk and prognosis should be provided to patients with an appreciation for the uniqueness of each person and his or her predicament. Different people respond differently to the same risk. A 1% risk for stroke during a 5- or 10-year period may be threatening to some but inconsequential to others. This can be explained by the very real competing risks that different people face because of other medical conditions or the environment in which they live. Similarly, different people have different attitudes about trade-offs between the present or near future and the distant future. Putting up with side effects or inconvenience now for some *possible* benefit in the future makes good sense to some but little sense to others. Again, competing risks explain some of these differences. Another important difference among patients relates to their desire for information about the future. Many demand such information. Others would rather not know details about prognosis, even when that means that they must defer to the clinician for important decisions. As in other aspects of patient education, respect for the patient's autonomy and personal values during the communication of information about illness and its implications for the future requires a negotiated approach to patient care.

CHAPTER 5 CHOOSING AMONG TREATMENT OPTIONS

ALBERT G. MULLEY, JR.

INTRODUCTION

Although discerning diagnosis and accurate prognosis are essential to effective patient care, the process of choosing among treatment options can have the greatest impact on relief of suffering and prolongation of life. The right choice depends on accurate information about the effects of various treatment strategies on health outcomes. Will symptoms be relieved or at least reduced? Will serious complications of disease be averted by timely intervention, or will treatment side effects or complications decrease the quality or length of life? Treatment choices also depend on patients' preferences for different possible health outcomes and on their attitudes toward risks or their willingness to endure morbidity now for some possible future benefit. And, as noted in Chapter 4, different patients have different preferences and attitudes toward risks and time trade-offs. Effective therapeutic decision making therefore requires both a strong clinical knowledge base and the communication skills necessary to gain an empathic understanding of the individual patient's wants and needs.

WHAT WE KNOW ABOUT TREATMENT EFFECTIVENESS

The cumulative knowledge base about the effectiveness of treatments of human disease is prodigious. And yet, the use of the vast majority of therapeutic interventions in clinical practice is not supported by evidence derived from clinical trials. Clinicians often rely on their own experience with similar patients, supplemented by published case series, to estimate the likelihood of relevant health outcomes with alternative treatments. This less-than-rigorous approach produces different opinions about treatment effectiveness that lead to wide variations in clinical practices for ostensibly similar patients. Because of less stringent regulatory control, the knowledge gaps are generally greater with devices and surgical procedures than with drugs. For example, diskectomy for lumbar disk disease was first described in 1934. Nevertheless, the first and only randomized trial was published in 1983 and included only 60 surgical patients. The collective experience of the millions of patients who have undergone diskectomy worldwide contributes relatively little to our knowledge. Similarly, transurethral prostatectomy represented the standard of care for benign prostatic hyperplasia for 40 years before publication of a clinical trial.

RANDOMIZED CLINICAL TRIALS AND TREATMENT EFFECTIVENESS

Even when randomized trials are performed, uncertainty remains about the effectiveness of treatment for a specific patient. This in part reflects the methods used in clinical trials to measure the isolated effects of the experimental treatment. Explicit inclusion and exclusion criteria are applied to ensure that the study population is homogeneous, which minimizes the impact of patient-specific variables on outcomes. Patients with severe disease or important comorbid conditions are often excluded. Others may be excluded because of age or sex. Patients who meet criteria are then randomized to one of two or more carefully defined treatment strategies. Barriers are erected to discourage patients from switching from one treatment to another, and other steps are taken to preserve the integrity of the treatments.

The course of patients in randomized trials is carefully monitored, with equal attention given to patients regardless of treatment, and their outcomes are determined by means of explicit, predefined measures. Ideally, both patients and those who measure outcomes are unaware of the treatment assignment, even if this requires the use of placebos or sham procedures. Otherwise, expectations may have a real effect on perceived treatment outcomes and be interpreted as specific effects of treatment.

All these steps serve to protect the validity of the trial as a test of the hypothesis that the treatments compared in the trial have different effects on outcome. However, these same steps often limit the applicability, or generalizability, of the study findings to patients for whom the study treatment might be considered. The clinician must be concerned both about the internal validity of the trial as a test of the effectiveness hypothesis, and about its external validity—that is, the extent to which results are applicable to the different patients seen in practice.

All too frequently, individual trials may not be large enough to provide definitive answers to clinical questions. Increasingly, data from multiple trials are being combined in metaanalyses to allow careful systematic interpretation of the evidence.

Treatments may also vary from one setting to another. This is especially true for surgical procedures. Many studies have suggested that the volume of particular procedures performed in a hospital is inversely related to mortality rate. A recent study indicates that these differences in risk can be quite significant clinically for complex procedures, including pancreatectomy, esophagectomy, and pneumonectomy. Other characteristics of hospitals and of particular surgeons have been studied less well. **Updated: 4/29/02**

OTHER STUDIES OF TREATMENT EFFECTIVENESS

Randomized trials are not always necessary. When a new treatment has unprecedented or dramatic effects, such as penicillin for pneumococcal pneumonia or pacemaker insertion for life-threatening bradycardia, a trial is neither possible nor desirable. When results of trials would be helpful because treatment effects are more equivocal, they are often not available. Randomized trials are costly, time-consuming, and poorly accepted by many clinicians and patients. Sometimes, a trial is obsolete before it is completed because the experimental treatment is modified or replaced altogether by a newer approach or technology.

For all these reasons, clinicians must rely on data from observational studies as well as randomized trial results. However, great caution must be used in the application of conclusions of observational studies to patient care. Differences in patient characteristics among alternative treatment groups may lead to erroneous conclusions about treatment effectiveness. Although there have been important advances in the use of statistical methods to control for such different prognostic factors in an attempt to isolate the treatment effect, the investigator can control only for those factors that are anticipated and measured. Observational studies complement randomized trials. They can be used to design efficient and targeted trials and to assess the generalizability of trial results. However, the clinician should be mindful of the quality of evidence when making treatment choices, and there is no substitute for a well-conducted randomized trial.

The Impact of Patients' Expectations on Outcomes

There is ample evidence demonstrating that patients' expectations regarding the effectiveness of treatment has a profound influence on the outcome of treatment. It is not at all unusual for patients receiving inactive agents (placebos) or sham surgical procedures to report an improvement in symptoms. For example, as much as two thirds of the symptom improvement appreciated by patients taking finasteride for benign prostatic hyperplasia was reported by those assigned to placebo in double-blind randomized trials. Furthermore, improvement in objective outcomes, such as mortality rates, have been reported following use of placebo agents or sham surgical procedures. There are also examples of studies in which patients who have sufficiently high expectations to comply faithfully with a prescribed regimen do better than patients who do not. These "compliance effects" occur regardless of whether the regimen includes an active agent or actual procedure. It is likely that the effect of patients' expectation plays a substantial role in the perceived effectiveness of many interventions, including those termed "complementary" or "alternative" because they are outside the mainstream of what is taught in medical schools. An important task of primary care is to teach patients the rules of evidence that are critical to the scientific basis of health services.

TREATMENT CHOICE AND PATIENT VALUES

Even if the probabilities of outcomes contingent on alternative treatment choices can be estimated precisely, there is still much work to be done to ensure a wise treatment choice for a particular patient. Consider the predicament of the 75-year-old man who is bothered by nocturia and urinary frequency resulting from benign

prostatic hyperplasia. He can live with his symptoms, but this means accepting a diminished quality of life. He may choose to try a medical approach, such as finasteride or an a-blocker, with hope of modest relief of symptoms. Alternatively, surgical therapy offers a good chance of more dramatic symptom relief but also confers a small but real risk of a catastrophic event that could result in death. Surgery also puts the patient at risk for complications, such as incontinence or impotence, that can diminish the quality of life as much as or more than nocturia and frequency.

The probabilities of these outcomes are critically important to the decision. Equally important, however, is how the patient feels about the outcomes. Different men feel differently about trade-offs between urinary function and sexual function, and they have different attitudes toward the small risk of perioperative death. These personal value judgments are as important in determining the "right" choice as are the probabilities that are derived from clinical research. The right choice, therefore, requires careful communication between clinician and patient about what the possible outcomes will mean for that patient's quality of life.

CHAPTER 6 IMMUNIZATION

EDWARD T. RYAN

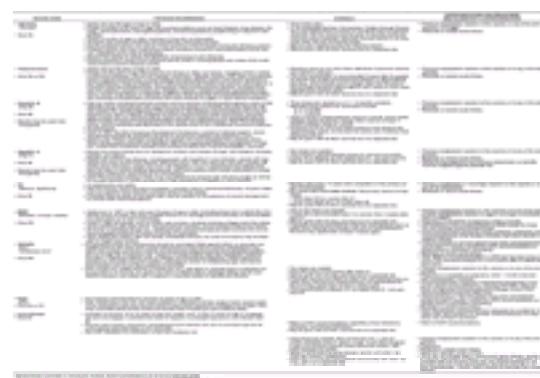
Immunization is the most cost-effective means of preventing disease. Immunizations are grouped into five major categories: (a) routine vaccinations of childhood, (b) routine vaccinations of adulthood (Table 6.1), (c) postexposure prophylactic immunizations, (d) travel-related immunizations, and (e) work-related/special circumstance immunizations. Of these, administration of vaccines during childhood has been most successful; fewer than 100 children die each year of vaccine-preventable illnesses in the United States. In comparison, 50,000 to 70,000 adults die each year in the United States of vaccine-preventable illnesses.


Table 6.1. Summary of Recommendations for Routine Adult Immunizations[a]

Compared with responses in young adults or children, responses are often lower in elderly or immunocompromised persons; however, vaccines still induce clinically meaningful protective immunity in most adult populations. Vaccine administration in adults is safe; most adverse reactions occur at the injection site and include induration, erythema, and tenderness; low-grade fever and mild constitutional symptoms may also occur. Severe complications such as anaphylactic shock occur in fewer than 1 in 1 million inoculations. Individuals with a high likelihood of having severe reactions can usually be identified before the administration of a specific agent. Although most people born in the United States receive standard immunizations during childhood, approximately 1 in 25 persons currently living in the United States was born in another country. Many of these people have been incompletely immunized.

GENERAL PRINCIPLES OF IMMUNIZATION

Types of Immunization

Immunizations can be either *active* or *passive*.

Active Immunization entails the administration of a *vaccine* (live attenuated microorganisms, killed microorganisms, or purified proteins or polysaccharides of microorganisms) or a *toxoic* (a deactivated toxin). Active immunization often provides long-term (lasting for years or, less frequently, for life) protective immunity; however, meaningful immunity is often not achieved until 2 to 4 weeks after vaccination. Vaccines that are live attenuated versions of an infectious agent are usually more efficacious and provide more long-lasting immunity than do nonliving vaccines. Similarly, polysaccharide-based vaccines are in general less immunogenic than protein-based vaccines; however, the coupling of polysaccharide antigens to "carrier" proteins can markedly increase immunologic responses against polysaccharide components.

Passive Immunization entails the administration of preformed antibody (such as immunoglobulin). Passive immunization results in immediate protective immunity, but such immunity is short-term (usually lasting for only 3 to 6 months).

Administration

A host of strategies are available for administration.

Technique. With a few exceptions, most vaccines can be administered simultaneously. An adult can usually tolerate the administration of up to four vaccines (two vaccines administered separately in each deltoid area) in a given appointment. Adults should be vaccinated in the *deltoid area* of their upper extremities. Because of unreliable absorption, inoculations (other than certain immunoglobulin preparations) should not be administered in the gluteal region. A new syringe and needle should be used for each vaccination/immunization. If more than one live attenuated viral vaccine (e.g., measles, mumps, and rubella; varicella; yellow fever) is indicated, the vaccines should be administered on the same day (at different injection sites) or at least 30 days apart. When live vaccines are administered on different days sooner than 30 days apart, immunologic responses decrease. For similar reasons, inoculations with the cholera vaccine (rarely, if ever, indicated) and the yellow fever vaccine should be separated by at least 3 weeks.

Combining Passive and Active Immunization. Immunoglobulin preparations (and immunoglobulin-containing blood products) should not be administered with live vaccines when the immunoglobulin preparation contains antibodies directed against such viruses. If a patient requires both an immunoglobulin preparation and a live viral vaccine, the viral vaccine should be administered at least 2 weeks before the immunoglobulin preparation (if possible). If the immunoglobulin preparation is administered first, 3 to 11 months (usually 3 to 6) should elapse before the live viral vaccine is administered. Simultaneous administration of immunoglobulin preparations, the oral polio vaccine, and all or any of the nonliving vaccines is not problematic. Persons with immunoglobulin A deficiency should not receive immunoglobulin preparations unless the risk of illness clearly outweighs the risk of anaphylaxis.

Allergic Reactions

A person who has an anaphylactic reaction to *eggs* or *egg proteins* should not receive vaccines grown in chick egg embryos or cell cultures. For special circumstances, vaccine desensitization protocols are available. Gastric or intestinal discomfort after eating eggs is not a contraindication to receiving these vaccines. Vaccines sometimes contain low levels of antibiotics that can trigger an allergic reaction. No vaccine that is available in the United States contains penicillin, so an allergy to penicillin does not contraindicate the use of any vaccine in the United States. However, the measles, mumps, and rubella (MMR), varicella, and inactivated polio virus (IPV) vaccines do contain low levels of *neomycin*; individuals with a history of anaphylactic reactions to neomycin should not receive these vaccines. IPV should also not be administered to individuals with a history of anaphylactic reactions to *polymyxin E* or *streptomycin*. Similarly, the oral polio vaccine should not be administered to individuals with a history of anaphylactic reactions to *streptomycin*.

If an individual has a history of a reaction to any vaccine, the repeated administration of that vaccine should be carefully weighed against the risk and severity of the illness in that individual and the severity of the previous reaction.

Vaccination during Pregnancy and Breast-feeding

As a general rule, live attenuated vaccines should not be administered to pregnant women (Table 6.2). Similarly, a woman who receives a live attenuated viral vaccine should be advised to avoid pregnancy for 3 months. Pregnancy in a household contact is not a contraindication to vaccine administration (except to varicella vaccine if the pregnant woman is herself not immune to varicella/chickenpox). Breast-feeding is not a contraindication to vaccine administration (only the rubella

vaccine has been reported to be transmitted through breast milk, and this attenuated virus has not been known to be harmful to neonates or infants).

Table 6.2. Vaccination During Pregnancy

Vaccination of Immunocompromised Persons

Severely immunocompromised persons should not receive vaccines of *live attenuated viruses* (Table 6.3 and Table 6.4). Moreover, an individual with an immunocompromised household contact should not receive the live oral polio vaccine or the varicella vaccine because person-to-person transmission can occur. The MMR vaccine, however, may be administered to individuals infected with the human immunodeficiency virus who are not severely immunocompromised. All vaccines of *inactivated viruses* can be safely administered to immunocompromised individuals, although immune responses may be less than optimal. Anecdotal reports associate administration of the tetanus-diphtheria (Td) vaccine with organ rejection in transplant recipients, but conclusive data are lacking.

Table 6.3. Summary of ACIP Recommendations on Immunization of Immunocompromised Persons

Table 6.4. Summary of ACIP Recommendations on Immunization of Immunocompromised Persons

Misconceptions about Contraindications

Mild or moderate *local reactions* to a previous vaccination (including tenderness, redness, or swelling at the injection site, or a low-grade fever) are not contraindications to subsequent vaccination. Neither are mild respiratory, intestinal, or *flulike illnesses, low-grade fever*, or a history of a recent illness contraindications to vaccine administration. Current antibiotic therapy is a contraindication only to the administration of the oral typhoid vaccine (an attenuated bacterial strain that is killed by antibiotics); all other vaccines can be administered to an individual receiving antibiotics. With the exception of allergies to neomycin, streptomycin, or polymyxin B, allergies to antibiotics are not a contraindication to vaccine administration. Moreover, a history of seizures is not a contraindication to vaccine administration, nor is a history of a non–vaccine-associated chronic demyelinating condition (such as multiple sclerosis or Guillain-Barré syndrome); many such individuals are at increased risk for a number of vaccine-preventable illnesses.

Record Keeping

The National Childhood Vaccine Injury Act of 1988 requires that all health care providers who administer MMR vaccines (in any combination), polio vaccines, or diphtheria, pertussis, and tetanus vaccines (in any combination) maintain immunization records and contact the Centers for Disease Control and Prevention (CDC) and the Food and Drug Administration (FDA) if an adverse reaction occurs. This is trueeven if a vaccine is administered to an adult. Records should include the date, name of the vaccine, manufacturer, lot number, inoculation site, route of administration, and name of the person administering the vaccine. Federal law also requires the distribution of vaccine information statements (VIS) to persons (even adults) receiving certain vaccines (MMR, polio, diphtheria, pertussis, and tetanus vaccines in any combination). VIS can be accessed at www.cdc.gov/nip/far.htm or www.immunize.org/vis (VIS sheets are available in 18 languages).

SPECIFIC IMMUNIZATION PROGRAMS

Tetanus

Despite the fact that almost half of all individuals older than 60 years of age lack protective levels of serum antitetanus toxin antibodies, fewer than 100 cases of tetanus occur each year in the United States. Almost all cases of tetanus reported in the United States occur in adults who did not complete a primary tetanus immunization series or who did not receive appropriate treatment for a tetanus-prone wound. Prevention of tetanus should, therefore, concentrate on primary vaccination and proper postexposure immunization (Table 6.5); immigrants and elderly persons are most likely not to have received a primary immunization series.

Table 6.5. Wound Management After Exposure: Tetanus

The tetanus vaccine can be administered as a *monovalent vaccine* (T) or in combination with the *diphtheria vaccine* (Td). The tetanus and diphtheria vaccines are based on formaldehyde-treated toxoids (detoxified toxins). Td should be administered rather than tetanus toxoid alone because the diphtheria toxoid does not increase the rate of adverse events and diphtheria is reemerging as an infectious disease problem worldwide. The more common reactions to Td vaccine include erythema, induration, and tenderness at the inoculation site. It is recommended that all adults receive a Td vaccine every 10 years, although some authorities suggest that a one-time tetanus booster at age 50 may suffice for individuals who have received a full primary series. Appropriate postexposure prophylaxis is required regardless of vaccination regimen.

Adults who require a primary Td series should receive two doses IM 4 weeks apart, and a third dose 6 to 12 months after the second inoculation. There is no need to repeat doses if the schedule is interrupted.

Diphtheria

In the United States, diphtheria in adults is rare (fewer than 10 cases per year), especially among adults who have received a complete primary series, even if it has been more than 10 years since the administration of a diphtheria booster. More than half of American adults lack protective levels of antidiphtheria toxin antibodies. Worldwide, there has been a resurgence of diphtheria in several countries, including the states of the former Soviet Union. Travelers to such countries should receive Td vaccine if it has been longer than 10 years since their last booster. Diphtheria antitoxin of equine origin may be used to treat respiratory diphtheria.

Pertussis

Because the pertussis vaccine is associated with frequent adverse events in older children and adults, its administration is restricted to children younger than 7 years. Many adults are not immunized and therefore susceptible. Adults presenting with a severe, persistent cough should be suspected of having pertussis infection (see Chapter 52). The new acellular pertussis vaccine is associated with a lower side effect profile but is approved only for use in children.

Measles, Mumps, and Rubella

Measles, measles and rubella (MR), and measles, mumps, and rubella (MMR) vaccines are available. Individuals immune to one or more components of the combination vaccines can still receive MMR vaccine. The MMR vaccines (in any combination) should not be administered to pregnant women or to severely immunocompromised persons; women of child-bearing age should be cautioned to avoid pregnancy for 3 months after vaccination. Individuals with a history of severe allergic reaction to eggs should not receive vaccines containing measles or mumps components, nor should the vaccine be administered to individuals with anaphylactic reactions to neomycin. Individuals who have received immunoglobulin preparations or blood/blood products in the preceding 3 to 11 months may not generate adequate immune responses to vaccination.

Measles. In most circumstances, use of the MMR vaccine is preferred. Persons born before 1957 are assumed to be immune to measles because of the very high likelihood of exposure; such persons do not require serologic evaluation for antibody. In the United States, measles is almost eradicated; most cases that currently occur are associated with international travel or educational institutions. After a single inoculation of the live attenuated measles vaccine (in any combination), protective antibody levels develop in approximately 90% to 95% of individuals. The remaining 5% to 10% remain at risk for measles. A second dose of the vaccine will result in protective immunity in almost all of these individuals. Those immunized between 1963 and 1967 may have received an inactivated measles vaccine and should receive the live viral vaccine.

Preexposure Immunization. Because of a resurgence of measles, it is now recommended that persons born after 1956 who are attending *postsecondary educational institutions*, who are *health professionals*, or who are *traveling to a foreign country* receive two doses of live attenuated MMR vaccine (or measles monovalent vaccine), separated by at least 1 month, unless they have a physician-documented case of measles or serologic confirmation of measles antibody. Many secondary schools now require documentation of two vaccinations against measles. It is more cost-effective to administer the two doses of the vaccine to all individuals than to screen patients for a serologic response after a single vaccination.

Postexposure Prophylaxis. A susceptible individual exposed to someone with measles should receive IM *immunoglobulin* (0.25 mL/kg, maximum of 15 mL) followed 6 months later by live measles vaccine. Immunoglobulin can prevent or modify infection if given within 6 days of exposure. The vaccine itself may afford some protection if administered within 72 hours of exposure. Postexposure immunoglobulin should also be administered to severely immunocompromised individuals exposed to active measles (regardless of immunization history). Because measles vaccination can temporarily suppress tuberculin reactivity, any tuberculosis skin testing should be performed on the day of vaccination or at least 4 to 6 weeks later.

Mumps. Because lifelong protective immunity develops in almost all individuals after immunization with a single inoculation of the live attenuated mumps vaccine, routine immunization with MMR results in adequate protection of almost all individuals. A mumps vaccination is indicated for individuals born after 1956 who have not received at least one live mumps vaccine, have not had a physician-documented case of mumps, or who lack serologic evidence of immunity. Administration of immunoglobulin after exposure to mumps has not been documented to be of clinical efficacy.

Rubella. Protective immunity develops in almost all individuals after a single vaccination with a live attenuated rubella vaccine. Routine vaccination with MMR is sufficient in almost all cases. Because rubella causes considerable morbidity if acquired during pregnancy, special emphasis should be placed on identifying susceptible women of childbearing age (especially among immigrant populations). Susceptible women should receive the rubella vaccine before they become pregnant or after they have delivered. Health care workers with antibody evidence of immunity should also be immunized. The vaccine is well tolerated, although mild and transient arthralgias or arthritis can occur.

Polio

In the United States, parenterally administered *inactivated polio vaccine* (IPV) is replacing the live *oral polio vaccine* (OPV) because the approximately 5 to 10 cases of poliomyelitis that occur each year in the United States are caused by OPV (risk in recipients or household contacts of recipients is 1 per 500,000 first doses administered). IPV does not cause poliomyelitis. There are now few indications for use of OPV: mass vaccination during out breaks of poliomyelitis; vaccination of unimmunized children traveling in fewer than 4 weeks to areas of the world with endemic or epidemic poliomyelitis; and, vaccination of individuals who refuse IPV. Although the World Health Organization (WHO) has targeted polio for eradication, it is still active in a number of regions of the world (especially South Asia and sub-Saharan Africa). As such, paralytic poliomyelitis could recur in epidemic fashion in the United States if population-based immunity is allowed to wane.

Routine polio vaccination of adults in the United States is not recommended. Individuals planning to travel to *Africa, Asia*, the *Middle East*, and some areas of *Eastern Europe* should receive a booster dose of IPV if more than 10 years has elapsed since primary vaccination. The clinical efficacy of additional boosters is unknown; some recommend repeated boost every 10 years for ongoing travel to endemic areas. *Laboratory workers* and *health care professionals* who are exposed to wild-type polio virus should also be vaccinated. A three-vaccine primary series of IPV can be administered to an adult at 0 and at 4 to 8 weeks, and at least 4 weeks (preferably

6 to 12 months) after the second inoculation.

Contraindications. The polio vaccine should never be administered to an *immunocompromised* individual, to anyone with a household contact who is immunocompromised, or to a person with a history of an anaphylactic reaction to *streptomycin*. IPV should not be administered to individuals with a history of anaphylactic reactions to streptomycin, polymyxin B, or neomycin. A prior episode of polio (caused by one strain of polio virus) is not a contraindication to receiving IPV (protective against three strains of polio virus).

Influenza

Approximately 20,000 people die of influenza each year in the United States. Most of these deaths occur in persons 65 years of age or older, with those having cardiopulmonary conditions at greatest risk. The vaccine is composed of inactivated viruses formulated yearly to include two influenza viral type A strains and one type B strain. Contrary to popular belief, the vaccine does not cause influenza. In young adults, the vaccine is quite effective at reducing the severity of clinical illness and time lost from work. In older persons, there is a 30% to 40% reduction in overall clinical illness and a decrease in pneumonia, hospitalization, and deaths from influenza. Despite these benefits, vaccination rates fall short.

Indications and Timing. Individuals with chronic cardiopulmonary disorders (including asthma), women who will be in their second or third trimesters of pregnancy during the flu season, high-risk women who will be pregnant at any point during the flu season, residents of long-term care facilities or nursing homes, immunocompromised individuals, those who care for elderly or immunocompromised persons, health care workers, and individuals over the age of 65 should receive the vaccine. Some groups recommend that the vaccine be administered to all individuals 50 years of age or older. The vaccine should be offered to anyone who wishes to avoid the flu. In the continental United States, administration should be between October and mid-November, but the vaccine can be administered at any time during the flu season. Although the influenza season is usually well defined in the temperate United States, influenza outbreaks occur at different times throughout the world. Protection begins 1 to 2 weeks after inoculation and continues for 6 months. The duration of protective immunity in frail, elderly, or immunocompromised individuals may be shorter. During a community outbreak of influenza, drugs effective against influenza viruses have a useful adjunctive role (see Chapter 52).

Side Effects and Contraindications. Transient low-grade fever, myalgia, and malaise can occur after immunization. Individuals with a history of influenza vaccine–associated Guillain-Barré syndrome should not receive the influenza vaccine. The risk of the vaccine in individuals with a history of Guillain-Barré syndrome not associated with influenza vaccination is controversial. Such persons may be at high risk for severe influenza.

Pneumococcal Pneumonia

Approximately 500,000 cases of pneumonia and 40,000 deaths are caused by *Streptococcus pneumoniae* each year in the United States. In addition, pneumococcal disease accounts for an estimated 3,000 cases of meningitis and 50,000 cases of bacteremia, annually. The current vaccine contains capsular polysaccharide components of 23 pneumococcal types; these account for approximately 80% to 90% of invasive pneumococcal infections and include the six serotypes most frequently associated with antibiotic resistance. Because antibiotic resistance is rapidly rising, immunization is of increasing importance.

Efficacy. The vaccine reduces the incidence of pneumococcal bacteremia and pneumonia among younger individuals and among older individuals who are able to generate a good antibody response. Overall, the vaccine is 60% to 80% effective at preventing invasive disease. Efficacy in immunosuppressed individuals is less well defined.

Indications. Severe disease is most likely to develop in persons more than 65 years of age and those with cardiopulmonary disease, immunocompromise, diabetes, alcoholism, or hepatic or renal failure, and they should receive the vaccine. The vaccine should be administered at least 2 weeks before elective splenectomy or immunosuppression (if possible). Alaskan natives, African-American adults, and certain American Indian populations are also at increased risk. Fewer than 20% of members of target populations have received the vaccine, and only 45% of the elderly have been vaccinated.

Because not all persons manifest a full antibody response on first vaccination and because antibody levels may decline with time, some recommend a booster vaccination if 5 or more years has elapsed since first vaccination, although the utility of booster vaccination has not been definitively established.

Safety. The pneumococcal vaccine is safe; most reactions are minor and occur at the inoculation site. Severe allergic reactions are rare but might become more frequent with subsequent immunizations. Pneumococcal and influenza vaccines can be administered at separate inoculation sites during a single office visit. A new pneumococcal 7 valent diphtheria CRM 197 protein conjugate vaccine has recently been approved for use in children, but has not been approved for use in adults.

Haemophilus influenzae Infection

Before the introduction of the *H. influenzae type b conjugate vaccine (Hib)*, most cases of invasive disease in children were caused by *H. influenzae* capsular type b, but with the application of Hib vaccine, most cases now represent non–type b disease. A number of Hib vaccines are available, all linking a polysaccharide molecule (polyribosylribotol phosphate, or PRT) to a carrier protein to increase immunogenicity. The vaccine is often administered to individuals with functional or anatomic asplenia or immunoglobulin deficiencies because such persons have a higher incidence of invasive disease caused by encapsulated organisms. However, definitive benefit has not been established, perhaps because many such individuals already have humoral immunity against *H. influenzae* type b.

Meningococcal Disease

Meningococcal disease is endemic throughout the world, and large epidemics can occur globally. Information on meningococcal disease activity is available at www.cdc.gov. In the United States, meningococcal infection is usually caused by *Neisseria meningitidis* serogroup B or C and occurs as isolated cases or as small outbreaks. A meningococcal polysaccharide vaccine that is quadrivalent for serogroups A, C, Y, and W-135 is available in the United States. Routine administration is not recommended, but persons with anatomic or functional asplenia and those with defective complement should be given the vaccine. Additionally, the vaccine should be recommended for travelers who visit certain areas of the world during "meningitis season" (e.g., the Sahel region of sub-Saharan Africa duringthe dry winter months (December through June). Controversy currently exists on whether the vaccine should be administered to college-age students in the United States. The low incidence of meningococcal disease in this population argues against routine administration of the vaccine. Some experts, however, recommend that the vaccine be administered to college freshmen who will reside in a dormitory. The vaccine is well tolerated; most adverse reactions are mild and local. The need for booster vaccination is not well documented, and a booster vaccination is not required within 3 to 5 years of primary inoculation. Saudi Arabia requires documentaion of meningococcal vaccination from all pilgrims.

Rabies

Rabies is a potentially fatal viral infection transmitted in the saliva of animals, usually through a bite. More rarely, cases result from the contamination of wounds with saliva of a rabies-infected animal; aerosol transmission occurs in special circumstances (e.g., research laboratories, bat-infested caves). Although dog bites account for the majority of rabies cases throughout the world, dog bites account for a minority (38%) of human rabies cases in the United States (and in 50% of such cases, the dog bite occurred overseas). Most rabies in the United States occurs in nondomesticated animals, especially bats, skunks, foxes, coyotes, raccoons, and woodchucks. Rabies should be considered in any case of *rapidly progressive encephalitis*, even in individuals who do not have a history of an animal bite. Therapy is preventive in nature and should be administered as either preexposure or, more commonly, postexposure prophylaxis.

Indications. Persons bitten by infected animals should receive *postexposure prophylaxis*. The risk of transmission of rabies through a ferret bite approximates that associated with a dog or cat bite. Because bat bites can be small, may not be recalled, and can be missed on physical examination, rabies postexposure prophylaxis is recommended for individuals who have a bat exposure and cannot exclude a bat bite. Such situations might include an individual who awakens in a room with a bat, someone who is unresponsive in a room with a bat (unconscious or intoxicated), or a person in a room with a bat who cannot report an exposure (a small child).

Postexposure prophylaxis consists of three crucial steps (Table 6.6):

Table 6.6. Rabies Immunization

- First, the wound should be immediately and thoroughly *cleaned* and extensively *irrigated* with soap and water. Cleaning the wound with iodine or alcohol is not sufficient.
- Second, 20 IU of *rabies human immunoglobulin* (HRIG) per kilogram should be administered to individuals with an exposure who have not received the rabies vaccine within the previous 2 years. The entire HRIG dose should be instilled directly into the animal bite. If the entire HRIG dose cannot be instilled into the wound, as much of the dose that can be administered should be locally instilled and the remainder inoculated IM at a site distinct from the vaccine inoculation. If there is more than one animal bite, the HRIG dose should be divided equally among sites.
- Third, all individuals should receive *rabies vaccine* (a 1-mL dose of any of the rabies vaccines administered IM in the deltoid). If an individual has received a rabies primary vaccine series approved in the United States within the previous 2 years (or a booster dose after a primary series within the previous 2 years), that individual should receive two rabies boosters (days 0 and 3). Individuals who have not received such rabies vaccines within the previous 2 years should receive five doses (days 0, 3, 7, 14, and 28). HRIG and rabies vaccine should never be administered at the same site or with the same syringe.

Vaccine Preparations and Administration. Currently, three rabies vaccines are approved in the United States, the HDCV (human diploid cell rabies vaccine; Imovax, Pasteur Merieux Connaught), the RVA (rabies vaccine adsorbed, SmithKline Beecham), and the PCEC rabies vaccine (purified chick embryo cell culture; RabAvert, Chiron). An intradermal 0.1-mL dose (approved for use with HDCV for preexposure prophylaxis) should never be used for postexposure prophylaxis. When postexposure prophylaxis is administered, no more than the recommended dose of HRIG should be administered (because HRIG can partially suppress the antibody response to rabies vaccine). Tetanus prophylaxis should be considered.

Adverse Effects. Most reactions to rabies vaccine are local and mild. Serum sickness–type reactions can occur, especially with multiple boosting doses of HDCV or RVA; the PCEC vaccine is rarely associated with such reactions. The PCEC rabies vaccine can be used for booster vaccination regardless of the identity of the primary vaccination series. HRIG available in the United States appears to be safe. The safety of antirabies immunoglobulin preparations (human and rabbit) manufactured overseas has not been formally evaluated. Because rabies is a fatal illness, pregnancy should not be considered a contraindication to postexposure prophylaxis if it is indicated.

Preexposure Prophylaxis. Individuals who may be at risk for rabies should consider receiving preexposure prophylaxis, including those who work with animals, laboratory researchers who work with rabies virus, travelers who plan on spending a prolonged period of time in endemic areas, and possibly short-term travelers who will be in rabies-endemic areas without access to medical care. Preexposure rabies vaccination consists of three 1-mL dose immunizations administered IM in the deltoid on days 0, 7, 21 *or* 28. The HDCV is approved as an intradermal injection of 0.1 mL; however, intradermal HDCV and malaria chemoprophylaxis (with chloroquine or mefloquine) should not be simultaneously administered. Antibody levels should be regularly checked in persons with ongoing exposure to rabies, and booster vaccinations should be administered as needed (Table 6.6). Further information can be obtained from the CDC (telephone 404-639-3111) or from the local department of public health, which may have an "on-call" rabies specialist.

Varicella

The complication rate of varicella infection (*chickenpox*) is higher in adults than in children; pneumonitis, hepatitis, encephalitis, and death are more frequent. Approximately 5% of American adults are not immune; the rate is higher among those born outside the United States. Since the varicella vaccine became a routine vaccine of childhood, the incidence of varicella infection has been falling rapidly. The varicella vaccine is a live attenuated viral vaccine that is most immunogenic in children (who need only a single inoculation). The vaccine is administered twice to adults, the second inoculation 4 to 8 weeks after the first. The vaccine is not completely protective, but a 70% reduction in the expected number of cases is achieved. When the vaccine is administered to adults who have a high frequency of exposure (through a household contact), approximately 27% of adults report breakthrough chickenpox, but of a mild nature. The efficacy of the vaccine for protection against the complications of chickenpox (including encephalitis, hepatitis, and pneumonitis) has not been assessed, but it may well be protective. The need for booster vaccination has not been established.

Indications. The vaccine should be administered to all susceptible adults and adolescents with a high risk of exposure (health care workers, day care workers, teachers, institutional care workers, those involved in postsecondary school educational institutions, military personnel, and travelers, among others) and to all susceptible persons who would be at risk for severe complications of varicella (nonpregnant women of childbearing age, family members of immunocompromised individuals). The majority of adults who do not report a history of chickenpox have serologic evidence of a previous episode of varicella. The serum of adults who deny a previous episode of chickenpox should be screened for antivaricella antibodies. The vaccine should not be administered to immunocompromised individuals or pregnant women. The manufacturer recommends that vaccinated women avoid pregnancy for 3 months after inoculation. Individuals who have received immunoglobulin preparations or blood/blood products within the previous 3 to 11 months may not adequately respond to the vaccine. The vaccine should not be administered to individuals with an anaphylactic reaction to neomycin. The vaccine requires storage at a temperature below −15°C.

Adverse Effects. The vaccine is well tolerated by most individuals. Common reactions are local in nature: A temperature of 37.7°C (100°F) or higher will develop in approximately 10% of individuals after the first or second vaccination; 25% to 30% will complain of local erythema, tenderness, and swelling at the inoculation site; in 3%, a *localized varicella-like rash* will develop at the injection site after the first inoculation, and such a rash will develop after the second inoculation in approximately 1%. Rashes occur 1 to 3 weeks after inoculation. A *generalized varicella-like rash* can occur in 5% after the first inoculation and in 1% after the second. The median number of lesions in such individuals is five.

Precautions. The vaccine strain of the virus has been *transmitted* to susceptible contacts. Persons receiving vaccine should avoid contact with immunocompromised individuals who lack immunity to varicella and should avoid contact with susceptible pregnant women. The manufacturer advises that such precautions be taken for 6 weeks after inoculation and that vaccinated individuals avoid contact with newborn infants of mothers who lack a documented history of chickenpox or laboratory evidence of prior varicella. The manufacturer also advises that *salicylate products* not be administered for 6 weeks after vaccination because of the theoretical risk of *Reye's syndrome*. In a number of individuals who have received the varicella vaccine, *herpes zoster infection* (shingles) has subsequently developed. In some of these cases, viral cultures disclosed the presence of wild-type varicella virus, demonstrating the incomplete protective efficacy of the vaccine.

Postexposure Prophylaxis. If susceptible pregnant or immunocompromised individuals are exposed to varicella, they should receive IM *varicella zoster immunoglobulin* (VZIG; 125 U/10 kg; maximum dose, 625 U). For susceptible individuals who are neither immunocompromised nor pregnant, postexposure use of the varicella vaccine is worth considering. The varicella vaccine appears effective in preventing chickenpox and in reducing the severity of the disease if used within 3 and possibly up to 5 days after exposure. The vaccine should not be administered concomitantly with varicella immunoglobulin.

Lyme Disease

Lyme disease is transmitted by *Ixodes* ticks. The causative agent of Lyme disease, the spirochete *Borrelia burgdorferi*, is usually transmitted when a nymphal tick feeds, usually during the late spring and summer. (Feeding of adult ticks occurs during the fall, winter, and early spring and is less likely to transmit *B. burgdorferi*.) OspA (outer surface protein A) is a *B. burgdorferi* antigen that the spirochete expresses only when it is within the digestive system of the tick vector. The first vaccine against *B. burgdorferi* is now available (LYMErix vaccine, SmithKline Beecham). Others are under development. It induces anti-OspA antibody responses. Vaccine efficacy is believed to be related to the transfer (during a blood meal) of a vaccine recipient's serum anti-OspA antibody into the tick's intestinal system; the antibody

attacks the organism while it is still within the tick.

Efficacy. Vaccine efficacy appears to be directly related to the titer of serum anti-OspA antibody and is maximized by frequent vaccine administration/boosting. When administered between January and April (immediately preceding the occurrence of nymphal feeding) as two monthly doses, the vaccine demonstrates efficacy of approximately 50%. Efficacy increases to 75% to 80% with an additional booster given at 1 year. Efficacy is reportedly near 100% for protection against asymptomatic Western blot seroconversion. To achieve the maximal 80% protection against definitive disease achieved in trials, three properly timed doses of the vaccine given during a 12-month period are required. Preliminary evidence suggests that similar protection may also be achieved with an accelerated vaccine schedule (0, 1, and 2 months).

Indications. The transmission of Lyme disease is very focal, with the overwhelming majority of Lyme disease cases in the United States occurring in focal areas of the Northeast and upper Midwest. Risk is related to exposure to infected ticks during outdoor activities, particularly in grassy and wooded areas. Individuals who should consider receiving the vaccine include those with (a) *intense and sustained* occupational or recreational *outdoor exposure* in tick-infested areas endemic for Lyme disease; (b) *long-term residents* of highly endemic areas (the yearly risk for such individuals is cumulative); (c) individuals with a history of *antibiotic-responsive Lyme disease* who have a recurrent or ongoing risk for acquiring Lyme disease (secondary infections can occur). The LYMErix vaccine is approved for use in individuals between the ages of 15 and 70 years.

Individuals with short-term exposures outdoors (<3 months) in highly endemic areas are at low risk for acquiring Lyme disease (risk approximately 0.1% to 1.0%). This risk can be markedly diminished with simple antitick measures, which include using insect repellents, wearing long trousers, and checking routinely for adherent ticks. These measures need to be continued even by persons who receive the vaccine because they will still be at risk for other tick-borne illnesses, such as babesiosis, tularemia, ehrlichiosis, and Rocky Mountain spotted fever. Administration of the vaccine to this population should be handled on an individual basis.

Contraindications. Those who should not receive the vaccine include (a) individuals with a history of *antibiotic-refractory (treatment-resistant) Lyme arthritis* (such arthritis is possibly related to anti-OspA immunologic responses); (b) *children* under 15 years of age (safety and efficacy not yet established); (c) *elderly persons* over 70 years of age (safety not yet established); (d) those with immunologically mediated *inflammatory joint disease* (anti-OspA antibodies could possibly worsen the arthritis—see below). Data are insufficient regarding use in persons with multiple sclerosis or demyelinating neurologic conditions, diffuse muscular pain, or chronic health conditions. The vaccine has also not been studied in pregnant or nursing women. Immunosuppressed individuals may have a less-than-optimal immune response.

Adverse Effects. The long-term safety of the anti-OspA antibody response induced by the vaccine is unknown. Anti-OspA antibodies may be related to the *immunologically mediated* joint disease that sometimes complicates Lyme disease (so-called antibiotic-resistant Lyme arthritis). Whether stimulating the production of such antibodies will increase the frequency of immunologically mediated joint injury remains to be seen and continues to be at least a theoretical concern.

The stimulation of Osp A antibody by Lyme vaccine may *interfere with serologic testing* for Lyme infection. Some enzyme-linked immunosorbent assays (ELISAs) test for OspA antibody and may produce a false-positive reading in an immunized person. In addition, an OspA band can appear on the more definitive Western immunoblot test. Although the screening ELISA will often be read as positive, the 31-kD anti-OspA band should not interfere with Western blot interpretation if strict CDC guidelines for interpretation are used.

Tuberculosis

Bacille Calmette-Guérin (BCG) is a live attenuated strain of *Mycobacterium bovis* that is used in *children* throughout the world to prevent tuberculosis. Vaccine trials in *adults* have yielded conflicting results. Overall, the vaccine may be approximately 30%-50% effective. Most immigrants to the United States will have received the BCG vaccine as children. A positive tuberculin skin test result, however, should not be ascribed to BCG vaccination in any individual, regardless of the country of origin. In the United States, where the prevention of tuberculosis rests on the proper identification and treatment of exposed individuals, BCG is rarely administered to protect individuals against tuberculosis (see Chapter 49). The vaccine may be considered for individuals exposed to multiple drug–resistant tuberculosis, including health care workers who practice in certain prison settings or in certain overseas clinics. It may also be useful for those who cannot receive preventive therapy but have close contact with an individual with active, untreated disease or with disease that is ineffectively treated or multiple drug–resistant. The vaccine is administered intradermally; ulceration and prolonged discharge at the site of vaccination, regional adenitis, and osteitis occur in up to 20%. Disseminated BCG can develop in immunocompromised individuals who receive the vaccine.

Hepatitis B

Hepatitis B vaccines contain recombinant, noninfectious hepatitis B surface antigen. Two hepatitis vaccines are available in the United States: Engerix-B (SmithKline Beecham) and Recombivax HB (Merck). They can be used interchangeably, even in a primary inoculation. Three doses induce protective antibodies in more than 90% of healthy young adults. Antibody responses decline with increasing age and are lower in immunocompromised individuals.

Indications. Because it has been difficult to carry out vaccination among many high-risk groups, the hepatitis B vaccine has been introduced as a *standard childhood vaccine.* Nonetheless, high-risk persons should still be offered vaccination, especially individuals likely to comply, such as those with occupational or other exposure to blood or body fluids and the household and sexual contacts of hepatitis B virus carriers. Other high-risk groups include intravenous drug users, those with multiple sexual partners, male homosexuals, and individuals with a recent history of a sexually transmitted disease. The hepatitis B vaccine should be considered for long-term overseas travelers, especially for those who may be exposed to blood or bodily secretions through employment or sexual contact. The prevalence of hepatitis B infection is much higher, and the carrier state and chronic active hepatitis are much more frequent, in Asia, Africa, and Latin America than in the Unites States.

Postexposure Prophylaxis should be administered to individuals with mucous membrane or percutaneous exposure to blood or bodily secretions of individuals known or suspected of being acutely infected with hepatitis B or of being a hepatitis B carrier. IM hepatitis B immunoglobulin (HBIG; 0.06 mL/kg) should be administered immediately after exposure, ideally within 6 days. The vaccine series should also be started.

Administration. The vaccine can be administered to adults in three doses (0, 1, and 6 months), although other vaccination regimens can be employed. The Engerix-B vaccine can also be administered at 0, 1, 2 and 12 months; this accelerated regimen results in a more rapid increase in the serum anti-hepatitis B response. The hepatitis B vaccine should routinely be administered IM in adults in the deltoid muscle; injection in the buttock has been associated with a lower antibody response.

Postimmunization Serologic Testing for hepatitis B surface antibody should be performed in individuals who are immunocompromised, 30 years of age or older when they receive the vaccine, or at high risk for ongoing exposure to hepatitis B. Those who do not respond to the vaccine should repeat the complete three-dose inoculation series (reboosting); serum should then be rechecked for antibody. Those who remain serologically negative after administration of six hepatitis B vaccines should be considered "nonimmune." Such persons may be chronically infected with hepatitis B, and their serum should be tested for hepatitis B surface antigen. Routine reboosting or serologic evaluation of individuals who respond to the vaccine is not recommended.

Adverse Effects. The vaccine is well tolerated, with a mild local reaction at the injection site being the most common adverse event. The risk for Guillain-Barré syndrome or multiple sclerosis is not increased.

Hepatitis A

Indications for vaccination against hepatitis A infection are increasing in the United States. The vaccine is most frequently administered before travel to countries other than the major industrialized nations, but vaccination should also be considered for high-risk groups (e.g., male homosexuals, users of illegal drugs, those regularly receiving clotting factor transfusions, and persons with chronic liver disease). Food handlers and day care workers should also consider vaccination. The Advisory Committee on Immunization Practices (ACIP) recommends that the vaccine be administered routinely to children living in communities and states with the highest rates of infection (>20 cases per 100,000 population) and considered in areas with somewhat lower rates (>10 cases per 100,000). Many communities in the Western United States have such incidence levels of hepatitis A.

Preparations and Administration. Two versions of the vaccine are currently available in the United States: HAVRIX (SmithKline Beecham) and VAQTA (Merck). The vaccines are administered to adults in a two-dose primary series at 0 and 6 to 12 months (HAVRIX) or at 0 and 6 months (VAQTA). A three-dose series for children and adolescents is also available. Protective antibody levels that persist for 6 to 12 months are achieved in more than 95% of recipients after a single dose. Protective

levels that last for more than 10 years can be induced with the second immunization.

Individuals who require immediate and full protection should receive *immunoglobulin* IM (0.02 mL/kg if short-term protection of 1 to 2 months is required, and 0.06 mL/kg if long-term protection of 3 to 5 months is required). Hepatitis A vaccine and immunoglobulin can be administered simultaneously at distinct inoculation sites. Individuals who have been exposed to a person with hepatitis A (e.g., close household or sexual contact of an individual with active hepatitis A, restaurant outbreak) should receive *postexposure prophylaxis* with IM immunoglobulin (0.02 mL/kg). Immunoglobulin prophylaxis given more than 2 weeks after exposure is unlikely to be of benefit and is not indicated. A combination hepatitis A and hepatitis B vaccine (three doses: 0, 1, 6 months) has recently been approved for use in the United States (Twinrix, SmithKline Beecham).

Typhoid

Because most cases of typhoid reported in the United States each year are acquired abroad, typhoid vaccine use is targeted for travelers to areas endemic for *Salmonella typhi* infection,especially when long-term nonhotel stays are planned. Currently, three typhoid vaccines are available.

The oldest is a heat/phenol-inactivated vaccine, approved for children 6 months to 2 years of age. A two-dose vaccine series confers immunogenicity; the second inoculation is administered at least 4 weeks after the first dose. Adverse effects include fever and pain with induration and erythema at the injection site. Two newer vaccines are better tolerated. A recombinant vaccine comprised of purified capsular polysaccharide Vi antigen (Typhim Vi, Pasteur Merieux Connaught) is approved for individuals 2 years of age or older. It is administered as a single dose and provides approximately 60% to 75% protection for 2 years.

An oral typhoid vaccine, based on a live attenuated strain of *Salmonella typhi* (Ty21a), is also available (Vivotif Berna vaccine; Swiss Serum and Vaccine Institute, Berne, Switzerland). The oral vaccine can be used in individuals 6 years of age or older and is administered as a single pill every other day for four doses (days 0, 2, 4, and 6). It provides approximately 60% to 75% protection for 5 years and is well tolerated by most individuals.

Patients should be reminded to keep their vaccine refrigerated between doses. Mild intestinal upset is the most common adverse event. The oral vaccine should be taken with cool liquid 1 hour before a meal. Immunocompromised individuals and those with chronic inflammatory bowel disease should not receive the oral vaccine, nor should persons taking antimicrobial agents (antibiotics or antimalarial agents).

Japanese Encephalitis

Japanese encephalitis (JE) is a mosquito-borne viral infection that exists throughout eastern, southeastern, and southern Asia. In most individuals who become infected, encephalitis or severe illness does not develop, but when it does, the death rate is 25% and the rate of severe neurologic sequelae is 50%. The disease occurs in rural environments and is transmitted by a mosquito vector that normally feeds on pigs and birds. Individuals from the United States at highest risk are those staying longer than 30 days in rural areas (usually in an Asian locale with extensive rice farming and pig husbandry) during the appropriate mosquito season (May through October in many areas of Asia, but year-round in endemic tropical areas). The overall risk to a traveler is approximately 1 in 1 million; however, this risk may increase to more than 1 in 20,000 per week for high-risk travel. Risk can be markedly decreased through the use of protective clothing and insect repellents, especially at dusk.

The JE vaccine (a formalin-inactivated product derived from infected mouse brains) is administered in a three-dose primary series (days 0, 7, and 14 or 30). Booster inoculation may be administered every 2 years. The most common adverse effects are local, but mild constitutional symptoms may develop in up to 10%. In 0.6% of recipients, the vaccine can cause *urticaria, angioedema, respiratory distress, hypotension*, and *anaphylaxis*. Most allergic reactions can be treated with antihistamines and corticosteroids; epinephrine and supportive care may be required. Severe reactions usually occur within a day of vaccination but have occurred as long as 2 weeks after administration of any of the three inoculations. Individuals with a history of severe allergic reactions, angioedema, or urticaria are at highest risk for severe reactions. Individuals should be observed in the office for approximately 30 minutes after administration, and those who receive the vaccine should have access to medical care for at least 10 days after completion of the vaccine series. Consequently, the vaccine series needs to be started at least 24 days before departure if the accelerated vaccination course of 0, 7, and 14 days is employed.

Yellow Fever

Yellow fever is a mosquito-borne hemorrhagic viral illness that can be severe; it is endemic in sub-Saharan Africa and tropical Latin America. The live attenuated virus vaccine is the only immunization legally required for crossing some international borders. Contraindications include allergy to eggs, immunocompromise, and pregnancy. Women who receive the vaccine should be advised not to become pregnant for 3 months after vaccination. The vaccine can be administered only through WHO-approved centers. State departments of public health keeps a list of such sites. Individuals who require yellow fever vaccination should be directed to a yellow fever vaccination center. Immunized individuals will receive a WHO vaccination certificate. The vaccination record becomes "acceptable" to immigration officers 10 days after the vaccine has been administered. The vaccine is effective for 10 years. Vaccination is recommended for individuals traveling to or living in endemic areas. Countries may require documentation of yellow fever vaccination, even from individuals who only pass through endemic areas. Countries reporting yellow fever are posted by the WHO and the CDC; a listing can be accessed at www.cdc.gov.

Most reactions to yellow fever vaccine are local in nature. More rarely, systemic symptoms may develop, usually 5 to 10 days after vaccination. Because of the risk for vaccine-associated encephalitis, the vaccine should never be administered to children 4 months of age or younger, and rarely to children 4 to 9 months of age. If an individual is proceeding to an endemic yellow fever area and the vaccine is contraindicated, a yellow fever waiver certificate can be issued from the WHO yellow fever vaccination center. Immunocompromised individuals and pregnant women who will live long-term in a highly endemic yellow fever area of the world should carefully weigh the risk of vaccination versus the risks of illness. A desensitization protocol is available for individuals with a history of a severe allergy to eggs. The injectable cholera vaccine and the yellow fever vaccine should not be administered within 3 weeks of each other. The effectiveness of the yellow fever vaccine is not affected by the administration of immunoglobulin.

Cholera

The risk of cholera for routine travelers is extremely low; the food and water that transmit *Vibrio cholerae* usually have to be heavily and grossly contaminated, and simple food and water precautions effectively eliminate any real risk of contracting cholera. Individuals who die of cholera die of dehydration, not of the infection itself. In the extremely unlikely event that a traveler does contract cholera, simple rehydration therapy will prevent death. The only cholera vaccine currently available in the United States is an injectable phenol-killed *Vibrio cholerae* vaccine. The vaccine is minimally protective and is associated with a very high rate of adverse events. These factors combine to limit the utility of cholera vaccination in the United States. The WHO has removed the cholera vaccine from its list of vaccines for travelers. During outbreaks, local governments may require documentation of vaccination against cholera fromsome travelers. If used, the vaccine is administered in two doses at least 1 week apart and, preferably, 1 month or more apart. Boosters are required every 6 months. Oral vaccines are available for use outside the United States.

Smallpox

In the United States, the smallpox vaccine is currently administered only to certain laboratory researchers and to individuals in the Armed Services. The vaccine contains a live attenuated virus and can result in disseminated vaccinia in individuals who are immunocompromised. Because of the risk for the reemergence of smallpox resulting from a bioterrorist act, the vaccine is once again being formulated.

Other Conditions

Vaccines exist for a number of other infections, including *anthrax, typhus*, and *plague*. Vaccines are usually administered to individuals at high risk for these disorders (usually through employment-related exposures) or to military personnel.

PART 2 SYSTEMIC PROBLEMS

CHAPTER 7 SCREENING FOR HIV-1 INFECTION

STEPHEN L. BOSWELL

Knowledge of the status of human immunodeficiency virus (HIV) infection in the asymptomatic period permits infected persons to seek potentially beneficial medical treatment in a timely fashion, including antiretroviral agents and other medications that decrease the risk for the development of opportunistic infections (see Chapter 13). These measures delay the onset of the acquired immunodeficiency syndrome (AIDS) and prolong survival. In addition, early identification of HIV-1 infection can increase the effectiveness of tuberculin skin testing and thus improve tuberculosis screening and prophylaxis (see Chapter 49). Appropriate counseling, an essential part of screening for HIV-1 infection, may help prevent some individuals from transmitting HIV-1 by modifying their behavior. However, indiscriminate testing, especially among patients at very low risk for HIV-1 infection, raises the chance of a false-positive result and its attendant psychosocial morbidity. The primary care physician should know how best to advise the patient who asks about HIV-1 testing and whom to recommend for testing.

ASSESSING THE RISK FOR HIV-1 INFECTION

In the United States, it is estimated that between 800,000 and 900,000 people are infected with HIV-1. A related retrovirus, HIV-2, can also cause immune dysfunction, although it is generally less pathogenic than HIV-1. HIV-2 is distributed primarily in West Africa, but a few cases have been identified in the United States. Those at highest risk for infection with HIV-1 are men with a history of homosexual or bisexual activity (approximately 50% of those infected); intravenous drug users and their sexual contacts (approximately 25% of those infected); the sexual contacts of homosexual or bisexual men; persons who received blood and blood products between 1978 and 1985; and children born to infected women. The risk for directly acquiring HIV-1 infection through processed blood or selected blood products (plasma and clotting factor concentrates) has dramatically decreased since 1985 as a consequence of the widespread screening of those who donate blood and plasma, the use of serologic tests for HIV, and the viral inactivation of various plasma products.

Knowledge of the epidemiology of HIV-1 infection is necessary to estimate the pretest probability of HIV-1 infection in the person for whom screening is being considered. Attention to the pretest probability estimate is important to the decision to screen. Placing too much weight on the high sensitivity and specificity of HIV-1 antibody testing and ignoring the pretest probability is a common error (see Chapter 2 and Chapter 3).

The pretest probability of HIV-1 infection in a given patient is a function of the patient's previous risk behavior and the geographic location of the behavior. The testing setting, too, may be helpful in assessing the likelihood of infection. Settings characterized by high seroprevalence include sexually transmitted disease clinics, psychiatric hospitals, homeless shelters, alcohol rehabilitation facilities, and inner city emergency departments. These factors should be weighed when the need for HIV-1 testing is assessed.

When the behavioral risk factors for acquiring HIV-1 infection are being assessed in an individual patient, the following questions are particularly useful in clinical practice. Has the patient

- had sex with someone known to have HIV-1 infection or AIDS?
- had a history of sexually transmitted diseases?
- had sex with many men or women or had sex with someone who has had sex with many men or women?
- had sex with someone who has used needles to take drugs?
- shared needles to take drugs?
- had a history of receiving blood transfusions or clotting factor between 1978 and 1985?

If the answer to any of these questions is yes, then the patient and physician should give serious consideration to having HIV-1 antibody testing performed.

In addition, the Centers for Disease Control and Prevention recommends counseling and early diagnosis of HIV-1 infection for the following persons:

- Persons who consider themselves at risk for infection,
- Persons attending sexually transmitted disease clinics and drug abuse clinics
- Women seeking family planning services
- Patients with tuberculosis

TESTING FOR HIV-1 INFECTION

Viral Dynamics and the Immunologic Response to HIV-1

After transmission of HIV-1, usually a 2- to 8-week period elapses before the acute retroviral syndrome develops. This flulike illness occurs in 50% to 90% of infected individuals, lasts 2 to 4 weeks, and resolves spontaneously. Coincidentally with the acute illness, high-grade viremia develops; titers of 50 to 100 million particles per milliliter have been reported. Viral titers begin to fall 2 to 3 weeks after the onset of acute symptoms, usually before an HIV-1 antibody response can be detected. This observation suggests that a response other than HIV-1 antibody formation may be responsible for the initial control of virus replication. Recent evidence suggests a central role for HIV-1–specific cell-mediated immunity in the control of virus replication during primary HIV-1 infection. Serial measurement of proliferative responses to HIV-1 antigens with the use of CD4+ lymphocytes from acutely infected individuals demonstrated a strong inverse correlation between the generation of HIV-specific CD4+ lymphocyte helper cells and plasma HIV-1 RNA levels. Similarly, among long-term nonprogressors, the highest HIV-specific proliferative responses were associated with the lowest plasma HIV-1 RNA levels.

Although the presence of symptoms is common among those who are acutely infected, symptoms often go unrecognized in the primary care setting because of their similarity to those of other common illnesses. Physicians should maintain a high level of suspicion for HIV infection in all patients presenting with a compatible syndrome. A careful evaluation of the patient's risk behaviors during the 3-month period before presentation should be obtained for all such patients. When appropriate, laboratory testing should be performed. This testing may include measurement of HIV RNA by HIV polymerase chain reaction or HIV branched-chain DNA and detection of HIV antibody. Although determination of HIV RNA is the preferred method of testing, a test for p24 antigen can be used when RNA testing is not readily available. A negative p24 antigen test result does not rule out acute infection, however. The information regarding the treatment of acute HIV infection is very limited, but the available data generally support antiretroviral treatment.

HIV-1 Antibody Assays

The diagnosis of HIV-1 infection is most frequently accomplished by detection of specific antibodies against viral antigens in serum. Recently, diagnostic testing of saliva and urine has been developed. Enzyme immunoassays (EIAs) for HIV-1 detection were first developed in 1985. Although EIAs are easily automated, inexpensive, and well suited for testing large numbers of samples, they can nonspecifically bind antibodies and produce false-positive results in patients exposed to other infections or vaccines. The assays have improved; first-generation tests used viral lysates as a source of viral antigens, whereas the current third-generation tests use recombinant DNA proteins coated on paper strips, beads, and microplate wells. The most advanced assays have a reported sensitivity and specificity of greater than 99.9% in serum from subjects with known HIV-1 infection and uninfected controls.

Rapid serologic screening tests have been developed for office use, including HIV antigen–coated gelatin or latex particle agglutination assays. These tests can be performed quickly (in some cases within 10 minutes), but they still require Western blot confirmation. Data suggest that some particle agglutination assays may be slightly less sensitive and specific than EIA is in moderate- or high-titer samples. Additional rapid screening assays based on the use of dipsticks and other technologies are available. When EIA is compared with several of these rapid assays, data suggest that the rapid assays can be significantly less sensitive in the testing of samples with a low titer of antibodies. This may be a particular problem during primary HIV-1 infection, when antibodies against selected antigens may not yet be present or may be present at very low titer. In general, EIA with confirmatory Western blot is the preferred screening test.

An important limitation of the HIV-1 screening assays used in the United States is that they primarily detect a single subtype of HIV-1. HIV-1 displays significant genetic variability. It can be categorized into a major group (M) and outlier groups (O). Group M can be further divided into subtypes or clades A through J. These clades show significant geographic variability. Many conventional assays for HIV-1 screening were developed by using a group M, subtype B virus, the predominant clade in the United States and Europe. Consequently, their ability to detect geographically diverse subtypes is limited. Several manufacturers are attempting to address this issue by adding nonsubtype B peptides to their assays, but it should be remembered that the geography of HIV-1 acquisition can affect the accuracy of HIV-1 screening.

Body fluids other than blood can be used to determine a person's HIV-1 status. Oral fluids and urine may contain antibodies against HIV-1. Recently, the United States Food and Drug Administration approved several tests in which these fluids are used. The *OraSure* test, developed by Epitope, collects oral mucosal transudate via a cotton swab that is inserted into the mouth for 2 minutes. The swab is then packaged and sent to a reference laboratory for standard EIA and Western blot confirmation. This test has demonstrated 99.99% sensitivity and specificity in comparison with standard Western blot confirmation. The *Calypte* urine EIA test identifies urine HIV-1 immunoglobulin G antibody. The sensitivity and specificity of this test are comparable with those of serum EIA. However, Western blot testing of blood is required for confirmation of results.

In an effort to widen testing options further, kits specifically designed to be used in the home have been developed. With one such kit, *Home Access System*, developed by the Home Access Health Corporation, blood is collected by means of a lancet. The blood is blotted onto a test card, mailed to a reference laboratory, and tested by standard EIA and confirmatory Western blot. Within a week, the person undergoing testing may retrieve results by calling an automated system that stores results by a specific number assigned to each kit. A counselor is available to discuss a negative result, if desired. A call for a positive result is connected immediately to a telephone counselor, who will discuss the results with the caller.

A positive EIA test result should be confirmed by Western blot testing. Relative to EIA, the Western blot is slower, more labor-intensive, and much more expensive, but it is able to measurespecific HIV-1 antibodies and so enhance the specificity of testing. It detects antibodies directed at specific HIV-1 proteins (core, envelope, and polymerase) after their separation by gel electrophoresis.

For the licensed Western blot, the interpretation of reactive and nonreactive test results is based on data from clinical studies submitted to the Food and Drug Administration for licensure. A test result is considered positive with this Western blot if antibodies to multiple virus-specific protein bands are pres-ent (i.e., p24, p31, and either gp41 or gp160). If fewer bands are present, the test is considered indeterminate; it is interpreted as negative only if no bands are present on the blot. When these criteria are used for interpreting test results, the probability of either a false-positive or a false-negative result is extremely small. It should be noted, however, that as many as 15% to 20% of tests on persons at low risk for HIV-1 infection may be described as indeterminate. Sera from persons recently infected with HIV-1 also may produce an indeterminate Western blot pattern. For such persons, a repeated Western blot on a second specimen obtained after the initial specimen often yields a positive blot pattern within 6 months. Conversely, follow-up testing of uninfected persons whose serum had an indeterminate blot pattern on initial testing usually will show no change in the banding pattern. Serum from some HIV-infected persons who have advanced immunodeficiency may have an indeterminate pattern because of a loss of antibodies to non-envelope proteins.

Despite the existence of a licensed Western blot test, many laboratories continue to use unlicensed tests because of cost and the stringent criteria required for interpreting the licensed test. The performance characteristics of the unlicensed tests have not been uniformly subjected to the same rigorous scrutiny required for licensure by the Food and Drug Administration. Although recommendations for standardization have been published, the extent to which these are followed is unknown. Information about production standards, variability between lots, or validation of criteria used for interpretation often is not available. The absence of standardization and appropriate quality controls may result in a lower sensitivity or specificity and therefore a higher probability of inaccurate results.

Other Tests

Tests for virus and viral components are now readily available in the United States. These tests include virus culture, p24 antigen assays, polymerase chain reaction assays, and signal amplification assays. In general, these assays are not used for the initial diagnosis of HIV-1 infection in adults.

Virus culture is time-consuming, costly, difficult to standardize, and relatively insensitive. Assays for p24 antigen are hampered by the low prevalence of antigen during the asymptomatic phase of HIV-1 infection. Polymerase chain reaction and signal amplification assays have a high false-positive rate and are not suitable for screening in most circumstances.

Surrogate markers do not test directly for virus and antibody. The most common is the CD4+ lymphocyte count, which is useful for assessing prognosis and therapeutic decision making but should not be used as an indirect method of determining whether a patient is infected with HIV-1.

Test Interpretation: Minimizing False-positive and False-negative Results

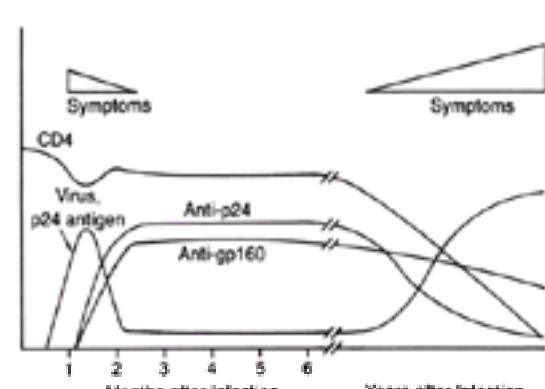
In testing for the presence of HIV-1 antibodies and interpreting the results, it is necessary to consider the timing of antibody responses to HIV-1 infection (Fig. 7.1), the sensitivity and specificity of the enzyme-linked immunosorbent assay (ELISA) and Western blot tests, and the pretest probability of the person being tested. For example, a negative ELISA result in a patient with a pretest probability of 0.1% (1 in 1,000) virtually rules out the diagnosis of HIV-1 infection. However, the same test result in a person with a 50% pretest probability of HIV-1 infection does not lower the posttest probability to zero (in biologic terms, it is possible that the patient is being tested before the appearance of antibody). Conversely, a positive ELISA result in a person with a low pretest probability (0.1%) produces a posttest probability of only 40%, which necessitates confirmatory testing.


FIG. 7.1. Natural history of HIV-1 infection. Adapted from Clark SJ, Saag MS, Decker WD, et al. N Engl J Med 324:951.

A major objective is to limit the risk for a false-positive result and its potentially adverse psychological and social consequences. Pretest counseling is especially important for low-risk persons, who need to be informed of the risk for a false-positive result. It is often advisable to repeat an ELISA if a positive result is found in someone with no identifiable risk factor or has been obtained from a site that performs anonymous testing. There is always the finite possibility of laboratory error or sample mislabeling. Confirmatory testing with Western blot is essential and is a standard procedure in most laboratories.

A negative Western blot result in the setting of a positive ELISA and a small pretest probability of HIV-1 rules out HIV-1 infection. A positive Western blot result following a positive ELISA virtually rules in the diagnosis of HIV-1 infection, even among persons with a low pretest probability, but an "indeterminate" result can be problematic.

Despite the enhanced specificity afforded by adding the Western blot to the testing sequence, a small but important proportion (15% to 20%) of individuals with a positive ELISA result will have an "indeterminate" Western blot result. The most frequent cause of this is the presence of a single band of antibody, usually against p24. In high-risk individuals, this may reflect ongoing seroconversion. Low-risk persons with this result are virtually never infected. Testing should be repeatedwithin 2 to 6 months of the initial indeterminate result. If the individual is infected with HIV-1, a positive ELISA result will usually be accompanied by two or more positive bands on the Western blot. Among low-risk persons, the single band will frequently persist. In general, low-risk individuals with indeterminate test results should be reassured that HIV-1 infection is unlikely.

False-negative test results most frequently occur when testing is performed during the "window period"—usually within 6 months after viral transmission. Alternative methods of identifying HIV-1 infection are available in cases in which further clarification is desirable. These include polymerase chain reaction, viral culture, and detection of p24 antigen. These tests should not be used in place of antibody testing, but occasionally they may be useful.

Repeated Screening

Repeated screening at 6- to 12-month intervals is indicated for those who continue to practice high-risk behavior. An essential part of HIV-1 testing is the provision of HIV-1 counseling. All persons should be carefully instructed regarding how to minimize the risk for HIV-1 transmission.

RECOMMENDATIONS

- Patients at high risk for HIV-1 disease should be screened (Table 7.1).

Table 7.1. Centers for Disease Control Recommendations for HIV Serologic Testing

- High-risk patients whose test results are negative but who continue high-risk behavior should be rescreened every 6 to 12 months.
- Patients at low risk who are donors of blood, semen, or organs should also be screened.
- Low-risk donors and low-risk persons who desire to know their HIV-1 status should be counseled about the possibility of a false-positive result, especially about an indeterminate Western blot result after a positive ELISA result.
- The interpretation of test results must take into account pretest probability, sensitivity and specificity of testing methods, and timing of the testing in relation to time of possible infection.
- Patient education regarding HIV-1 transmission and HIV-1 risk reduction should be part of every screening effort.
- Once a diagnosis of HIV-1 infection is established, the patient should be referred to a clinician with expertise in its management.
- Whenever possible, HIV-1 testing should be conducted in an anonymous fashion.
- Clinicians should be alert to the possibility of the acute retroviral syndrome when evaluating patients with a compatible symptom complex.

CHAPTER 8 EVALUATION OF CHRONIC FATIGUE

Chronic fatigue ranks as one of the most common complaints in primary care practice, with a reported frequency in excess of 20%. It can also be one of the more frustrating problems to assess because it is a sensitive but nonspecific indicator of underlying medical or psychological pathology. Regardless of cause, the patient typically reports a lack of energy, listlessness, and being too tired to participate in family, work, or even leisure activities. Many speculate that they have a vitamin or mineral deficiency and self-treat accordingly before coming for evaluation. Others fear an underlying malignancy, endocrine disorder, or serious infection (e.g., HIV infection, tuberculosis, hepatitis, "chronic mono") and request extensive testing.

Most patients bothered by chronic fatigue come to the primary physician looking for an organic cause, especially those with a rather abrupt onset of symptoms. Although most studies of chronic fatigue find the vast majority of cases to have a psychological basis (e.g., depression), few patients initially report psychological symptoms, and if they do, they view such symptoms as secondary to a medical illness. Attempts by the physician to address psychological issues may be misinterpreted by the patient as not being taken seriously. Thus, the primary physician has the difficult tasks of sorting through a vast number of potential etiologies and patient concerns, determining what proportion of the problem is physiological and what part is psychological, and helping the patient to understand and deal effectively with the underlying condition and its consequences.

PATHOPHYSIOLOGY AND CLINICAL PRESENTATIONS

Almost all illnesses are capable of causing fatigue; however, a few are noteworthy for the prominence of the symptom in the clinical presentation.

Psychological Etiologies. As just noted, fatigue is an important somatic symptom of *depression*, often coexisting with early morning awakening, appetite and sexual disturbances, and multiple bodily complaints. Abnormalities of central nervous system neurotransmitter metabolism and function are believed to play a major role in the pathogenesis of depression (see Chapter 227). *Chronic anxiety* may result in generalized fatigue, in part because it interferes with obtaining adequate physical and psychological rest. Patients report trouble falling asleep and a host of associated bodily complaints. Many maintain their neck muscles in a constantly tensed state, which gives rise to occipital–nuchal headaches. Seemingly unprovoked episodes of palpitations, difficulty breathing, and chest tightness may occur, especially in those whose anxiety is accompanied by a panic disorder (see Chapter 226).

Patients in whom somatization represents an underlying *personality disorder* may complain of chronic fatigue, often accompanied by a host of other refractory symptoms. Such individuals have a lifelong history of bodily complaints that elude diagnosis and treatment. Their symptoms are a cross they bear in a crude attempt to achieve a modicum of self-esteem (see Chapter 230).

Medications. Many of the medications used to treat anxiety, depression, and insomnia have substantial sedating effects. When used in excess, they may actually worsen the patient's symptoms and sense of fatigue rather than alleviate them. Of the antidepressants, *amitriptyline, doxepin*, and *trazodone* are among the more sedating, which makes them useful when agitation is a problem, but they can also lead to a feeling of being "knocked out" (see Chapter 227). Long-term use of *hypnotics* and withdrawal from them may exacerbate difficulty in falling asleep (see Chapter 232). Excessive use of *minor tranquilizers* can cause tiredness, especially when daily doses are sufficient to produce high serum levels of the drug and its active metabolites (see Chapter 226).

Antihypertensives that penetrate the central nervous system (e.g., *reserpine, methyldopa, clonidine, propranolol*) may precipitate depression or fatigue. Reserpine can cause depression when used in doses exceeding 0.5 mg daily, especially in patients with a prior history of depression. The same is true for b-blockers, although fatigue is the more common side effect (see Chapter 26) and a major reason for discontinuing the medication. *Antihistamines* used for allergic rhinitis are another common pharmacologic precipitant of fatigue, especially those that penetrate the central nervous system (e.g., *diphenhydramine, chlorpheniramine*).

Endocrine Disturbances are important, treatable precipitants. Dysfunction of the thyroid, adrenal, pituitary, parathyroid, or endocrine pancreas can be subtle in onset, starting out inconspicuously as fatigue, perhaps accompanied by more specific symptoms. For example, *hypothyroidism* may present as fatigue, perhaps in association with weight gain, dry skin, mild hoarseness, or cold intolerance (see Chapter 104). In the elderly, hyperthyroidism may take an atypical form (*apathetic hyperthyroidism*), characterized by fatigue, marked weight loss, apathy, and otherwise unexplained atrial fibrillation (see Chapter 103).

Patients with *Addison's disease* manifest an insidious onset of fatigue in conjunction with weight loss, vague gastrointestinal upset, postural hypotension, and eventually hyperpigmentation. *Panhypopituitarism* from postpartum hemorrhage or a tumor of the sellar region can cause fatigue. The postpartum patient fails to lactate or resume menstruation; lassitude, decreased libido, and loss of axillary and pubic hair ensue. Later, symptoms of hypothyroidism may develop. The patient with a pituitary tumor may note galactorrhea and amenorrhea (see Chapter 100).

Poorly controlled *diabetes mellitus* may present as fatigue accompanied by polyuria when glycosuria is severe enough to produce caloric wasting and volume depletion (see Chapter 102). Similarly, fatigue may be the initial symptom of *hyperparathyroidism* and other causes of hypercalcemia.

Metabolic Disturbances. *Chronic renal failure* may present inconspicuously with fatigue and few localizing symptoms or signs aside from laboratory findings of azotemia, mild anemia, impaired renal concentrating ability, and an abnormal urinary sediment (see Chapter 142). *Hepatocellular failure* is an important source of lassitude. Jaundice, ascites, petechiae, asterixis, spider angiomata, and other signs of hepatic insufficiency usually contribute to the clinical picture. However, in anicteric hepatitis and mild forms of chronic hepatitis, jaundice may be minimal or absent while fatigue is prominent; the same holds for the prodromal phase of acute viral hepatitis (see Chapter 70 and Chapter 71).

Hematologic and Oncologic Etiologies. *Iron deficiency* is often blamed for fatigue, although the correlation between iron deficiency anemia and fatigue is poor, especially when the anemia is mild (see Chapter 79). In a double-blind study of menstruating women with mild anemia resulting from iron deficiency, no significant difference was noted between the effects of iron and of placebo on fatigue. The relation between severe anemia (hematocrit <20) and fatigue is more direct. Lassitude prevails, at times in association with exertional dyspnea or with postural hypotension when blood loss is acute.

Occult malignancy is a much feared etiology. Although fatigue and lassitude accompany most cancers, *pancreatic carcinoma* is the archetypal example of a tumor that may present initially as marked fatigue with few localizing symptoms. Severe weight loss, depression, and apathy may also dominate the clinical picture before other manifestations of the malignancy become evident. Malignancies causing hypercalcemia (e.g., breast cancer, myeloma) may present with fatigue, although usually the hypercalcemia is a late development.

Cardiopulmonary Disease. The hallmark of fatigue associated with cardiopulmonary disease is a history of exertional dyspnea. Fatigue sometimes dominates the clinical presentation of patients with *chronic congestive heart failure* or *chronic lung disease*, especially when patients with heart failure are treated aggressively for symptoms of pulmonary congestion (see Chapter 32 and Chapter 47). Disturbed sleep resulting from *sleep apnea* is an often overlooked cause of chronic fatigue. Daytime sleepiness, excessive snoring, irregular breathing, disturbed sleep, and hemoglobin desaturation are characteristic. If untreated, sleep apnea may progress to pulmonary hypertension (see Chapter 46).

Infectious Diseases. Profound fatigue, low-grade fever, and lymphadenopathy are the hallmarks of a number of much feared infectious etiologies, including *mononucleosis, viral hepatitis*, and *HIV disease*. Other viral illnesses, such as *cytomegalovirus infection* and the possibly virus-triggered *chronic fatigue syndrome* (see below), may also present in this way. *Tuberculosis* and *subacute bacterial endocarditis* are important infectious etiologies of fatigue in which few localizing symptoms may be present. A history of cough, night sweats, HIV infection, or exposure is sometimes elicited from the patient with tuberculosis (see Chapter 49). Recent dental work, a heart murmur, and IV drug abuse are risk factors for subacute bacterial endocarditis. *Lyme disease* is noteworthy for fatigue accompanied by joint complaints, headache, and low-grade fever (see Chapter 160).

Connective Tissue Disease and Other Forms of Immune Dysfunction. Marked fatigue may dominate the initial clinical presentation of most *rheumatoid diseases*, before characteristic inflammatory connective tissue manifestations become evident (see Chapter 156).

Chronic Fatigue Syndrome (CFS) is an idiopathic condition characterized by new onset of persistent or relapsing fatigue lasting at least 6 consecutive months in patients with no prior history of such fatigue. Associated symptoms may include migratory arthralgias, myalgias, sore throat, tender lymph nodes, new generalized headache, unrefreshing sleep, postexertional malaise, and impaired memory or concentration. The initial presentation may be flulike, but unlike the typical symptoms of postviral fatigue, these symptoms persist far beyond 1 to 2 months. CFS accounts for about 5% to 10% of all cases of chronic fatigue. Peak prevalence is among persons ages 20 to 50 years; women outnumber men by 3 to 1.

Etiology. The etiology of CFS remains unknown. The most consistent finding of CFS etiologic studies has been the inconsistency of results. Early, uncontrolled studies revealed intriguing suggestions of *Epstein-Barr virus* (EBV) *reactivation, immunologic dysfunction*, and even *chronic candidal infection*. The findings encouraged early etiologic designations such as "chronic mononucleosis," "chronic fatigue and immune dysfunction syndrome" (CFIDS), and "chronic candidiasis." Attempts at treatment with antiviral agents, immunoglobulin injections, and systemic antifungal agents proved ineffective when studied in controlled fashion. Moreover, subsequent controlled studies found many CFS patients with no evidence of EBV infection/reactivation, immunologic dysfunction, or chronic candidal infection. Still, some investigators continue to explore the relation between stress (a known risk factor for CFS), immune modulation, and reactivation of latent viruses, with an eye toward these conditions triggering neuroendocine responses.

Current research focuses on *neuroendocrinologic mechanisms*. Interest derives from the observation that *neurally mediated hypotension* occurs with increased frequency in CFS patients; however, questions remain as to whether this is a cause or an effect of the deconditioning that occurs in CFS patients. An association with *fibromyalgia* has been noted, but it is unclear whether this represents a common pathophysiology or overlapping diagnostic criteria (see also Chapter 159).

Some view CFS as predominantly a *psychiatric condition*, given the high prevalence of concurrent psychiatric disease, particularly *somatization disorder*, found in CFS patients subjected to detailed psychiatric study (range, 20% to 70%). Some wonder whether this association is a consequence of the original diagnostic criteria for CFS, which had many features overlapping with those of somatization disorder (see below). Nonetheless, there is a trend toward an increased risk of suicidality and a high prevalence of major depression, but no higher than that found in patients with other chronic disabling disease. In addition, the physical manifestations noted above are atypical for such psychiatric disorders as depression and anxiety, and the anhedonia, guilt, and low motivation that characterize depression are infrequent in CFS. In fact, these patients are highly motivated and work hard to deal with their illness.

DIFFERENTIAL DIAGNOSIS

Although the list of conditions that may present with fatigue is extensive, most cases have a strong overlay of anxiety, depression, or both, even when the cause is medical. Fatigue, of course, may accompany any illness, but those listed in Table 8.1 are notable for the prominence of lassitude in the clinical presentation. Depression and associated psychiatric conditions account for about two thirds of cases of persistent fatigue subjected to comprehensive medical and psychological evaluation. Another one fourth of cases remain idiopathic, having some but not enough features to qualify as CFS. About 5% meet the Centers for Disease Control and Prevention (CDC) criteria for chronic fatigue syndrome, and 3% turn out to be previously unrecognized medical disorders.

Table 8.1. Some Conditions Presenting as Chronic Fatigue

WORKUP

In most instances, the evaluation of fatigue can be conveniently performed in the office. Two or three visits may be needed to establish the underlying etiology; at times, the patient may insist that medical illness be ruled out before agreeing to discuss psychosocial matters.

History. The inquiry should begin with a thorough *description of the fatigue* to be sure that the patient is not confusing focal neuromuscular disease with generalized lassitude. Because *depression* underlies many cases of fatigue, it is essential to check for its somatic manifestations, such as early morning awakening, alteration of appetite, and multisystem functional complaints. It is also important to ask about significant losses, low self-esteem, and occurrence of crying spells and suicidal thoughts. *Anxiety* is suggested by unresolved conflict, persistent nervousness, recurrent bouts of excessive uneasiness, and trouble falling asleep. A lifelong history of *refractory bodily complaints* that defy diagnosis and treatment should raise suspicion of a personality disturbance.

Any abuse of *hypnotics* or *tranquilizers* needs to be ascertained and considered as a cause of disturbed sleep and resultant fatigue. Fatigue in the elderly patient should not be ascribed to age; an underlying psychogenic or medical illness is likely.

A history of *fever, sweats, weight loss*, and *adenopathy* points toward smoldering infection and occult neoplasm. Symptoms suggesting a metabolic or endocrinologic cause include *polyuria*, polydipsia, changes in skin pigmentation and texture, hoarseness, *cold intolerance*, nausea, and *abnormal menses*. Symmetric *joint pain* and morning stiffness are clues to underlying rheumatoid disease.

Checking into factors that might disturb sleep can lead to detection of treatable etiologies such as *sleep apnea* (see Chapter 46), *esophageal reflux* (see Chapter 61), and *allergic rhinitis* (see Chapter 222).

The *past medical history* should be investigated for anemia, rheumatic fever, mononucleosis, heart murmur, recurrent urinary tract infection, proteinuria, liver disease, alcohol and drug abuse, and depression. *Epidemiologic considerations* ought to include exposure to tuberculosis, mononucleosis, and hepatitis; any risk factors for AIDS are important to note (see Chapter 13). *Travel* to areas where parasitic infections are endemic, work in meat-packing industries or on a farm, and a sudden common source outbreak of illness are other potentially important epidemiologic clues.

A full listing of all the patient's *medications* should be obtained. Often overlooked are over-the-counter antihistamines that patients use for sleep, allergies, and colds. Most centrally acting antihypertensive agents are capable of causing fatigue, and their use should be noted, as should that of all psychotropic agents.

Physical Examination. Vital signs including *postural pulse* and *blood pressure, temperature*, and *weight* should be determined. If no fever is noted on examination in the office but it is suggested by history, then a 10 p.m. reading at home is indicated. *Skin* is assessed for change in pigmentation, purpura, dryness, rash, jaundice, and pallor. Endocarditis may first be suggested by the finding of splinter hemorrhages or petechiae. *Funduscopic examination* may reveal Roth's spots, diabetic retinopathy, or even, in rare instances, a tuberculoma. The sclerae are observed for icterus. If examination of the *pharynx* reveals petechiae at the junction of the hard and soft palate, mononucleosis ought to be considered. The *thyroid* is checked for goiter.

Careful examination of all *lymph nodes* is essential; size, degree of tenderness, and distribution should be noted. Diffuse adenopathy suggests malignancy and

infection and is sometimes a sign of HIV infection (see Chapter 12). *Breasts* should be checked for masses, as breast cancer and its attendant hypercalcemia may present as fatigue. The *lungs* are examined for rales, consolidation, and effusion, and the *heart* for murmurs, rubs, gallops, and rhythm disturbances. Unexplained atrial fibrillation in the elderly may be a manifestation of apathetic hyperthyroidism.

The *abdomen* is palpated for organomegaly, masses, ascites, and hepatic tenderness. The *rectal examination* includes a look for masses, prostatic pathology, and occult blood. The *genitalia* should be checked for masses suggestive of malignancy and tenderness indicative of infection. The *joints* are assessed for signs of inflammation. A complete *neurologic examination* is necessary to be sure that the patient's fatigue is not really a manifestation of neuromuscular disease. Any tenderness, atrophy, focal weakness, or fasciculations in the muscles are noted. Deep tendon reflexes that have a slow relaxation phase are suggestive of hypothyroidism. Even visual field testing is important, for a pituitary lesion may produce a bitemporal hemianopsia. *Mental status assessment* is critical, including observation of affect, thinking, judgment, and memory. Formal testing for suicidality is indicated (see Chapter 227) because of the high prevalence of depression in this patient population.

Laboratory Tests. In the overtly depressed patient with an otherwise completely normal history and physical examination, there is no need to proceed with an extensive laboratory workup for occult medical illness. A *complete cell blood count* (CBC) and *erythrocyte sedimentation rate* (ESR) are often ordered for screening purposes. The CBC, particularly if accompanied by a look at the peripheral smear and differential, may provide important clues to underlying infection, inflammatory disease, hepatocellular failure, or malignancy. Unfortunately, the ESR has not proved to be sensitive or specific enough to help in detecting or ruling out occult illness. Consequently, many physicians no longer order the ESR, whereas others continue to use it with the intent of acting on it only if the result is markedly elevated (e.g., >75 mm/h).

A particularly difficult situation is the patient with no evidence of depression as a primary cause and an unrevealing history and physical examination. Here, a few extra serum chemistries (*calcium, albumin, blood urea nitrogen, creatinine, glucose,* and *transaminase-aminotransferase*) are warranted to help rule out clinically subtle conditions that may present as fatigue, such as hypercalcemia, mild renal failure, early diabetes mellitus, and anicteric hepatitis. A *thyrotropin* (TSH) test is worth considering because thyroid disease represents a very treatable cause that can have a very subtle presentation, and the improved TSH assay is very sensitive for the detection of most forms of hyperthyroidism and hypothyroidism. The elderly fatigued patient with weight loss and unexplained atrial fibrillation is a prime candidate for a TSH determination. Other thyroid indices add little and should not be obtained unless the TSH level is abnormal (see Chapter 103 and Chapter 104).

Patients with recent onset of persisting fatigue and adenopathy should undergo a *heterophile* test for acute mononucleosis. However, *viral antibody titers* (with the exception of testing for *viral hepatitis* and *HIV infection*) are of no known utility in patients with undiagnosed chronic fatigue. Ordering a battery of viral antibody titers was popular when CFS was thought to be caused by chronic EBV infection or reactivation of other viruses. Without a proven etiologic role for viruses in CFS, viral titers proved to be useless and sometimes misleading, especially when results were "positive" in a patient with severe depression who refused to accept a psychiatric diagnosis. The same holds true for *Candida* and *fungal testing. Lyme titers* are also of little use in the absence of other evidence suggestive of Lyme disease, such as polyarthritis, history of tick bite, or erythema chronicum migrans (see Chapter 160). Testing for viral hepatitis is clearly indicated in those with a transaminase elevation, and HIV testing is appropriate when diffuse adenopathy or a history of high-risk behavior is present.

Neuroimaging studies have been used investigationally in persons with CFS to assess regional brain function. Positron emission tomography (PET) and single-photon emission computed tomography (SPECT) have demonstrated areas of brain hypometabolism and hypoperfusion, respectively, in CFS patients. Because the specificity and pathophysiologic significance of these findings remain to be determined, these imaging techniques are not indicated at present for the workup of chronic fatigue or diagnosis of CFS.

Diagnosis of Chronic Fatigue Syndrome. No test or set of tests is diagnostic for CFS. Diagnosis is based on clinical findings and the ruling out of other etiologies. A *working case definition* was developed by the CDC in 1988 to provide a more uniform basis for identifying and studying patients with CFS. Patients had to fulfill two major criteria, plus either six symptom criteria and two physical criteria or eight symptom criteria (Table 8.2).

	1988 CRITERIA	1994 CRITERIA
Major criteria		
New onset	+	+
No previous history	+	+
Duration >6 months	+	+
Does not improve with bed rest	+	+
All other illnesses excluded	+	+
Activity reduction >50%	+	−
All psychiatric illnesses excluded	+	+/−
Minor criteria	Need 8 of 14	Need 4 of 8
Sore throat	+	+
Painful lymph nodes	+	+
Muscle discomfort	+	+
Prolonged fatigue after exercise	+	+
Generalized (new) headache	+	+
Migratory arthralgias	+	+
Impaired concentration or memory	+	+
Unrefreshing sleep	+	+
Low-grade fever	+	−
Generalized weakness	+	−
Acute onset	+	−
Documented low-grade fever	+	−
Documented nonexudative pharyngitis	+	−
Documented palpable or tender lymph nodes	+	−
Subclassifications		
Presence of comorbid conditions (depression)	None	Yes
Current level of fatigue	None	Yes
Duration of fatigue	None	Yes
Current level of physical function	None	Yes

Table 8.2. Centers for Disease Control Case Definition Criteria for Chronic Fatigue Syndrome

Despite the development of a case definition, studies continued to produce unacceptably inconsistent results, suggesting that the case definition was producing too much heterogeneity in CFS populations and too much overlap with somatization disorders. In 1994, the CDC sponsored a revision of the case definition (Table 8.2). Two major criteria were eliminated: (a) more than 50% reduction in activity, because it is too difficult to quantify, and (b) absence of any psychiatric disease, because nonpsychotic depression and anxiety are frequent in CFS. In addition, the number of minor criteria was reduced from eight to four (Table 8.2) to reduce overlap with somatization disorder.

Subgroup classifications were recommended to facilitate identification for the study of patients who might have similar prognoses and responses to therapy. Subgroupings criteria include comorbid conditions, severity of fatigue, duration, and current level of physical function. Finally, a designation of *idiopathic chronic fatigue* was proposed for the substantial number of persons with unexplained fatigue meeting some but not all of the criteria for chronic fatigue syndrome.

Clinicians need to keep in mind that case definitions are only consensus views intended to facilitate research. Although such definitions can be used for clinical diagnosis, they are not based on scientifically established criteria and remain somewhat arbitrary, requiring clinical judgment for proper use in patient care. Until the etiology of CFS is better understood, these shortcomings will have to be taken into consideration when the working definition is used for diagnostic purposes. (The reader is urged to watch the literature closely for further developments.)

PATIENT EDUCATION

It is often useful to determine patients' views of their illness before proceeding with patient education, so that the explanation will address patient concerns and perspectives. Patients who have a medical view of their condition are more receptive to a biologic explanation for their symptoms, even if the cause is psychogenic. However, one must be careful not evoke a misleading medical explanation, such as "viral infection" or "immune dysfunction," especially in the setting of a suspected or possible psychogenic etiology, because this might cause a patient to delay or refuse psychiatric intervention. Patients with evidence of underlying psychogenic disease need an especially thorough review of the evidence for their diagnosis and a careful explanation of their symptoms because many come to the physician thinking they have a medical problem. For example, reviewing the diagnostic criteria for depression and describing the neurochemical mechanisms by which depression leads to fatigue (see Chapter 227) can be helpful.

The attention given to CFS in the lay press often necessitates addressing the issue of its likelihood and some of its purported, although unfounded, causes (e.g., EBV infection, yeast infection, immune dysfunction). Many patients with a psychogenic etiology prefer to cling to this diagnosis as an acceptable explanation of their psychophysiologic symptoms rather than face a diagnosis of depression, anxiety, or somatization disorder. In addition to a careful workup, a respectful, sympathetic, open-minded approach is essential (see Chapter 230).

The Patient with Chronic Fatigue Syndrome. In addition to the measures noted above, the physician should emphasize the legitimacy of the patient's symptoms

and summarize the workup, its rationale, and findings. Also useful is a review of the idiopathic nature of the illness, its generally self-limited course, and often favorable response to simple measures (see below). Establishing a partnership with the patient is key to successful management. Certain beliefs and behaviors known to perpetuate disability and lead to a worse outcome in CFS must be addressed, particularly the view that a purely physical disease mechanism is present that is unresponsive to intervention and that exercise is harmful. Such beliefs and associated behaviors contribute to resignation, anxiety, and depression and exacerbate deconditioning and the feeling of fatigue. At times, referral for formal *cognitive behavior therapy* is worth pursuing to achieve the educational and behavioral goals so important to recovery (see below). It is important that any new symptoms or signs be investigated thoroughly and not simply attributed to CFS.

SYMPTOMATIC RELIEF

When the cause of fatigue is endocrinologic, metabolic, or infectious, treatment needs to be specific and aimed at the underlying condition. Malignancy is often accompanied by a reactive depression that can be helped by development of a strong, supportive *doctor–patient relationship* (see Chapter 87). The fatigue of endogenous depression can be treated with support and tricyclic *antidepressants*; imipramine may be less sedating than amitriptyline (starting dose is 25 to 50 mg at bedtime, increased by 25 to 50 mg at a time). The sleep disorder caused by depression may respond well to small doses, with the fatigue dissipating as the patient gets a good night's sleep. Affective changes may not occur at low doses (see Chapter 227).

Anxiety-related fatigue can be difficult to treat. Prescribing antianxiety agents can lead to excessive use and worsening of symptoms (see Chapter 226); however, a brief and limited trial of *benzodiazepine* therapy at bedtime is worth an attempt. For example, 5 mg of chlordiazepoxide can help the patient to fall asleep and get much-needed rest. There is no evidence that any one benzodiazepine is superior to any other for sleep, although flurazepam is widely promoted and prescribed, often in conjunction with another benzodiazepine. (This can sometimes lead to excessive benzodiazepine intake). Once symptomatic control of anxiety is accomplished, work can begin on helping the patient to deal with his or her problems.

If fatigue results from sleep disturbed by sleep apnea, reflux, or allergic rhinitis, then treatment should be directed toward the underlying pathophysiology (see Chapter 46, Chapter 61, and Chapter 222).

Approach to the Patient with Chronic Fatigue Syndrome. Some of the best results to date have been achieved with *cognitive behavior therapy*, a nonpharmacologic treatment that focuses on identifying and reversing beliefs and coping mechanisms that perpetuate disability and block recovery. More than 75% of patients experience a return to normal daily activity by 12 months, in comparison with 25% randomized to standard medical care alone. Although this approach does not directly address the underlying etiology of CFS (which remains unknown), it does seek to deal with ideas and behaviors that encourage passivity and hinder self-help and symptomatic improvement. Treatment begins by elucidating the patient's beliefs about the illness and by exploring the behaviors that follow from these beliefs. Those marked by helplessness and passivity are targeted for change during a series of sessions in which the therapist works in partnership with the patient. The goal is to have the patient regain a sense of control and active participation in recovery. Although most studies of cognitive behavior therapy in CFS involve formally trained therapists, there is no theoretical reason why the primary care physician cannot personally conduct the basic steps of the program (Table 8.3).

1. Problem assessment and formulation
2. Identification of beliefs and coping behaviors that perpetuate illness-related disability
3. Development of more adaptive beliefs and coping behaviors
4. Patient testing of new approach to the illness and adopting it if it works
5. Consolidating gains and planning further self-help

From Sharpe M. Cognitive behavior therapy for chronic fatigue syndrome: efficacy and implications. Am J Med 1998;105:104S, with permission.

Table 8.3. Basic Steps in Cognitive Behavioral Therapy

A basic part of the cognitive behavior program is a gentle, graded *exercise program*. Some have even speculated that exercise is the key element, but exercise in the absence of a cognitive component leads to a high dropout rate. Those bothered by disordered sleep may benefit from *low-dose antidepressant therapy* (e.g., 25 mg of nortriptyline at bedtime, 10 to 20 mg of doxepin at bedtime, or 10 mg of paroxetine every morning). Higher doses do not appear to confer better results. *NSAIDs* provide symptomatic relief in patients bothered by myalgias, arthralgias, or headache.

A host of enthusiastic reports from uncontrolled studies have appeared claiming marked benefit from *liver extract, antifungal therapy, antiviral drugs, vitamins, immunoglobulin infusions, fatty acids, fludrocortisone*, and so on. Almost without exception, none has proved beneficial when subjected to randomized, double-blind, placebo-controlled study. Definitive etiologic therapy will have to await a better understanding of CFS pathophysiology. Fortunately, it appears that symptoms are self-limited, often improving or even clearing within 12 to 18 months. A strong *patient–doctor alliance* is essential, not only for providing support, but also for protecting the patient from unnecessary testing and unproven therapies.

CHAPTER 9 EVALUATION OF WEIGHT LOSS

Involuntary weight loss is a sensitive, although nonspecific, complaint frequently encountered in primary care practice. Reports of prevalence range as high as 10% to 20%, with frequency greatest among the elderly. Unexplained weight loss often suggests the presence of serious pathology, yet a substantial fraction of patients turn out to be free of organic illness. For example, in a series of patients with involuntary weight loss followed for 1 year, 50% either died or deteriorated during the course of the study; however, another 35% were well at the time of follow-up. Involuntary weight loss in excess of 2.5 kg is usually considered a reasonable threshold for evaluation, as more than 95% of patients with an organic etiology will have lost at least that much weight. However, unless extreme, the amount of weight loss is not predictive of an organic etiology. In many cases of weight loss, accompanying symptoms readily suggest the cause, but when a marked fall in weight is the sole or predominant complaint, the assessment can be difficult. The primary physician needs to determine at the time of initial presentation who requires an extensive medical evaluation and who can be followed expectantly.

PATHOPHYSIOLOGY AND CLINICAL PRESENTATION

Pathophysiology

When the number of calories available for utilization falls below daily needs, weight is lost; 1 lb of fat is consumed for every 3,500-calorie deficit. The principal mechanisms resulting in caloric deficits are reduced food intake, malabsorption, excess nutrient loss, and increased caloric requirements. Loss of fluid will also register as a fall in weight, with about 1 kg (2.2 lb) lost for every liter removed. Although more than one mechanism may be operating in a given case, each mechanism has a few characteristic clinical features. Anorexia or disinterest in food typifies causes of *reduced intake*. Foul-smelling, bulky, greasy stools are seen in the later stages of *malabsorption*; subtle changes in stool consistency and frequency are noted earlier (see Chapter 64). Recurrent vomiting, profuse diarrhea, polyuria, or fistulous drainage can lead to *excessive loss*. Increased food intake, hyperactivity, and fever are prominent in cases of *increased demand*.

Clinical Presentation

Although many causes of weight loss are readily evident, some conditions may be clinically subtle and present as unexplained weight loss. These deserve special elaboration.

Major depression is the leading cause of unexplained weight loss, especially in the elderly, in whom the condition accounts for up to 30% of cases. As frequent as it is, depression is often overlooked unless specifically considered. Somatic manifestations include appetite disturbance, early morning awakening, multiple bodily complaints, and fatigue; anhedonia, low self-esteem, feelings of guilt, and suicidal thoughts are among the characteristic psychological features. The death of a loved one, social isolation, and poverty are important psychosocial precipitants (see Chapter 227).

Eating disorders may involve covert behaviors. The patient suffering from *anorexia nervosa* may deny any disturbance of appetite yet persist in restricting food intake to the point of cachexia. Prevalence is highest among adolescent girls and young women. They decide to diet to an extreme degree, are preoccupied with a phobic concern about being fat, and are motivated by a relentless pursuit of thinness. Dieting persists because its psychological gratifications outweigh those derived from the intake of food. Paradoxically, the patient often reports feeling well and initially appears bright and undisturbed by the weight loss; anorexia is usually denied. At times, a few specific foods are the only ones consumed (e.g., vegetable juices). Amenorrhea is invariable and appears shortly after weight loss begins. A variant of anorexia nervosa consists of surreptitiously induced vomiting following engorgement with food; hypokalemic alkalosis results (see Chapter 234).

Carcinoma of the pancreas is the prototypical neoplasm associated with dramatic weight loss. The mean age of onset is 55; men outnumber women 2 to 1. There are about 9.5 cases per 100,000 population. Weight loss is found in 79% to 90% of patients at the time of diagnosis and averages 15 to 20 lb. The degree of weight loss does not seem to correlate with size, location, or extent of disease. For example, in a series of 100 cases, eight patients had resectable tumors; of the eight, two had weight loss of 25 and 40 lb, respectively. Aversion to food is more typical of this malignancy than is true anorexia. In many instances, weight loss precedes all other symptoms; once jaundice and abdominal pain supervene, the tumor is usually far advanced. Many other gastrointestinal malignancies follow a similar clinical course.

Most patients with *HIV infection* come to experience weight loss, and the spectrum of causes is wide. One may be inadequate intake resulting from dysphagia, depression, or medication. Early satiety is another mechanism that can result from gastrointestinal invasion by lymphoma, Kaposi's sarcoma, or *Mycobacterium avium-intracellulare* infection. Weight loss in the setting of adequate caloric intake suggests disseminated infection by *Mycobacterium avium-intracellulare* or *cytomegalovirus* as well as occult malignancy. Often, the later stages of *AIDS* are characterized by a *wasting syndrome*, which includes loss of more than 10% of baseline weight, recurrent fever, and persistent diarrhea in the absence of alternative explanations (see Chapter 13).

Marked weight loss is a late sign of *malabsorption*, but modest reductions can occur in the early stages of illness, when stools are noted to be a bit softer and more frequent than usual. Steatorrhea, abdominal discomfort, bloating, and pain accompany more dramatic falls in weight when disease is further advanced. Early *Crohn's disease* in adolescents has been noted on occasion to begin inconspicuously with anorexia predominating. For example, in a small series of 11 adolescent girls labeled as having anorexia nervosa, three were shown to have Crohn's disease when barium studies were obtained. *Blind loop syndrome* and *giardiasis* may also have indolent presentations with weight loss and vague abdominal discomfort; however, changes in stools are usually present also, with patients reporting mushy, foul-smelling bowel movements (see Chapter 58).

Increased caloric demand resulting from hyperthyroidism is usually obvious; however, *apathetic hyperthyroidism* of the elderly may be mistaken for malignancy because weight loss is profound and the patient appears listless. The typical symptoms of excess thyroid hormone are absent, and unexplained atrial fibrillation is often present (see Chapter 103).

Although *diabetes mellitus* is commonly found in overweight adults, it may be the cause of weight loss when substantial wasting of calories occurs because of poorly controlled glycosuria. Young male insulin-dependent diabetic patients are sometimes plagued by diarrhea, which exacerbates fluid and nutrient losses; true malabsorption has been noted in a few (see Chapter 102).

Patients with an *underlying medical cause* for their weight loss usually present with symptoms and signs that strongly suggest organic illness. In a Veterans Administration study of 91 patients with involuntary weight loss, the cause in the overwhelming majority was readily diagnosed on the basis of the initial history and physical examination; only one patient had a truly occult malignancy (see below).

DIFFERENTIAL DIAGNOSIS

The extensive number of causes of weight loss can be grouped pathophysiologically. Decreased intake, impaired absorption, increased loss, and excess demand are the principal mechanisms around which the differential can be organized (Table 9.1). Almost any illness can cause involuntary weight loss; the table emphasizes those conditions seen in the ambulatory setting that may present as unexplained loss of weight.

Decreased Intake
 HIV infection, AIDS
 Depression, bereavement
 Anxiety
 Poor dentition, loss of taste
 Esophageal disease
 Gastrointestinal disease worsened by food (e.g., peptic ulcer)
 Drugs (e.g., digitalis success, quinidine, amphetamines, NSAIDs, antitumor agents)
 Hypercalcemia
 Alcoholism
 Pernicious or viral hepatitis
 Hypothyroidism
 Uremia
 Malignancy
 Chronic congestive heart failure
 Chronic inflammatory disease
 Anorexia nervosa
 Social isolation, poverty
 Dementia
Impaired Absorption
 Cholestasis
 Pancreatic insufficiency
 Postgastrectomy
 Small bowel disease
 Parasitic infection (e.g., giardiasis)
 Small bowel syndrome
 Drugs (e.g., cholestyramine, colchicine)
 AIDS
Increased Nutrient Loss
 Uncontrolled diabetes mellitus
 Persistent diarrhea
 Recurrent vomiting
 Discharge from a fistulous tract
Excess Demand
 Hyperthyroidism
 Fever
 Malignancy
 Emotional states (e.g., manic disease)
 Amphetamine abuse

Table 9.1. Some Important Causes of Weight Loss

Studies from primary care practices find depression to be the leading cause of unexplained weight loss, with prevalence reported in the range of 15% to 30%. Among the elderly, psychosocial factors such as loss of a spouse, social isolation, andpoverty can exacerbate inadequate food intake resulting from depression. Occult malignancy, although much feared in the elderly, is usually a distant runner-up, with half the prevalence of depression. In some series, therapeutic diets, particularly those for hyperlipidemia and diabetes, also rank high in the list of causes, followed by uncontrolled diabetes and oropharyngeal problems. In the elderly, immobility, poor dentition, dementia, side effects of medication, and a decrease in sense of taste are additional causative factors that require consideration.

WORKUP

Increased attention to the detection of depression and a strategy of close follow-up have reduced the percentage of idiopathic cases from about 25% to 7%. Because extensive testing for unexplained weight loss can be arduous and expensive, it is helpful, when possible, to recognize first by history and physical examination those patients unlikely to have a medical cause. The probability of serious medical illness is low and the prognosis is good for persons with a history and physical examination devoid of evidence for organic pathology. Screening laboratory studies add little to the determination. Those deemed to have a low probability of medical illness might be more productively assessed for underlying depression and psychosocial factors leading to poor caloric intake. Subjecting them at the outset to extensive diagnostic testing in search of an occult malignancy is likely to be wasteful and of low yield when the pretest probability of cancer is low. The overall strategy is to conduct a clinical assessment that focuses on defining the underlying mechanism of weight loss so that any laboratory investigation can proceed in a logical and parsimonious fashion.

History

The first task is to document that weight loss has indeed occurred and to determine its extent. In some settings, almost half of patients do not prove to have lost weight once available records have been checked. In the absence of recorded weights, meaningful historical data include a change in clothing size, the ability to report an exact weight change, and confirmation of the history by a family member.

The history can be used to help identify the mechanism(s) responsible for the decline in weight by obtaining the details of daily food intake (including calorie count) and inquiring into the presence of any appetite disturbance, dysphagia, odynophagia, steatorrhea, diarrhea, vomiting, polyuria, or symptoms of a hypermetabolic state.

When *decreased intake* is suspected, one needs to inquire into the somatic and affective symptoms of depression (see Chapter 227). Other areas of questioning should include checking for nausea and vomiting, abdominal pain, melena, early satiety, excessive use of alcohol (see Chapter 228), exposure to and risk factors for hepatitis, poor dentition, oral candidiasis, aphthous ulcers, discomfort induced by eating, medication use, history of renal or liver disease, and anxiety. Risk factors for HIV infection should also be explored (see Chapter 13). If the patient is a young woman, anorexia nervosa should be considered, and a gentle inquiry into eating habits, self-image, and attitudes about weight is indicated (see Chapter 234). Family members should also be questioned.

In the elderly, questions about social isolation, bereavement, physical impairment, poor dentition, and poverty can be of critical importance in identifying impediments to adequate food intake. A review of drug use in the elderly is also essential because of the large number of medications prescribed and their potential for inducing anorexia and gastrointestinal upset. Additionally, patients should be checked for a loss of taste, which is sometimes responsible for poor intake in the elderly.

When *impairment of absorption* is suspected, inquiries are made into previous gastrointestinal surgery, the character of the stools, jaundice, history of pancreatitis, travel to an area known for giardiasis or other parasites, symptoms of inflammatory bowel disease (see Chapter 73), easy bruising, paresthesias, and sore tongue. Increased nutrient loss is assessed historically by ascertaining the quality and quantity of material lost in addition to the frequency and duration of the condition. Of major importance is checking for symptoms of diabetic enteropathy (diarrhea in conjunction with polyuria and polydipsia).

When *excess demand* is under consideration, the patient needs to be questioned about fever, malignancy, symptoms of hyperthyroidism, amphetamine abuse (see Chapter 235), chronic anxiety (see Chapter 226), manic states, and HIV disease (see Chapter 13).

Physical Examination

The examination should begin with an accurate weight determination, followed by the notation of any wasting, apatheticappearance, fever, tachycardia, pallor, ecchymoses, jaundice, stigmata of hyperthyroidism or hepatocellular failure, or signs of Kaposi's sarcoma. Next, the head and neck are examined for glossitis, stomatitis, poor dentition, goiter, and lymphadenopathy. The lungs and heart are examined for crackles, wheezes, consolidation, effusion, cardiomegaly, murmur, and a third heart sound. The abdomen is studied for surgical scars, organomegaly, hyperactive bowel sounds, focal tenderness, distention, ascites, and masses. The rectum is examined for masses, tenderness, discharge, blood, and the appearance of the stool. The neurologic examination includes a check for signs of vitamin B_{12} deficiency suggestive of terminal ileal disease (see Chapter 79) as well as any tremor, manic or depressive affect, or signs of dementia.

Laboratory Testing

Because the number of potential investigations is enormous, laboratory testing should be selective to avoid being wasteful, burdensome, and misleading. The history and physical examination will usually identify the basic mechanism(s) of weight loss and suggest specific causes that can be confirmed or ruled out by further investigation. As noted earlier, patients with perfectly normal physical examination findings and a history devoid of any symptoms suggestive of serious underlying medical illness are at low risk. It is reasonable to watch them for a month, focus on psychosocial determinants, and not immediately initiate an extensive laboratory workup. They should be given nutritional advice and a follow-up appointment at 4 weeks and asked to keep a diary of food intake and weight. Those with clinical evidence suggesting an important underlying mechanism can proceed to a focused laboratory workup if the diagnosis remains unconfirmed by history and physical examination.

Decreased Intake. When decreased intake is manifested by a markedly reduced appetite accompanied by nausea, it is worth obtaining a few selected serum chemistries, including measurement of *calcium, potassium, creatinine, transaminase*, and *amylase*, to check for a possible gastrointestinal or metabolic precipitant. Patients with such symptoms who are taking a digitalis preparation, quinidine, or any other drug that can cause gastrointestinal upset should have a *serum drug concentration* determined. If NSAIDs are being taken, they should be stopped. Those not taking an NSAID should be considered for endoscopic or radiologic evaluation of the upper gastrointestinal tract and *Helicobacter* testing (see Chapter 68). In the HIV-infected patient, endoscopy may be indicated to search for upper gastrointestinal mucosal erosion (see Chapter 13).

Impaired Absorption. Stool should be obtained for gross and microscopic examination and guaiac testing performed. A *qualitative stool fat* examination, in which fecal material is stained for neutral fat, is a basic step in the workup of suspected malabsorption. If doubt persists, a 72-hour stool collection for *quantitative stool fat* provides more precise information, with values of less than 8 g/d ruling out malabsorption. The *serum carotene* level is another useful marker of fat absorption. Its absorption is independent of pancreatic function, so that a normal level in the setting of malabsorption suggests pancreatic dysfunction. Similarly, the D-*xylose* test

can help distinguish pancreatic dysfunction from small bowel disease, because D-xylose absorption also does not require pancreatic enzyme activity (see Chapter 74). An elevated serum amylase or the radiologic demonstration of *pancreatic calcification* indicates pancreatitis (see Chapter 72), but a *secretin stimulation test* may be necessary to assess pancreatic exocrine function better. Sprue and blind loop syndrome are the most common forms of small-bowel pathology responsible for malabsorption. A small-bowel radiologic *contrast study* might be suggestive, but a *small-bowel biopsy* is necessary for the diagnosis of sprue; an abnormal *carbon 14 glycolate breath test* will help document bacterial overgrowth, although usually the test is unnecessary.

For the diagnosis of *giardiasis*, a *stool sample for ova and parasites* suffices in many instances. Because parasites are passed intermittently, three or more stools on alternate days should be examined. Because the cysts are hardy, a fresh stool specimen is not required. Trophozoites are more likely to be found in acute cases. Examination of a duodenal aspirate or jejunal biopsy specimen is resorted to when suspicion is high but stool findings are negative. Although these tests are more productive, they are cumbersome; some clinicians instead advocate a diagnostic trial of an antigiardial drug such as metronidazole.

Increased Nutrient Loss. Any patient suspected of diabetes mellitus should have a *urinalysis* for glycosuria. Marked glycosuria should be present in the patient with weight loss caused by diabetes.

Excess Demand. Suspicion of hyperthyroidism necessitates a *thyrotropin* (TSH) determination, especially in the elderly, apathetic patient with unexplained atrial fibrillation and weight loss (see Chapter 103). In the febrile HIV patient with adequate caloric intake, the weight loss likely represents excessive demand; *cultures* of blood and stool for *acid-fast bacilli* and of blood and urine for *cytomegalovirus* are required.

One of the most difficult diagnostic issues encountered in the workup of weight loss concerns the possibility of *occult malignancy*. Deciding when to embark on a search for tumor requires an estimate not only of the likelihood of finding a malignancy but also of the chances that it will be treatable. Unfortunately, by the time weight loss has occurred, most gastrointestinal malignancies are rather far advanced. When weight loss is the only symptom, pancreatic carcinoma may still be resectable if no other symptoms have appeared. *Abdominal ultrasonography* and *computed tomography* have improved case detection in some settings but not in others. Impact on survival remains to be realized (see Chapter 76). In a primary care study of elderly patients with undiagnosed weight loss, the yield of computed tomography was very low in the absence of clinical evidence of an underlying lesion.

SYMPTOMATIC THERAPY

The first task is to be sure food is available to the patient, particularly the elderly person who may be too isolated, impoverished, infirm, or depressed to take in adequate calories. It is estimated that the intake of 10% to 15% of elderly persons is below 1,000 kcal/d. Ensuring at least one hot meal per day is essential and can usually be arranged with the help of local social service agencies.

Most medical causes of weight loss must be corrected and cannot be readily treated symptomatically. However, there are important exceptions to this generalization. Sometimes, the severe anorexia associated with malignancy or use of antitumor agents can be overcome by pharmacologic means (see Chapter 91). The poor intake seen with hepatitis can be improved by providing small, frequent feedings, especially in the morning, when nausea is less severe (see Chapter 70). Appetite disturbances associated with depression are often amenable to tricyclic therapy (see Chapter 227). Maldigestion resulting from pancreatic insufficiency can be compensated for by the use of oral pancreatic enzyme preparations (see Chapter 72). The bacterial overgrowth of blind loop syndrome responds to oral broad-spectrum antibiotic therapy (e.g., 250 mg of tetracycline four times daily or 250 mg of amoxicillin three times daily), given for multiple 10-day courses or for 3 or 4 days each week indefinitely. Caloric supplements in the form of medium-chain triglyceride and dextrose preparations can provide marked improvement when severe fat and carbohydrate maldigestion or malabsorption is present. Initially, 3 oz is given with each meal; gradually this is increased to 6 oz, including supplements between meals. If sprue is suspected, a gluten-free diet can be tried empirically.

Fat-soluble vitamin supplements are also needed in cases of malabsorption to prevent malnutrition, even though caloric intake may be replenished. The fat-soluble vitamins A, D, and K are the most likely to be depleted. Dosage requirements in such cases are 25,000 to 50,000 U daily for vitamin A, 30,000 U for vitamin D, and 4 to 12 g for oral vitamin K. Monthly vitamin B_{12} injections of 1,000 mu are needed for terminal ileal disease presenting with megaloblastic anemia (see Chapter 82). Methods to control excessive vomiting and diarrhea are discussed in Chapter 59 and Chapter 64, respectively.

INDICATIONS FOR REFERRAL AND ADMISSION

Anyone with a weight loss in excess of 15 kg is likely to have a life-threatening condition and requires prompt hospitalization. The AIDS patient with unexplained weight loss may also benefit from some form of inpatient care while undergoing further evaluation. Any person with substantial weight loss who is suspected of having anorexia nervosa should be hospitalized and seen by a psychiatrist experienced in dealing with anorexia because this too can be a life-threatening condition (see Chapter 234). When malabsorption is documented by 72-hour stool fat assessment, consultation with a gastroenterologist should coincide with proceeding to further assessment. HIV patients with weight loss can certainly be evaluated by their primary care physician provided that the physician is familiar with the evaluation of such patients. Otherwise, referral is indicated.

CHAPTER 10 EVALUATION OF OVERWEIGHT AND OBESITY

ALLAN H. GOROLL

INTRODUCTION

Overweight and obesity have become major health concerns in modern postindustrial societies, affecting an estimated 55% of Americans over the age of 20. The personal and social costs are enormous—approaching $100 billion annually when medical complications, lost wages, and expenditures for weight reduction efforts are taken into account, not to mention the accompanying emotional pain, social stigmatization, and discrimination that may ensue. Excessive weight is a major risk factor for cardiovascular disease, type II diabetes mellitus, and hypertension, and it is also associated with impaired pulmonary function (including sleep apnea), surgical risk, osteoarthritis, gallbladder disease, and a risk for some cancers.

The tasks for the primary physician in the evaluation of patients with excess weight include not only an attempt to identify etiologic factors, but also a careful assessment of weight status and fat distribution as risk factors for major disease. This chapter focuses on the diagnostic evaluation; see Chapter 233 for the approach to treatment.

PATHOPHYSIOLOGY AND CLINICAL PRESENTATION

Definitions. The currently preferred definitions of overweight and obesity are based on *body mass index* (BMI) determinations, which approximate total body fat content and correlate with disease risk (Table 10-1). *Overweight* is defined as a BMI of 25 to 29.9 kg/m^2. *Obesity* is defined as a BMI greater than 30 kg/m^2, and *morbid obesity* by a BMI greater than 40 kg/m^2.

CLASS	BMI (KG/M²)	WAIST CIRCUMFERENCE*	RELATIVE RISK†
Normal	18.5–24.9	Normal	Normal
		Increased	Increased
Overweight	25.0–29.9	Normal	Increased
		Increased	High
Obese	30.0–34.9	Normal	High
		Increased	Very high
	35.0–39.9	Normal	Very high
		Increased	Very high
Obese, morbid	40.0+	All are increased	Extremely high

*Increased, >102 cm (40 in) in men, >88 cm (35 in) in women.
†For diabetes type 2, hypertension, coronary artery disease.
BMI, body mass index.

Table 10-1. Definition and Classification of Excess Weight

Physiology. Caloric intake and energy expenditure are linked through hypothalamic regulation of appetite and metabolism. The hypothalamus integrates a complex and redundant set of afferent signals, including *leptin* released from adipose tissue; *norepinephrine* from the autonomic nervous system; *epinephrine, insulin, androgens, glucocorticoids, peptide YY, progesterone*, and *estrogens* from endocrine glands; *glucagon, cholecystokinin, bombesin peptides, neurotensin, growth hormone–releasing hormone, somatostatin*, and *glucose* from the gastrointestinal tract; and *dopamine,* t-*amino butyric acid, galanin, opioids, growth hormone–releasing factor, somatostatin*, and *serotonin* from the central nervous system. The efferent output from the hypothalamus controls energy expenditure and appetite by the release of *norepinephrine, serotonin, neuropeptide Y, glucagon-like peptide I*, and *corticotropin-releasing hormone*, which act on the autonomic nervous system and the thyroid gland.

Pathophysiology. Obesity is often the consequence of physical inactivity in persons with an underlying disturbance in metabolism, appetite control, or dietary composition. In most instances, the etiology is multifactorial, although one factor may predominate. Susceptibility is influenced by genetic determinants that were once advantageous in regard to evolution, such as those that reduce energy expenditure or encourage the intake of energy-rich foods. However, such inherited traits can be counterproductive to good health in postindustrial societies, in which physical demands are greatly reduced and high-calorie food is plentiful and inexpensive.

Physical inactivity emerges as a leading cause of obesity in modern society, underscored by the increasing prevalence of obesity despite a decline in average daily caloric intake. When daily life makes few physical demands, caloric needs drop precipitously, which leads to an epidemic of excess weight, even among those without major genetic susceptibility to weight gain. Some genetic variability in the propensity for exercise has been described, which may contribute to inactivity in some.

Metabolic factors are important, genetically determined contributors to excessive weight and include resting energy expenditure, thermic effect of food, and exercise-induced energy expenditure. Among these, a reduction in energy utilization with exercise correlates the most strongly with risk for weight gain. Ninefold to 30-fold variations have been observed. Because exercise-induced energy expenditure accounts for about 30% of total energy demand, any genetic propensity for reduced energy expenditure with exertion could substantially increase the risk for obesity.

Dietary composition actually plays a much smaller role than might be expected. In most persons, changing the percentages of dietary fat, protein, and carbohydrate *without* changing the number of calories consumed has little or no influence on the development of obesity. Diets high in fat contribute to obesity mostly because they are rich in calories, not because they are rich in fat. Despite claims to the contrary by those promoting weight loss diets, there is no evidence that dietary composition alone is a major determinant of obesity for the vast majority of persons. Almost all weight loss diets work by restricting total calories (see Chapter 233). The *timing of food intake* may contribute modestly to obesity; eating once daily, particularly before going to bed, predisposes to the accumulation of adipose tissue in some persons.

Appetite disturbances have long been suspected as a cause of obesity. Many obese individuals appear to eat without satiety. In some, there appears to be resistance to normal appetite controls, such as the appetite suppressant leptin, serum levels of which actually increase in obese subjects. Moreover, the effects of appetite suppressants can be overcome in some animals by providing easy access to palatable, energy-rich foods.

Genetic factors, as noted earlier, play a substantial role by influencing energy utilization, appetite, food preferences, and even propensity for physical activity. The importance of genetic factors is underscored by findings from studies of twins, families, and adoptees, which reveal a strong relation between weight class of adoptees and their biologic parents, but none between adoptees and their adopted parents. Parental obesity doubles the risk for adult obesity in obese and nonobese children under the age of 10 years. Obese children under the age of 3 years who have an obese parent have a very high risk for adult obesity, but they experience no increase in risk if neither parent is obese. Genetic factors are estimated to account for nearly 50% of the risk of becoming overweight, and even more for becoming obese.

Developmental and environmental factors, manifested by parenteral influences and childhood environment, contribute to the development of adult obesity. As the age of the child increases, the influence of environment increases. Over the age of 10 years, heredity becomes a less dominant determinant of adult obesity, and environment increases in importance. Persons growing up in the current era of plentiful, inexpensive high-calorie fast food are at greater risk of obesity than are cohorts from earlier eras. Teenagers, especially, consume large amounts of such food, with potentially serious long-term consequences. Natural history studies find a strong relation between increased weight during the teenage and young adult years and risk of becoming frankly obese later in life. Those who become obese tend to remain obese their entire lives.

Psychological and behavioral factors have long been thought important; however, there is no known psychological explanation for why reactive hyperphagia develops in some persons as a response to emotional stress, whereas anorexia is the reaction of others. Considerable research has been unable to determine any particular personality organization or cluster of psychological defense mechanisms clearly linked to obesity. Nonetheless, psychological problems frequently contribute to the onset and perpetuation of obesity-inducing behavioral changes. For example, some individuals characteristically overeat in response to stress, loss, or frustration. Those with the *night eating syndrome*, characterized by insomnia, massive late-evening "refrigerator raids," and morning anorexia, also experience particular emotional distress when they try to reform their eating behaviors. Usually, coinciding social stresses are present as well. The appetite disturbance associated with *major depression* may lead to either an increase or decrease in weight.

Social factors are key determinants of the frequency and nature of feasts, timing of meals, role and meaning of food, types of foods consumed, and norms of appearance. In our society, excess weight occurs far more frequently among minorities and the socioeconomically disadvantaged than among others. Young African-American and Hispanic women are 2.1 and 1.5 times, respectively, more likely to become obese than are young white women. Whether this difference represents dietary preference, socially motivated behavior, or interactional factors is unclear. In certain occupations, such as wrestling, obesity is a help, not a hindrance. In former times, corpulence was a sign of prosperity and was cultivated by bankers and businessmen.

Clinical Presentation. Most cases of overweight and obesity occur independently of an underlying medical condition, although they may exacerbate or lead to illness. Onset of exogenous obesity is often evident by early adulthood and tends to persist. Those who are overweight by their early twenties are at considerable risk of developing frank obesity by their late thirties. Persons with an underlying hereditary etiology usually manifest obesity before age 10 years. In 5% to 10% of adult cases, an underlying medical condition or medication that affects energy expenditure, fuel utilization, appetite, or physical activity may be responsible. Often, the mechanism is an effect on one of the substances involved in regulating energy intake or expenditure (see above).

Pharmacologic agents prescribed for clinical conditions other than obesity may cause weight gain. b -*Blockers* and *central sympatholytics* (e.g., clonidine) can decrease metabolic rate and energy expenditure. *Glucocorticosteroids* cause hypertrophic obesity in a characteristic truncal pattern. *Antidepressants*, such as the *tricyclics* and *selective serotonin reuptake inhibitors*, and some *antihistamines* (e.g., cyproheptadine) act as appetite stimulants. Weight gain is also common with oral contraceptive use.

Endocrine disturbances are more often the result rather than the cause of excess weight. However, *hypothyroidism* (see Chapter 104) has been found to account for up to 5% of cases in some series. *Cushing's syndrome* is a rare cause and is usually accompanied by characteristic features of truncal obesity and peripheral muscle wasting. *Stein-Leventhal syndrome*—polycystic ovaries, absent menses, and moderate hirsutism (see Chapter 112)—often goes unrecognized as an endocrinologic form of obesity; the precise mechanism of the obesity is unknown. *Eunuchism* and *hyperinsulin states* may also be associated with obesity.

Neurologic causes of obesity are usually not cryptic; they mostly result from *hypothalamic injury*, as occurs with craniopharyngiomas, encephalitis, or trauma. Visual field defects or headaches are usually present. Two rare types of neurologic disease without obvious central nervous system symptoms have been described. Kleine-Levin syndrome consists of periodic hyperphagia and hypersomnia. A second syndrome is characterized by preoccupation with food and accompanying electroencephalographic abnormalities that respond to phenytoin.

Mental illness may heralded by weight gain. The appetite disturbance of *major depression* is one of the cardinal manifestations of the condition and may be a presenting complaint (see Chapter 227).

DIFFERENTIAL DIAGNOSIS

The causes of obesity can be primary or secondary, with the latter being medical conditions that result in obesity. Some forms of secondary weight gain are a consequence of salt retention and fluid overload rather than an increase in fat cell mass. Among the important causes of sodium retention are congestive heart failure, severe hepatocellular disease, and renal failure (see Chapter 32, Chapter 71, and Chapter 142). Primary forms of obesity can be classified by their underlying pathophysiology. The vast majority of cases are primary in nature. An etiologic/pathophysiologic diagnosis is essential to the design of an effective management program (Table 10-2).

Primary
  Psychological factors
    Depression
    Anxiety
    Frustation
  Biologic factors
    Reduced thermogenesis
    Increased fat cell mass
    Autonomic dysfunction
    Altered hypothalamic set point
    Single large daily meal taken before bedtime
    Decreased energy expenditure
    Drugs (e.g., tricyclic antidepressants, oral contraceptives, corticosteroids, phenothiazines)
  Genetic influences
    Familial obesity
  Social and occupational factors
    Lower socioeconomic class
    Social/occupational situation
Secondary
  Endocrine disease
    Hypothyroidism
    Stein-Leventhal syndrome
    Cushing's syndrome
  Neurologic disease
    Hypothalamic injury (e.g., trauma, encephalitis, cranio-pharyngioma)

Table 10-2. Important Causes of Obesity

WORKUP

Particular attention should be paid to detection and early intervention in persons at greatest risk for becoming obese, namely overweight teenagers and young adults, especially women from minority groups. A principal objective of the overweight/obesity evaluation is to determine how much risk the weight problem confers. The risk assessment begins with an estimate of the amount and distribution of fat, followed by a consideration of other risk factors and underlying conditions that add to morbidity and mortality risks; it concludes with estimates of relative and absolute risk. Additional components of the workup pertinent to management include elucidation of the underlying mechanism(s) responsible for the patient's weight problem, detection of any underlying illnesses presenting as weight excess, and assessment of the patient's motivation to lose weight.

Weight Assessment. To establish whether an individual has a weight problem that poses a health risk, an estimation of the *amount* and *distribution* of fat is required. Both are independent determinants of disease risk. Fat distribution is particularly important, even among persons who are not obese.

Measurement of Body Fat. This is best accomplished by calculating the *BMI*:

$$BMI = \frac{Body\ Weight\ (kg)}{Height\ (m^2)}$$

The BMI determination assumes that weight is measured with shoes and heavy clothing removed. If weight is obtained with shoes and all clothing on, then 5 lb should be subtracted for men and 3 lb for women. The BMI is calculated by taking the weight in kilograms and dividing it by the square of the height in meters (or by multiplying by 703 the weight in pounds divided by the square of the height in inches). This ratio of weight to height actually calculates total body mass rather than fat

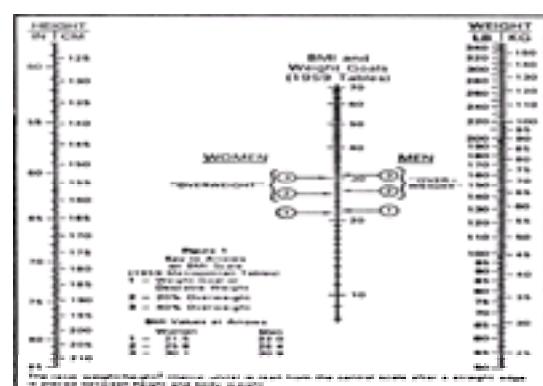
mass, but it correlates highly with the amount of body fat and its associated health risks except in very muscular individuals, who might be falsely labeled as overweight with use of the BMI. The BMI range of 20 to 24.9 is classified as "normal" because no actuarial increase in disease mortality is noted within it. Mortality begins to increase as the BMI exceeds 25, and it is here that health professionals should be concerned. Most expert consensus panels recommend that health professionals adopt the BMI as the preferred measure for evaluating weight status because it provides the best estimate of disease risk (Fig. 10-1 and Table 10-1).


Figure 10-1. Nomogram for body mass index (kg/m^2). Weights and heights are without clothing. With clothes, add 5 lb (2.3 kg) for men and 3 lb (1.4 kg) for women. Add 1 in (2.5 cm) in height for shoes. (New weight standards for men and women. J Am Diet Assoc 1985;85:1119, with permission. Stat Bull Metropolitan Life Insurance Company 1959;40:1.)

Height and weight tables have the advantage of simplicity. However, there are serious limitations to their use. Standard charts typically list "ideal" or desired weights based on actuarial data, yet it is not weight *per se* that minimizes morbidity or the incidence of disease. The person having a significant percentage of lean body mass, such as a physical laborer, may well exceed "ideal" body weight yet not be obese. On the other hand, some individuals may be within the ideal range but have non–insulin-dependent diabetes mellitus, hypertension, or other conditions that would benefit from weight reduction. The Metropolitan Life Insurance Company has published revised reference weights in an attempt to isolate the effect of weight alone on longevity; individuals with major diseases, such as cancer, diabetes, or heart disease, were omitted from the study (Table 10.3). Life tables, based only on mortality, ignore possible nonfatal risks associated with increased weight.

Table 10-3. Optimal Weights,[a] in Pounds, for Adults Ages 25 and Over (Light Clothing)

Height and weight formulas are sometimes used to determine ideal body weight and estimate the degree of obesity, but they provide only the crudest of estimates and should not be used to set goals for weight reduction. They are provided here only because they are sometimes referred to. (Appropriate weight goals for patients can be determined only by a thorough analysis of their medical history and physical findings, supplemented by appropriate laboratory evaluation.)

Female weight: Allow 100 lb for first 5 ft of height plus 5 lb for each additional inch.

Male weight: Allow 106 lb for first 5 ft of height plus 6 lb for each additional inch.

The measurement of *skinfold thickness* is used by some to quantify adiposity. Calipers are used to measure skinfold thickness in the triceps and subscapular regions. However, reliability can be a problem when skinfold measurements are used because body fat increases with age, grossly obese patients are difficult to measure, and results vary among providers using the calipers.

Bioelectric impedance analysis is sometimes used to measure body fat. Electrodes are applied to one arm and leg, and the impedance is measured. Impedance is proportional to the aqueous composition of the body. Formulas are used to estimate the percentage of fat in the body. Although accurate, this method is expensive and not readily available.

The old-fashioned "*eyeball test*" remains a mainstay of assessment: If a person looks fat, he or she is likely to be fat. However, quantification and correlation with risk are crude with this common sense method.

Measurement of Fat Distribution. The other independent determinant of health risk associated with excess weight is fat distribution, which can be quantified by measuring *waist circumference*. The circumference of the waist is obtained at the narrowest area above the umbilicus. Measurements in excess of sex-specific cutoffs (>102 cm, or 40 in, in men and >88 cm, or 35 in, in women) confer an increased relative risk of disease morbidity and mortality (see Table 10-3). The effect of fat distribution on risk is so strong that waist circumference is important even in persons who are not technically overweight. However, in morbidly obese patients, waist circumference is always exceeded and the measurement confers no additional risk.

The *ratio* of *waist* or *abdominal circumference* to *hip* or *gluteal circumference* provides an even more precise quantitative index of regional fat distribution. The hip circumference is measured at the maximal gluteal protrusion. Individuals with excess upper body fat (android obesity) are at higher risk for diabetes, atherosclerosis, and stroke than are those who have more adipose tissue in the hips, buttocks, and thighs (gynecoid obesity). In quantitative terms, individuals with waist-to-hip ratios greater than 0.8 for women and 1.0 for men have an increased risk for coronary disease.

Estimation of Disease Risk. One begins with determinations of total body fat and fat distribution, represented respectively by BMI and waist circumference. These parameters correlate well with *relative risk*, especially among persons under the age of 65 years (see Table 10-3). Relative risk from obesity is greatest among younger persons and declines somewhat with advancing age.

Determination of the *absolute risk* associated with obesity requires checking for underlying *coronary heart disease* (see Chapter 20), *type 2 diabetes mellitus* (see Chapter 93), *noncoronary atherosclerotic disease* (see Chapter 23 and Chapter 171), *hypertension* (see Chapter 19), and *sleep apnea* (see Chapter 46), in addition to the end-organ injuries that may result from them (see Chapter 26, Chapter 30, Chapter 35, Chapter 46, and Chapter 102). The cardiovascular risk assessment is enhanced by screening for principal risk factors such as *hyperlipidemia* (see Chapter 15), *hypertension* (see Chapter 14), *smoking* (see Chapter 54), and premature coronary disease in first-degree relatives. Calculations of absolute risk are possible from a consideration of these factors (see Chapter 26 and Chapter 27). Searches for *osteoarthritis* (see Chapter 146), *cholelithiasis* (see Chapter 69), and *stress incontinence* also help predict risk of weight-related consequences.

Assessment of Etiology and Consequences. As important as risk assessment is, etiologic factors and health consequences deserve attention because they are

relevant to the approach to management.

History. An extensive weight history should include age of onset of obesity, weight status of parents and siblings, and any identifiable circumstances associated with the onset of obesity. Although dietary composition *per se* is not a risk factor for obesity, dietary composition and quantity need to be ascertained to determine total caloric intake. A high-fat diet is likely to provide excessive calories. Because physical inactivity is a major precipitant of excess weight, the patient's daily activities should be elucidated in detail to estimate daily energy requirements. Proclivity toward exercise should also be ascertained. A careful review of ongoing psychological and situational stresses is essential and should include screening for depression (see Chapter 227). Any recent attempts at smoking cessation should be reviewed for effect on weight. The social and cultural dimensions of the history should be explored for their possible contribution to weight gain.

Even in a patient without obvious medical pathology, a workup that screens for underlying endocrinologic and neurologic diseases is essential, as is a check for drug-induced causes. The history requires a thorough neuroendocrine review of symptoms: fatigue, unexplained weight gain, cold intolerance, hoarseness, change in skin and hair texture, amenorrhea, hirsutism, easy bruising, weakness, visual disturbances, and headache. Medications are reviewed for agents that may stimulate appetite or affect metabolism, such as antidepressants, oral contraceptives, corticosteroids, phenothiazines, antithyroid medications, b-blockers, and insulin.

A review of systems for the consequences of obesity should include inquiry into chest pain, shortness of breath, polyuria, polydipsia, impotence, numbness, limb pain or coldness, transient neurologic deficits, daytime sleepiness, apneic periods at night, and pain in weight-bearing joints.

The Physical Examination. The physical examination includes a check for such etiologic clues as moon facies, hirsutism, dry and thickened skin, coarse hair, truncal obesity, pigmented striae, goiter, adnexal masses, lack of secondary sex characteristics, delayed relaxation of ankle jerks, and visual field deficits. The physical examination should include a search for the consequences of obesity, including blood pressure elevation, diabetic retinopathic changes, carotid bruits, obstruction of soft tissues in the upper airway, cor pulmonale, rales, cardiac enlargement, degenerative changes in the hips and knees, and signs of peripheral arterial insufficiency and peripheral neuropathy.

Laboratory Testing. Laboratory testing includes two components: the diagnosis of an underlying medical etiology and the detection of metabolic consequences. A strategy of routinely testing for all possible medical causes in the absence of suggestive clinical findings adds to expenses and increases the risk of generating a high percentage of false-positive results (see Chapter 2). Nonetheless, some clinicians routinely screen for hypothyroidism with a *thyrotropin* determination because the test is sensitive, the condition has a relatively high frequency, and the clinical presentation of hypothyroidism can be very subtle (see Chapter 104).

The laboratory evaluation is most productive when directed at causes suggested by the history and physical examination. For example, the obese patient suspected of having Cushing's syndrome because of truncal obesity, peripheral wasting, and pigmented striae is a reasonable candidate for an overnight *1-mg dexamethasone suppression test*. If headaches accompanied by a visual field disturbance are present, then *computed tomography* of the sella turcica is needed to check for the possibility of a pituitary tumor (see Chapter 100).

Testing for the metabolic consequences of obesity is straightforward and includes a random serum glucose measurement and lipid profile (see Chapter 15). These results help determine overall cardiovascular risk. Patients bothered by daytime sleepiness and a history of excessive snoring and disturbed sleep resulting from irregular breathing should be considered for an evaluation of sleep apnea (see Chapter 46). At the present time, measures of energy expenditure, thermogenesis, autonomic function, fat cell count, and set point are relegated to the research laboratory, but in time they may become part of the clinical evaluation.

INDICATIONS FOR REFERRAL

Patients who are morbidly obese and demonstrate such adverse sequelae as marked respiratory compromise, disabling arthritis, or symptomatic coronary disease require consultation for consideration of a very low-calorie diet under the supervision of persons experienced in its implementation (see Chapter 233). Referral for consideration of surgical approaches to treatment may also be indicated in such persons. Obstructive sleep apnea in patients with mild to moderate obesity may not require such extreme measures, but pulmonary consultation in conjunction with a weight loss program is indicated (see Chapter 46).

PATIENT EDUCATION

Most patients come for evaluation out of concern for an underlying medical condition. The vast majority have no such cause and need to know that inactivity is the principal reason for their weight gain. Although they may have genetically determined risk factors, such as a proclivity for high-fat food and a reduced exercise-related energy expenditure, they will benefit when the physician reemphasizes the overwhelming importance of exercise and an active life-style to weight control (see Chapter 233). The occasional patient whose obesity is driven predominantly by heredity (both parents obese, onset before age 3 years) appreciates knowing that the weight problem is not a consequence of defective character. For the vast majority, the education process begins by drawing attention away from diets, medical conditions, and "metabolism problems" and to the importance of exercise. The goals are to provide the patient with an estimate of the disease risk posed by the excessive weight and an assessment of the factors contributing to it.

RECOMMENDATIONS

- Make overweight detection and early intervention an important goal of the health maintenance/prevention agenda for teenagers and young adults. **Updated: 7/22/02** Focus efforts on those at greatest risk for becoming obese, namely overweight teenagers and young adult women from minority groups.
- Begin the weight assessment by determining amount of body fat and fat distribution, which independently correlate with the relative risk associated with excess weight.
- Estimate body fat content by calculating the BMI (body weight in kilograms divided by the square of the height in meters).
- Determine fat distribution by measuring the waist circumference at the narrowest area above the umbilicus.
- Estimate the relative risk of cardiovascular disease, type 2 diabetes, and hypertension from these determinations.
- Search for major cardiovascular risk factors and for evidence of end-organ damage to determine the absolute risk of cardiovascular morbidity and mortality.
- Check the history and physical examination for etiologic factors, ranging from familial propensity and early age of onset to dietary excess, physical inactivity, and underlying medical and psychological conditions.
- Use laboratory testing only to test etiologic hypotheses suggested by the history and physical examination or to screen for cardiovascular risk factors (e.g., hypercholesterolemia, diabetes).
- Provide the patient with an estimate of the disease risk posed by the excessive weight and an assessment of the factors contributing to it.

CHAPTER 11 EVALUATION OF FEVER

HARVEY B. SIMON

Since antiquity, fever has been recognized as a cardinal manifestation of disease. Indeed, people identify fever as a sign of illness more readily than they recognize the importance of most other symptoms. In addition to causing concern, the presence of fever usually raises high therapeutic expectations. Even in the era before antibiotics, John Milton observed that "the fever is to the Physitians, the eternal reproach" (1641). In the popular mind today, fever is equated with infection, and infections are expected to respond to the administration of "wonder drugs." As a result, the physician is faced with the challenge of defining the cause of the fever, instituting appropriate therapy, and explaining the reasons for limiting antibiotic use to bacterial infections.

PATHOPHYSIOLOGY AND CLINICAL PRESENTATION

"Normal" Body Temperature. Popular lore notwithstanding, 98.6°F (37°C) is *not* normal body temperature. In fact, there is no single normal value; like so many other biologic phenomena, body temperature displays a circadian rhythm. In healthy individuals, mean rectal temperatures vary from a low of about 97°F (36.1°C) in early morning to a high of about 99.3°F (37.4°C) in late afternoon. In children, the normal range may be even greater. Moreover, physiologic factors such as exercise and the menstrual cycle can further alter body temperature. In practical terms, understanding the diurnal rhythm of body temperature is important for two reasons. First, many patients have been unnecessarily subjected to extensive workups and even psychologically incapacitated in the erroneous quest for a cause of deviation from the mythical "normal" temperature of 98.6°F. Second, the fever of disease states is superimposed on the normal cycle, so that fevers are generally highest in the evenings and lowest in the mornings. As a result, frequent temperature recordings throughout the day are required to monitor fever in sick patients. The absence of fever in a single office visit does not exclude a febrile illness.

Clinical Manifestations of Fever. The presenting complaints of the febrile patient may be explained by the underlying disease process or by the fever itself. The signs and symptoms of fever vary tremendously. Some patients are asymptomatic; more often, they have a sensation of warmth or flushing. Malaise and fatigue are common. The hypothalamus, acting through somatic efferent nerves, increases muscle tone to generate heat and raise body temperature; many febrile patients experience *myalgias* as a result.

These same factors account for one of the most dramatic manifestations of fever: the *shaking chill* or *rigor*. It is taught that rigor is a manifestation of bacteremia, but in fact any stimulus that raises the hypothalamic set point rapidly may produce a rigor. Patients experiencing a rigor exhibit uncontrolled violent shaking and trembling, and they characteristically heap themselves with blankets even as their temperatures are shooting up. This phenomenon also has a physiologic basis. Despite their high central or core temperature, these patients subjectively feel cold because their surface temperature is reduced. To generate fever in response to hypothalamic stimuli, cutaneous vasoconstriction occurs, skin temperature falls, and cold receptors in the skin sense this as cold. Quite the reverse occurs during defervescence; body temperature falls in response to cutaneous vasodilation, and drenching sweats typically terminate an episode of fever.

Other manifestations of temperature elevation include central nervous system symptoms that range from a mild inability to concentrate to *confusion, delirium*, or even stupor, especially in the elderly or debilitated patient. High fevers (104° to 106°F) may produce *convulsions* in infants and young children without any primary neurologic disorder. Increased cardiac output is an invariable consequence of fever, and *tachycardia* typically accompanies fever. Tachycardia is so usual that its absence should lead one to suspect uncommon problems such as typhoid fever, in which relative bradycardia is typical (for unknown reasons), drug fever, and factitious fever. Patients with underlying heartdisease may respond to the high-output stress of fever with angina or heart failure.

Another sign of fever is the so-called fever blister— *labial herpes simplex*. The problem is probably not precipitated by fever *per se*, for it is much more common in some infections, such as pneumococcal pneumonia and meningococcal meningitis, than in other febrile states.

Because fever accompanies infection so frequently, numerous investigators have tried to determine if fever has any protective or beneficial role. There are a few circumstances, such as central nervous system syphilis, in which elevations of body temperature may exceed the thermal tolerance of the infectious agent. In fact, induced fever was once a form of therapy for syphilis. In several animal models, fever enhances recovery from experimental infections; however, there is no such proven clinical benefit from fever in humans.

Consequences of Fever. Is fever detrimental? Most otherwise healthy individuals can tolerate temperatures up to 105°F (40.5°C) without ill effects, although even in these individuals symptoms often warrant therapy. In children, high fevers should be suppressed because convulsions may occur. Patients with heart disease should also receive antipyretic therapy. Each increase of 1°F in temperature increases the basal metabolic rate by 7%, which results in increased demands on the heart, so that myocardial ischemia, failure, or even shock can ensue. In addition, extreme hyperthermia beyond 108°F (42.1°C) may cause direct cellular damage. Vascular endothelium seems particularly susceptible to such damage, and disseminated intravascular coagulation frequently accompanies extreme hyperthermia. Other structures that may be directly damaged are brain, muscle, and heart. Finally, metabolic derangements such as hypoxia, acidosis, and sometimes hyperkalemia can result from extreme pyrexia and, in turn, further contribute to coma, seizures, arrhythmias, or hypotension, which can be lethal. Nevertheless, patients have survived temperatures of up to 108°F without demonstrable organ damage, although mortality in this temperature range is appreciable. Body temperatures as high as 113°F have been demonstrated in humans, but these have been uniformly lethal.

DIFFERENTIAL DIAGNOSIS

Many inflammatory, infectious, neoplastic, and hypersensitivity processes can produce fever. Most *acute fevers* encountered in the office setting are of obvious causes such as upper respiratory or urinary tract infection. Viral illnesses, drug allergy (especially to antibiotics), and connective tissue disease are other important precipitants.

Recurrent or *intermittent* fever is most characteristic of infectious conditions with cyclic features, such as malaria, hepatitis B, leptospirosis, brucellosis, and disseminated fungal infection. Migration of intraluminal parasites (as in schistosomiasis, amebiasis, and trypanosomiasis) can lead to intermittent fever, as can cell lysis by intracellular parasites (e.g., *Bartonella* and *Ehrlichia*). A cyclic pattern of high fevers for 1 to 2 weeks alternating with afebrile periods suggests the pathognomonic *Pel-Ebstein fever* of Hodgkin's disease.

Unexplained persistent fever can be a major diagnostic challenge. "Fevers of unknown origin" (FUOs) are defined as those persisting for 3 weeks, exceeding temperatures of 101°F, andeluding 1 week of intensive diagnostic study. In both community and referral centers, infection (localized and systemic), neoplasms, and collagen vascular diseases account for more than 75% of cases (Table 11.1). Most of these represent unusual presentations of common diseases rather than rare conditions. In the community setting, intraabdominal abscesses and lymphomas account for nearly a third of cases. The spectrum of FUO disease has evolved in the past two decades. HIV infection raises a whole new set of diagnostic possibilities [e.g., *Pneumocystis* pneumonia, *Mycobacteria avium* infection (see Chapter 13 and Table 11.2)] as does immunosuppression from cancer chemotherapy, intravenous drug abuse, and the increasing use of prosthetic devices. Newly discovered infectious etiologies, such as Lyme disease, also add to the list.

"The Big Three"
I. Infections: 30–40%
  A. Systemic
    1. Tuberculosis (miliary)
    2. Infective endocarditis (subacute)
    3. Miscellaneous infections: cytomegalovirus infection, toxoplasmosis, brucellosis, psittacosis, disseminated mycosis, chronic meningococcemia, disseminated mycosis
  B. Localized
    1. Hepatic infections (liver abscess, cholangitis)
    2. Other visceral infections (pancreatic, tuboovarian, and pericholecystic abscesses; empyema of gallbladder)
    3. Intraperitoneal infections (subhepatic, subphrenic, paracolic, appendiceal, pelvic, and other abscesses)
    4. Urinary tract infections (pyelonephritis, renal carbuncle, perinephric abscess, prostatic abscess)
II. Neoplasms: 7–20%. Especially lymphomas, leukemias, renal cell carcinoma, atrial myxoma, and carcinoma metastatic to liver or lung
III. Collagen-vascular and other multisystem disease: 15–25%. Including temporal arteritis and juvenile rheumatoid arthritis as well as systemic lupus erythematosus, rheumatoid arthritis, polyarteritis nodosa, Wegener's granulomatosis, mixed connective tissue disease, sarcoidosis

Less Common Causes: 9–19%
I. Noninfectious granulomatous diseases (e.g., granulomatous hepatitis)
II. Inflammatory bowel disease
III. Pulmonary embolization
IV. Drug fever
V. Factitious fever
VI. Hepatic cirrhosis with active hepatocellular necrosis
VII. Miscellaneous uncommon diseases (familial Mediterranean fever, Whipple's disease)
VIII. Undiagnosed

Modified from Jacoby GA, Swartz MN. Fever of unknown origin. N Engl J Med 1973;289:1407, with permission.

Table 11.1. Causes of Fever of Undetermined Origin

HIV Patients
Infection (75% of cases)
  Mycobacterial infection (*M. tuberculosis*, *M. avium* complex)
  Cytomegalovirus infection
  Toxoplasmosis
  Pneumocystis infection
  Cryptococcal infection
  Salmonella infection
  Aspergillosis
  Herpes zoster
  Underlying HIV infection
Noninfectious (10%)
  Lymphoma (non-Hodgkin's)
  Drug fever
Unexplained (15%)
Cancer Patients
Infection (50%), usually as a consequence of neutropenia
  Gram-negative bacilli
  Fungi
Malignancy
  Extension and widespread dissemination of underlying malignancy

Adapted from Hirschman JV. Fever of unknown origin in adults. Clin Infect Dis 1997;24:291, with permission.

Table 11.2. Fever of Unknown Origin in Patients with HIV Infection or Cancer

WORKUP

The acutely febrile patient presents a common but demanding problem in differential diagnosis. In most cases, a careful history and physical examination will reveal the diagnostic clues, so that laboratory studies can be used selectively. The evaluation of persistent fever can be more demanding. The initial office evaluation should help determine the proper pace of diagnostic testing and need for therapeutic intervention. If the illness is insidious in onset and only slowly progressive, or if the patient is nontoxic and clinically stable, one may proceed with the workup in a deliberate manner on an ambulatory basis, utilizing serial clinical observations and time as key diagnostic tools. On the other hand, if the patient is a compromised host or is acutely ill and toxic, several immediate diagnostic studies are mandatory, and treatment may be required even before all the results are available; hospitalization is usually necessary in such cases. Table 11.3 lists some factors that should prompt an aggressive approach to diagnosis and therapy.

Vulnerable Hosts
  Age (very young or very old)
  Corticosteroid or immunosuppressive therapy
  Serious underlying diseases (neutropenia, sickle cell anemia, diabetes, cirrhosis, advanced chronic obstructive pulmonary disease, renal failure, malignancies, AIDS)
  Implanted prosthetic devices (heart valves, joint prostheses)
  Intravenous drug abuse
Toxic Patients
  Rigors, prostration, extreme pyrexia
  Hypotension, oliguria
  Central nervous system abnormalities
  Cardiorespiratory compromise
  New significant cardiac murmurs
  Petechial eruption
  Marked leukocytosis or leukopenia

Table 11.3. Febrile Patients Who Require Special Attention

Febrile illnesses are most commonly acute processes that are either readily diagnosed and treated (common bacterial infections) or self-limited despite the lack of a specific diagnosis (viral infections, allergic reactions). However, patients will occasionally present with undiagnosed fevers, fulfilling the classic criterion for FUO. In both situations, the keys to diagnosis are a careful history and a meticulous physical examination, which almost always suggest the diagnosis and guide the rational use of imaging studies and other diagnostic modalities.

History

The infectious disease history should stress several items not routinely emphasized: (a) host factors, (b) epidemiology, (c) symptomatology, and (d) drug history.

Host Factors. One should determine if patients are basically healthy or if they have an underlying disease that may render them unusually susceptible to infection. Patients taking *corticosteroids* or other *immunosuppressive agents* are especially vulnerable to infection. Patients with hematologic and other *malignancies, HIV infection, chronic liver disease, diabetes mellitus, neutropenia,* or *sickle cell anemia* may become infected with unusual opportunistic pathogens or may fail to respond normally to common infectious agents. Individuals with implanted *prosthetic devices*, such as artificial heart valves or hip prostheses, are also at increased risk for serious infection. Finally, patients with a *past history* of certain infectious processes, such as pyelonephritis, may be prone to relapses or recurrences of similar problems.

Epidemiology. Epidemiologic inquiry is often very productive. Inquiry is necessary about *high-risk sexual activity* in screening for HIV infection, *travel* in determining exposure to parasitic infections, and *intravenous drug abuse* for estimating risk of endocarditis and viral hepatitis. Less obvious factors, such as *animal contacts*, may be of great importance. Vectors of infection can be found even among household pets, such as cats (cat-scratch disease and *Pasteurella multocida* cellulitis from bites or scratches, toxoplasmosis from fecal contamination), parakeets (psittacosis), and turtles (salmonellosis). A history of *bites* by stray dogs, skunks, or bats may suggest the possibility of rabies. Animal contacts can also provide exposure to insect vectors such as *ticks*. *Homelessness* places patients at great risk for a host of infectious etiologies, including tuberculosis, HIV infection, viral hepatitis, right-sided endocarditis from intravenous drug abuse, and even louse-borne infections such as the one caused by *Bartonella quintana*, the notorious organism responsible for trench fever in World War I.

An inquiry into what is "going around" in the *community* may be helpful. A very localized outbreak of a flulike illness or atypical pneumonia may be a clue to *Legionella* infection (see Chapter 52). Being exposed to or part of a *population with a high incidence* of tuberculosis (see Chapter 49), HIV infection (see Chapter 13), or viral hepatitis (see Chapter 70) raises the risk of contracting the infection. Intravenous drug abusers are at notoriously high risk for such conditions, in addition to bacterial endocarditis. The patient's *occupation* is also sometimes revealing. For example, abattoir workers may be exposed to brucellosis, leather workers to anthrax, and gardeners to sporotrichosis.

Symptomatology may serve to pinpoint the site of infection. *Localizing symptoms* should be sought. They include rash, headache, cranial tenderness, sinus discomfort, ear pain, toothache, sore throat, tender thyroid gland, breast mass or tenderness, pleuritic chest pain, cough, dyspnea, abdominal pain, flank pain,

dysuria, vaginal discharge, pelvic pain, anorectal or perineal discomfort, testicular pain, bone pain, joint swelling, joint stiffness or pain, calf or vein tenderness, neck stiffness, focal neurologic deficit, and alteration in consciousness. The *pattern of fever* can be useful diagnostically; periodicity suggests parasitic etiologies and Hodgkin's disease.

Medications. A full review of all drug use and any substance abuse (see Chapter 235) is essential. Is the patient taking any medications that may be responsible for fever as a manifestation of hypersensitivity? Does the patient have any drug allergies? Has the patient been taking antibiotics, which can alter susceptibility to infection by favoring drug-resistant organisms or mask infection by rendering the patient culture-negative? Is there an underlying problem (e.g., renal failure) that may alter the choice of therapeutic agents and lead to the use of a less common agent?

Physical Examination

Vital signs should be determined in all cases. Fever is an important but nonspecific sign of infection; some patients with infections are afebrile, whereas others may have a fever resulting from noninfectious causes, such as hypersensitivity states and lymphoreticular malignancies. The shaking chill or rigor may suggest bacteremia, but it is also not specific. In the neonate or in occasional adults with overwhelming sepsis, hypothermia may be present. Respiratory distress may signal pulmonary infection or septic shock, and hypotension may be the presenting finding leading to a diagnosis of sepsis.

The *skin and mucous membranes* may provide crucial information. To cite a few examples: Petechial eruptions on the skin suggest meningococcemia or Rocky Mountain spotted fever, and those at the junction of the hard and soft palate occur with infectious mononucleosis. Pustular lesions raise the question of gonococcemia (see Chapter 137) or staphylococcal endocarditis. Splinter hemorrhages and conjunctival petechiae herald endocarditis. Ecthyma gangrenosa is a hallmark of *Pseudomonas* septicemia. Macular or vesicular eruptions occur with viral infections, and bullae with *Vibrio vulnificus* infection. Erythema chronicum migrans is an important sign of Lyme disease.

The *sinuses* should be percussed for tenderness and transilluminated for evidence of sinusitis. In the elderly, the *scalp* is palpated for the tender arteries of cranial arteritis. The optic *fundi* are examined for the retinopathy of connective tissue disease (see Chapter 146), the Roth spots of endocarditis, and the choroidal tubercles of miliary tuberculosis and *Candida* septicemia. The *tympanic membranes* should be examined for effusion and erythema, and the oral cavity for tonsillar pathology, tooth abscess, and salivary gland tenderness. The *neck* is checked for thyroid gland tenderness and local adenopathy. Careful examination of all the *lymph nodes* for enlargement may provide a very important clue to etiology, as might the distribution of the adenopathy (see Chapter 12).

The *breasts* are examined for masses, tenderness, and nipple discharge. The *chest* is noted for rubs and signs of consolidation and effusion. A careful *heart* examination for murmurs and rubs is essential. The *abdomen* is checked for organomegaly, masses, tenderness, guarding, rebound, and tenderness of the costovertebral angle.

The *genitorectal area* is all too frequently overlooked, yet it is often a source of key information. The woman without an obvious source of fever must have a careful pelvic examination with a search for cervical discharge, adnexal tenderness, and mass lesions (see Chapter 114). In men, the prostate and testicles need to be checked gently for tenderness and masses and the penis for discharge and rash (see Chapter 136). The rectal examination should include evaluation for discharge, tenderness, and masses (see Chapter 66), and the stool should be tested for occult blood.

Musculoskeletal examination may suggest inflammation or infection of the bone or joints if swelling, increased warmth, or tenderness is present. The *lower extremities* are examined for evidence of phlebitis (asymmetric swelling, calf tenderness, palpable cord). The *neurologic evaluation* should include a look for signs of meningeal irritation, the presence of focal deficits, and disturbances in mentation.

Laboratory Studies

If the history and physical examination findings provide strong indications of an infectious process, laboratory studies can be used selectively to confirm or refute the clinical diagnosis. For example, in the patient with an obvious viral upper respiratory infection, no studies are necessary. In patients with bronchitis, a sputum smear and culture may be all that is required, but if pneumonia is a possibility, a chest radiograph and complete blood cell count (CBC) are minimal additional requirements (see Chapter 52). In the patient with probable lower urinary tract infection, a urinalysis and perhaps a culture may suffice, but if there is concern about upper tract infection, especially as a complication of obstruction, then renal function tests, blood cultures, renal ultrasonography, and intravenous pyelography deserve serious consideration (see Chapter 133).

In other patients, however, more extensive tests are needed to establish a diagnosis when the cause of fever remains unknown. Although such studies must be individualized, the approach to the diagnosis of an obscure fever should include the following.

Complete Blood Cell Count, Differential, and Sedimentation Rate. Leukocytosis and a "shift to the left" suggest but do not prove bacterial infection. Toxic granulations, Döhle's bodies, and vacuoles in polymorphonuclear leukocytes are suggestive of bacterial sepsis but are not entirely specific. In most instances, the erythrocyte sedimentation rate (ESR) lacks the sensitivity and specificity needed for it to serve as an adequate means of detecting or ruling out such causes of fever as tumor, connective tissue disease, and infection. Although a very elevated ESR is an invitation to additional testing and may be a clue to a specific process such as temporal arteritis (see Chapter 161), many elevations are a consequence of trivial conditions unrelated to the cause of fever. The ESR should be ordered and interpreted cautiously and not viewed as a screening test for "disease."

Urinalysis. Pyuria strongly suggests urinary tract infection. Gram's stain of the unspun urine specimen can be diagnostic (see Chapter 127). Isolated hematuria may be a clue to an underlying glomerular disease or urinary tract malignancy, such as hypernephroma, which is notoriously difficult to diagnose early and a classic FUO etiology.

Radiographic Studies. *Chest radiographs* may detect infiltrates, effusions, masses, or nodes even in the absence of abnormalities on physical examination, whereas *kidney–ureter–bladder* (KUB) and upright abdominal films can disclose air–fluid levels in the bowel. *Ultrasonographic* or *computed tomographic* (CT) study may be needed if a mass lesion is suspected, such as an abscess or tumor (see below). *Plain films of bone* will show diagnostic changes of osteomyelitis after 10 to 14 days; for earlier diagnosis, consider *radionuclide bone scanning and magnetic resonance imaging* (MRI).

Blood Chemistries. The blood sugar determination is helpful in a search of previously unsuspected diabetes mellitus. The test is also important in evaluating the significance of the sugar concentration in various body fluids. Liver function tests are useful in helping to define obscure sources of fever. For example, transaminase elevation suggests hepatitis, and isolated rises in alkaline phosphatase point to infiltration of the liver.

Examination of Body Fluids. If there is any possibility of meningitis, a lumbar puncture is mandatory. Aspiration and study of pleural effusions, ascitic fluid, or joint effusions may be diagnostic. Such specimens should be examined directly by cell counts and stains (see below). Sugar and protein determinations help differentiate etiologies; in general, bacterial, mycobacterial, and fungal infections produce low sugar and high protein levels in body fluid.

Cultures. If the patient has a heart murmur or a prosthetic heart valve or other implantable device, or if the patient appears seriously ill, *blood cultures* should be obtained. Having three sets of two blood cultures from separate venipunctures maximizes test sensitivity. Most patients should have cultures taken of *urine* (clean catch or catheterized specimen) and *sputum*. If other body fluids are obtainable, they should likewise be cultured. Special mycobacterial and fungal media are required for culturing if the patient is a compromised host or has undergone prolonged antibiotic therapy. Anaerobic cultures are important when one is dealing with a possible abscess or other infection of the pulmonary, gastrointestinal, or pelvic regions.

Microscopic Evaluation. Any body fluid that can be obtained should be examined by the *Gram's stain* technique. Sputum, urine, wound exudates, cerebrospinal fluid, pleural fluid, ascitic fluid, and joint fluid often reveal the cause of infection on Gram's stain. Even Gram's stains of the stool may be helpful in certain specific situations, such as acute diarrhea (see Chapter 64). The presence of bacteria in a specimen of body fluid that is normally sterile is presumptive evidence of infection. This is particularly true when one is examining the spun sediment obtained from cerebrospinal fluid. Likewise, bacteria are not found in normal ascitic, joint, or pleural fluid. The presence of bacteria in unspun urine correlates well with significant urinary tract infection. However, Gram's stains must be examined and interpreted with a certain amount of caution. For example, if one sees epithelial cells in a sputum specimen, one can be certain that the specimen contains mouth organisms and is not representative of conditions in the tracheobronchial tree. In such instances, one should obtain a better sputum sample. In the presence of bacterial pneumonia, the sputum usually contains many polymorphonuclear leukocytes and a large number of bacteria. *Acid-fast stains* are required to visualize mycobacteria (see Chapter 49),

and specially stained *wet mounts* of body fluids can be useful in uncovering numerous types of fungal infections.

Immunologic Studies. In selected instances, serologic testing for evidence of infection can be of great help. Examples include suspected HIV infection [*enzyme-linked immunosorbent assay* (ELISA) and *Western blot testing* (see Chapter 13)], rheumatic fever and other streptococcal infections (*anti-DNAase B titers*), infectious mononucleosis (*heterophile test*), and salmonella (*Widal titers*). Skin tests (especially the *tuberculin test*) can provide confirmatory evidence and need to be considered when clinical findings are suggestive. Testing for *antinuclear antibody* and *rheumatoid factor* may help in the diagnosis of a suspected vasculitis or rheumatoid disease. The presence of rheumatoid factor or immune complexes can be clues to "culture-negative" endocarditis or underlying connective tissue disease (see Chapter 146). In the diagnosis of obscure fevers, it is often useful to freeze and save an "acute-phase serum" for later comparison with a "convalescent serum."

The Febrile Patient without a Diagnosis

Although an enormous number of studies are available for the evaluation of undiagnosed febrile illnesses, it is important to proceed with these in a logical, step-by-step fashion instead of subjecting the patient to a random series of expensive, time-consuming, uncomfortable, or even hazardous studies. The first step in the subsequent workup is to *document fever* by measuring rectal temperatures every 4 hours. If fever is documented, further evaluation should be directed to the most common causes of FUO, listed in Table 11.1. The history remains the best source of clues to the diagnosis. Although MRI and CT can confirm suspected etiologies, blindly ordering such expensive imaging studies is usually unnecessary and wasteful. In a study from the community hospital setting, the history, physical examination, and basic laboratory studies supplemented by serologic testing revealed the diagnosis in more than 85% of instances. In the United States and Europe, malignancy, infection, and connective tissue disease each account for a quarter to a third of cases. In developing nations, infection is the predominant cause. About 8% of cases are without a diagnosis after workup, but the cause is usually identified after a period of close follow-up.

Radiographic and Invasive Studies may be revealing, but they require careful selection. At times, a contrast study or radionuclide scan will reveal a source of fever. *Ultrasonography* is useful for noninvasively identifying pathology in the liver, gallbladder, pancreas, kidneys, and pelvis. *Abdominal CT* helps visualize a suspected source of fever in the retroperitoneum (e.g., lymphoma), upper abdomen (e.g., pancreatic or liver cancer), and large bowel (e.g., diverticular abscess). *Bone scan* or *MRI* may localize an abscess or malignancy that has invaded bone; MRI is the more sensitive test to detect early disease. *Bone marrow* or *liver biopsy* may detect a granulomatous or neoplastic process. A *lumbar puncture* is unlikely to help unless nuchal rigidity or neurologic abnormalities are present. A blind *laparotomy* is not performed unless clear clues to intraabdominal abnormalities are present that cannot be evaluated with less invasive procedures.

Therapeutic Trials. Only in the acutely ill, toxic patient is it necessary to begin broad antibiotic coverage before the diagnosis is established. It is essential, although commonly forgotten, to obtain cultures of blood, urine, and other pertinent fluids before treatment is initiated, so that rational decisions can be made later concerning therapy. In the nontoxic patient with an acute febrile illness and in the person with a true FUO, blind therapeutic trials are rarely helpful and are often confusing or even harmful. In this context, it is useful to remember one definition of empiric therapy: what the ignorant do to the helpless. In occasional patients with FUO, therapeutic trials may be necessary. If it has not already been done, the simplest trial is to halt all but the most essential of medications. Other trials include administration of IV antibiotics for suspected culture-negative endocarditis, combinedchemotherapy for occult tuberculosis, or salicylates or steroids for noninfectious inflammatory disease. Such trials should always be conducted with a specific end point or time limit in mind, carefully planned observations, patient consent, and a mixture of humility and trepidation.

The Second Look. Despite the array of sophisticated technology available for the study of febrile illnesses, the history and physical examination remain the keys to diagnosis in most cases. Time can be a most valuable diagnostic tool. Unless the patient is progressively deteriorating, it may be advisable to interrupt the workup for a period of clinical observation, possibly with the aid of symptomatic therapy such as antipyretics. A second look, beginning with the history and physical examination, may then be fruitful.

Unexplained Fever in High-risk Patients (with HIV Infection or Cancer). The risk for infection is markedly increased in patients with HIV infection (especially when CD4+ cell counts fall below 100/cm^3) and in those with cancer complicated by neutropenia. Opportunistic organisms dominate the list of causes (Table 11.2). A careful history and physical examination remain the cornerstone of assessment. When the cause remains unclear, laboratory testing should include blood cultures for bacteria, fungi, and mycobacteria. If blood cultures are negative but the suspicion of mycobacterial and fungal infection persists, then liver and bone marrow biopsies with cultures are indicated. Serum cryptococcal antigen testing provides a sensitive means of identifying disseminated infection. In cancer patients, unexplained fever also suggests dissemination of malignancy. Chest CT with contrast can be useful when intrathoracic spread (including involvement of mediastinal lymph nodes) is a concern, and abdominal CT with contrast can help detect spread to the liver and retroperitoneal nodes. Lymph node enlargement should trigger consideration of node biopsy.

SYMPTOMATIC THERAPY

The best therapy is obviously to treat the underlying cause. However, antipyretic therapy may provide comfort and prevent complications. The first issue, of course, is to determine if fever should be treated. An elevated temperature itself does not necessarily call for therapy. However, if unpleasant symptoms are pres-ent, the patient has a limited cardiac reserve, or the complications of fever are imminent, antipyretics should be administered. Antipyretic therapy depends on the use of both chemical agents and physical methods. The most effective antipyretic drugs are the *salicylates* and *acetaminophen*; both appear to act on the hypothalamus to lower the thermal set point. Although parenteral salicylates are available, oral or rectal administration of either aspirin or acetaminophen is preferable. Doses of up to 1.2 g of either drug may be given to adults to initiate antipyretic therapy. In addition to their intrinsic toxicities, it must be remembered that both aspirin and acetaminophen occasionally produce an exaggerated response, with hypothermia and even dangerous hypotension. Patients with typhoid fever or Hodgkin's disease and elderly and debilitated patients seem to be at somewhat greater risk for this uncommon complication.

Physical cooling is also extremely effective. At the simplest level, undressing and exposing the patient to a cool ambient temperature will allow cooling by radiation; a bedside fan will promote cooling by convection also. Sponging with cool water or alcohol is helpful and promotes evaporation. With extreme elevations (>106°F), more drastic measures are necessary and hospitalization is urgent. *Immersion in an ice water bath* is the most efficient of these methods and may be indicated in hyperthermic emergencies, such as heat stroke. All methods of physical cooling present the risk for hypothermic overresponse and should therefore be discontinued when the body temperature begins to fall below critical levels.

Hyperthermic emergencies are rare, but fever is common and most often presents as an unpleasant symptom rather than a medical crisis. It seems appropriate, therefore, to conclude with a comment about patient comfort. Although fever causes discomfort in most patients, physical cooling produces discomfort in virtually all of them; often, the treatment is remembered as far worse than the illness itself. As a result, these measures should be employed only when fever itself presents medical problems. The same is true to a lesser extent of aspirin and acetaminophen. In particular, many patients find rapid rises and falls of temperature very distressing; therefore, administering antipyretics every 4 hours for the first day or two of treatment may be preferable to waiting for the fever to spike.

INDICATIONS FOR ADMISSION

The very toxic or vulnerable patient (Table 11.2) should be admitted promptly for aggressive study, monitoring, and consideration of means to lower temperature. In cases of weight loss and debilitation, early hospitalization should also be considered. Moreover, when fever remains elevated above 101°F for weeks and ambulatory diagnostic efforts have been unsuccessful, it is often beneficial to bring the patient into the hospital for closer evaluation and documentation of fever; the advice of an infectious disease consultant can be helpful.

PATIENT EDUCATION

Whenever fever is suspected in the ambulatory setting, the patient should be instructed to keep a record of temperatures, preferably rectal, taken each evening, when elevations are most likely to occur. The patient needs to be reassured that there is nothing abnormal about temperatures in the range of 97.0°F to 99.3°F.

CHAPTER 12 EVALUATION OF LYMPHADENOPATHY

HARVEY B. SIMON

Of the nearly 600 lymph nodes throughout the body, only a few are normally palpable, including small nodes in the submandibular, axillary, and inguinal regions. Nevertheless, lymphadenopathy is a very common presenting symptom. Most often, adenopathy indicates benign, self-limited disease; this is particularly true in children and young adults, who are more prone to reactive lymphatic hyperplasia. Despite this, patient concern is often substantial because of worry about serious infectious processes (e.g., AIDS) on the one hand and neoplastic diseases on the other. A systematic evaluation of lymph-adenopathy will provide both reassurance and a correct diagnosis. A critical decision for the primary physician is when to refer the patient for a lymph node biopsy.

PATHOPHYSIOLOGY AND CLINICAL PRESENTATION

Localized Adenopathy. Small lymph nodes in the neck, axilla, and groin may be palpable in normal individuals. Palpable nodes in other regions or any node exceeding 1 cm in size should be regarded as potentially abnormal. Inflammation and infiltration are responsible for pathologic enlargement. Although size alone is not itself diagnostic, nodes *larger than 3 cm* suggest neoplastic disease. Localized lymphadenopathy may represent spread of disease from an area of drainage. Of particular importance are palpable supraclavicular nodes. The left one, sometimes referred to as the *"sentinel" node*, is in contact with the thoracic duct, which drains much of the abdominal cavity. The right supraclavicular node drains the mediastinum, lungs, and esophagus.

Hilar Adenopathy. Bilateral hilar adenopathy encountered as an incidental finding on a chest radiograph in an otherwise asymptomatic patient is likely to be caused by *sarcoidosis*. In about 80% of such cases, the adenopathy will resolve spontaneously. In areas endemic for fungal infection, asymptomatic bilateral hilar adenopathy may result from *coccidiomycosis* or *histoplasmosis*. *Lymphoma* and *bronchogenic carcinoma* can cause bilateral hilar adenopathy, but the patient is rarely asymptomatic at the time of presentation. The same pertains, although to a lesser degree, to primary *tuberculosis*.

Unilateral hilar adenopathy is most often a manifestation of lymphoma or bronchogenic carcinoma, although granulomatous diseases may also present in this fashion.

Generalized Lymphadenopathy results from systemic processes, such as infection, malignancy, hypersensitivity, and sometimes even metabolic disease with node infiltration. The adenopathy associated with infection may be caused by the disease itself (e.g., *HIV* infection) or to secondary infection (e.g., with *cytomegalovirus*). It may result from an illness that first produces localized adenopathy (e.g., *cat-scratch disease*). At the intersection of neoplastic and reactive lymphadenopathy is *Castleman disease*, a rare idiopathic atypical lymphoproliferative disease that can be localized or multicentric. Its clinical presentation can mimic that of lymphoma and HIV disease. Localized disease has a benign clinical course, but multicentric disease produces disseminated lymphadenopathy, systemic symptoms, and an increased risk for infection and cancer.

Other Lymphatic Abnormalities. In addition to lymphadenopathy, abnormalities of the lymphatic system may present in other ways. *Lymphangitis*, appearing as red, warm streaks along the course of superficial lymphatic networks, suggests an acute inflammatory response to pyogenic infection in the drainage area; staphylococci and streptococci are frequently responsible. *Lymphadenitis*, presenting as a tender, warm, soft, rapidly enlarging node, has a similar significance and often reflects acute pyogenic infection of the node itself. An idiopathic variant, necrotizing lymphadenitis (*Kikuchi's disease*), causes self-limited tender cervical adenopathy. *Lymphedema* results from the interruption of lymphatic drainage; surgical node dissection, radiotherapy, or fibrosis caused by chronic infections such as filariasis or lymphogranuloma venereum are causes of lymphedema.

DIFFERENTIAL DIAGNOSIS

The causes of lymphadenopathy can be conveniently considered in terms of location of the enlarged nodes (Table 12.1). In children and young adults, most adenopathy is a result of reactive hyperplasia and is less likely to represent serious pathology than it is in adults. In persons under the age of 30, the cause proves to be benign in 80% of cases; in persons over age 50, the rate of benign disease falls to 40%.

Table 12.1. Important Causes of Lymphadenopathy

WORKUP

History and Physical Examination

A number of basic questions arise in the evaluation of lymphadenopathy that can be readily addressed by a careful history and physical examination:

1. Is the palpable mass indeed a lymph node? A variety of other structures, including enlarged parotid glands, cervical hygromas, thyroglossal and branchial cysts, hemangiomas, abscesses, lipomas, and other tumors, may on occasion be confused with lymphadenopathy.
2. Is the lymphadenopathy acute or chronic? Clearly, lymph node enlargement resulting from acute viral or pyogenic infection becomes less likely as the days and weeks pass, and granulomatous inflammation (sarcoidosis, tuberculosis, fungal infection) and neoplastic disease become greater worries. Even so, chronicity alone is not always a harbinger of serious disease, for on occasion reactive hyperplasia can persist for many months.
3. What is the character of the enlarged node itself? Tender, mobile nodes most often reflect lymphadenitis or lymphatic hyperplasia in response to acute inflammation. Firm, rubbery, nontender nodes may be found in lymphoma. Painless, stone-hard, fixed, matted nodes suggest metastatic carcinoma.
4. Is the adenopathy localized or generalized? Numerous systemic processes that include *infections* (e.g., infectious mononucleosis and other viral infections, toxoplasmosis, secondary syphilis), *hypersensitivity reactions* [serum sickness, reactions to phenytoin (Dilantin) and other drugs, and vasculitis, including systemic lupus erythematosus and rheumatoid arthritis], *metabolic diseases* (hyperthyroidism and various lipidoses), and *neoplasia* (especially leukemia) can produce generalized lymphadenopathy. However, Hodgkin's disease is usually unicentric in origin and spreads to contiguous regional nodes, so that generalized adenopathy is rare except in very advanced disease. Although certain non-Hodgkin's lymphomas may be multicentric, generalized adenopathy is also a late finding and is usually asymmetric, unlike the earlier and more symmetric adenopathy of some leukemias, such as chronic lymphocytic leukemia.

Generalized adenopathy, particularly if accompanied by weight loss, fever, or other constitutional symptoms, should raise the question of *AIDS* or HIV infection.

Male homosexuals, IV drug abusers, hemophiliacs and other multiply transfused individuals, and Haitians are at particular risk (see Chapter 13).

Localized adenopathy should raise additional possibilities, depending on the area involved. For example, *submandibular* lymphadenopathy, which is perhaps the most common type of adenopathy, frequently results from pharyngitis (viral, streptococcal, gonococcal) or head and neck or intraoral infection. Although these benign processes vastly predominate, it should be remembered that patients with Hodgkin's disease most often present with cervical lymphadenopathy. *Preauricular* adenopathy may be a component of "occuloglandular fevers" resulting from adenoviral conjunctivitis, sarcoidosis, tularemia, cat-scratch disease, and other processes. *Posterior auricular* or *posterior cervical* adenopathy frequently reflects infections of the scalp but may also be prominent in systemic processes, such as rubella or toxoplasmosis.

Whereas *anterior cervical* lymphadenopathy often results from head and neck infections, isolated supraclavicular node enlargement is more indicative of metastatic malignancy; the *right supraclavicular* nodes drain the mediastinum, esophagus, and thorax, and *left supraclavicular* adenopathy (Virchow's node) is suggestive of primary intraabdominal neoplasia. *Axillary* nodes become enlarged in response to infection of the upper extremities, but breast cancer must also be considered. Although enlarged *epitrochlear* nodes are traditionally associated with secondary syphilis, this finding reflects generalized lymphadenopathy in lues; epitrochlear lymphadenopathy can be seen in many other systemic processes and in response to hand infections. Inguinal lymphadenopathy is much more common. Inguinal nodes are palpable in most normal individuals, but they can enlarge substantially in infections of the genitalia or perineum, and in infections of the lower extremities.

Bilateral hilar adenopathy in an asymptomatic patient raises the possibilities of sarcoidosis and fungal exposure. Unilateral hilar disease suggests lymphoma, cancer, and granulomatous disease, as does bilateral disease in a symptomatic patient or one with abnormal physical examination findings.

5. Are there associated systemic or localizing symptoms or signs? Fever, rash, weight loss, sore throat, dental pain, genital inflammation, and infections of the extremities are clues that may be particularly helpful. Of these symptoms, night sweats and weight loss are suggestive of granulomatous and neoplastic disease. Ear, nose, and throat symptoms suggest reactive lymphatic hyperplasia secondary to viral or localized bacterial infection.

   A careful examination of the skin for a primary inoculation site may provide the clue to a diagnosis of cat-scratch disease or tularemia. A check for scalp infections, dermatophytes, and scabies is also needed. The liver and spleen are carefully examined; organomegaly may be an important clue for mononucleosis, sarcoidosis, or malignancy. Sternal tenderness may be present in leukemia.

6. Are there unusual epidemiologic clues? To cite a few examples, in patients exposed to cats, cat-scratch disease or toxoplasmosis, which can also result from eating poorly cooked meat, may develop. Travel to the southwestern United States may suggest the possibility of plague. An appropriate travel history or exposure to bird droppings may suggest fungal infection, as may lacerations sustained during gardening in the case of sporotrichosis. Contact with wild rodents can result in tularemia, as can tick bites. A history of exposure to tuberculosis may be an important clue to scrofula. More commonly, community outbreaks can provide clues to the diagnosis of streptococcal pharyngitis or rubella, whereas a history of sexual exposure may raise the question of gonorrhea, syphilis, genital herpes, or lymphogranuloma.

Laboratory Studies

Laboratory studies need not be very elaborate. A *complete blood cell count* with *differential* often provides useful information and is almost always indicated. For example, atypical lymphocytosis suggests mononucleosis, other viral infections, and toxoplasmosis; granulocytosis is indicative of pyogenic infection; eosinophilia raises the question of a hypersensitivity reaction; pancytopenia is consistent with marrow suppression by tumor and HIV infection.

Other studies are based on the clinical presentation of the lymphadenopathy. A variety of blood chemistries may help in selected cases. Elevations of *uric acid* may reflect lymphoma or other hematologic malignancies. *Serum liver chemistries* (especially the *alkaline phosphatase* level) provide objective parameters to follow. Although such abnormalities are nonspecific, they do suggest liver involvement, which can be further evaluated by biopsy.

Localized Adenopathy. If pharyngitis and cervical or submandibular adenopathy are present, a *throat culture* is mandatory. It should be remembered that although these specimens are routinely processed for streptococci, a special Thayer-Martin medium also must be used if gonococci are suspected. *Urethral* or *cervical cultures* and smears should also be obtained if gonorrhea is a potential cause of inguinal lymphadenopathy. *Blood cultures* are indicated in the rare cases of suspected plague, tularemia, or brucellosis or if the clinical picture suggests staphylococcal or streptococcal lymphadenitis. Biopsy may be necessary to rule out lymphoma and Hodgkin's disease if the adenopathy is progressive and the remainder of the workup is unrevealing (see below).

On occasion, lymphomatous retroperitoneal or intraabdominal nodes may enlarge enough to present as an abdominal mass. When lymphoma is a serious possibility, or when staging is necessary in known lymphoma or Hodgkin's disease, *abdominal computed tomography* (CT) can be used to detect enlargement of the retroperitoneal nodes; *bone marrow biopsy* may provide a tissue diagnosis (see Chapter 84).

Generalized Adenopathy. Serologic tests can be of great value. The *heterophile test* and *serologic tests for syphilis* are obvious examples. In addition, a serum sample from the acute phase of the illness can be frozen to be submitted with a later, convalescent-phase serum specimen for antibody titers against viruses, fungi, and toxoplasmosis. Brucellosis can also be diagnosed serologically. Serologic tests, including those for *antinuclear antibodies* and *rheumatoid factor*, may suggest a noninfectious process, such as collagen vascular disease.

Hilar Adenopathy. *Tuberculin skin testing* with purified protein derivative (PPD) and the *angiotensin-converting enzyme* (ACE) determination can facilitate the assessment. If the results of both are negative and the patient is white, then bronchoscopy and mediastinoscopy may be necessary to rule out lymphoma. If the patient is ACE-positive and PPD-negative, then the probability is very high that sarcoidosis is the cause, and there is little need for further evaluation. If the patient is ACE-negative and PPD-positive, then primary tuberculosis is likely. Reliable skin tests are also available for coccidioidomycosis and tularemia. On the other hand, cutaneous anergy may suggest sarcoidosis or lymphoma, but this is a nonspecific finding. Skin testing can be very helpful in the diagnosis of cat-scratch disease, but, as with the Kveim test, the necessary antigen is available only on a research basis in selected centers.

Among radiologic studies, the *chest radiograph* is particularly valuable because hilar adenopathy may be present in patients with enlargement of peripheral nodes. Hilar adenopathy may also be detected on chest radiograph in the absence of peripheral lymphadenopathy. Sarcoidosis, lymphoma, fungal infection, tuberculosis, or metastatic carcinoma (particularly from a lung primary) should be among the diagnostic considerations. *CT* can provide additional definition. *Mediastinoscopy* may be required for tissue diagnosis, although not in asymptomatic patients with bilateral hilar adenopathy and clear lung fields, who most likely have sarcoidosis or a fungal exposure.

Lymph Node Biopsy should be considered as the most direct approach to the diagnosis of lymphadenopathy. Although the majority of such procedures are technically easy and can be accomplished under local anesthesia, this is an invasive test that can sometimes prove nondiagnostic. It should be employed only when simpler approaches have failed to give a diagnosis and suspicion of a therapeutically important cause remains (e.g., tuberculosis, lymphoma, cancer, sarcoidosis, cat-scratch disease). Sometimes, careful *observation* for a period of time may be diagnostically useful before biopsy is undertaken. In many cases of benign lymphadenopathy, the nodes will regress spontaneously even if no etiologic diagnosis has been made. However, some lymphomas may regress transiently and simulate a more benign etiology.

If undiagosed adenopathy persists during a period of weeks to months, especially if the nodes are enlarging or if neoplastic disease remains a concern, then consideration of node biopsy is indicated. In one retrospective study, weight loss, night sweats, nodes larger than 2 cm, and abnormal chest radiographic findings were the strongest predictors of important disease before biopsy. In the case of fluctuant nodes, *needle aspiration* can be used to diagnose infectious processes in some cases.

The node to be sampled should be selected with care; if generalized adenopathy is present, it is best to avoid inguinal or axillary nodes if possible because reactive hyperplasia in these areas may make interpretation difficult. In general, enlarged *supraclavicular nodes* have the highest diagnostic yield. When possible, *excisional biopsy* is preferred. At the time of biopsy, tissue should be submitted for appropriate bacteriologic smears and cultures in addition to histologic study. Touch preparations may be useful. Special stains for bacteria, mycobacteria, and fungi may be helpful, as may specific stains for unusual processes, such as periodic acid–Schiff (PAS) stains for Whipple's disease or lipidosis and Congo red stains for amyloid. The interpretation of lymph node pathology can be quite difficult and requires careful study by experienced observers. With such study, benign processes such as toxoplasmosis or cat-scratch disease can be suspected histologically, and detailed analysis of serial sections may reveal lymphomas that are not diagnosed with less intensive pathologic study. Finally, if pathologic study reveals reactive hyperplasia or is nondiagnostic, patients should be followed carefully, as up to 25% may eventually exhibit an illness responsible for the lymphadenopathy, most often

lymphoma.

Evaluation of Lymphadenopathy in the HIV-infected Patient. In most patients who are HIV-positive, the lymphadenopathy represents follicular hyperplasia in response to HIV infection. However, the list of possible causes includes lymphoma, mycobacterial and viral infections, Kaposi's sarcoma, and other cancers (see Chapter 13). The principles for evaluation and biopsy are similar to those for the non-HIV patient, with the proviso that the probability of serious underlying pathology is increased. Suggested criteria for lymph node biopsy in these patients include a diameter greater than 2 cm, rapidly enlarging or asymmetric adenopathy, constitutional symptoms, and intrathoracic adenopathy on chest radiograph. When these rather restrictive criteria are used and needle aspiration is the mode of biopsy, yields of less than 50% have been reported, with most patients having follicular hyperplasia.

INDICATIONS FOR REFERRAL

Any patient suspected of harboring a malignancy should have a consultation with an oncologist or oncologic surgeon to consider further the need for biopsy and to determine the best approach to obtaining a tissue diagnosis. Simply arranging for the biopsy of an accessible node may fail to achieve a diagnosis and will subject the patient to an unnecessary invasive procedure. Consultation may also be useful if one is thinking about a period of observation and wants to be sure that this represents a reasonable approach.

CHAPTER 13 APPROACH TO THE PATIENT WITH HIV-1 INFECTION

STEPHEN L. BOSWELL

Despite the fact that a cure remains elusive, the management of the person infected with human immunodeficiency virus (HIV-1) has improved significantly in recent years. Most care is now conducted in the outpatient setting, even for patients with the acquired immunodeficiency syndrome (AIDS). Intervention in the asymptomatic period, new therapies, and innovative strategies to prevent secondary infections have significantly decreased morbidity and increased survival. With the shift in management to the outpatient setting, primary care physicians have assumed an increasingly central role in the comprehensive care of the patient infected with HIV-1; they are responsible for initial diagnosis, counseling, prevention of spread, initiation of antiviral and prophylactic therapies, outpatient treatment of secondary infection, determination of need for hospitalization, and provision of supportive care in the late stages of illness. This requires that the primary care physician be knowledgeable about HIV-1 risk behaviors, disease manifestations, laboratory techniques, current therapy, and prophylaxis strategies. It is recommended that an expert be involved in the care of all those who are infected with HIV-1. This can be accomplished by an expert primary care clinician or by an expert consultant.

CASE DEFINITION AND EPIDEMIOLOGY OF HIV-1 INFECTION AND AIDS

Case Definition. The Centers for Disease Control and Prevention (CDC) criteria for *HIV-1 infection* in patients older than 13 years of age include the following:

- repeatedly reactive results on screening tests for HIV-1 antibody, with specific antibody identified by the use of supplemental tests, *or*
- direct identification of virus in host tissues by virus isolation, *or*
- detection of HIV-1 antigen, *or*
- a positive result on any other highly specific licensed test for HIV-1.

In 1993, the CDC revised the criteria for the *definition of AIDS* to incorporate clinical presentations in women and heterosexuals and advances in understanding the significance of counts of CD4+ lymphocytes (also known as helper T lymphocytes or CD4 cells). This CDC surveillance definition of AIDS requires the following:

- a CD4+ T-lymphocyte count below 200/mm^3 and laboratory evidence of HIV-1 infection, *or*
- presence of an AIDS-indicator disease, *or*
- presence of pulmonary tuberculosis, recurrent pneumonia, or invasive cervical cancer in a patient with laboratory evidence of HIV-1 infection, *and*
- absence of another reason for immune impairment.

Epidemiology. HIV-1 infection is a pandemic. It has become the world's leading infectious cause of death, a position previously held by tuberculosis. In 1998 alone, an estimated 2.3 million people died of AIDS-related causes worldwide. It has moved to this position from relative obscurity when five cases of AIDS were reported in Los Angeles in 1981. HIV-1 is spreading most rapidly in Asia, with more than 5 million cases estimated. The epidemic continues to expand in South America but appears to have slowed significantly in North America and Europe. In developing countries, the virus is spread primarily through heterosexual contact and affects males and females on a more equal basis than in Western countries.

In the United States, between 800,000 and 900,000 Americans are now infected with HIV-1, and the numbers continue to rise. Despite this fact, the death rate from AIDS has dropped significantly in most Western countries in the past several years. This is attributable to significant improvements in medical treatment. The African-American and Hispanic communities are increasingly affected. The epidemic appears to have plateaued in the gay population. The incidence of HIV-1 infection continues to rise in injection drug users, women, and persons who have acquired HIV-1 through heterosexual contact.

In the United States, those at highest risk for infection are men with a history of *homosexual* or *bisexual* activity; *IV drug users* and their sexual contacts; the *sexual contacts* of homosexual or bisexual men; persons who received *blood and blood products before 1985*; and *children* born to infected women. The risk for directly acquiring HIV-1 infection through processed blood or selected blood products (plasma and clotting factor concentrates) has dramatically decreased since 1985 as a consequence of the widespread screening of those who donate blood and plasma, the use of serologic tests for HIV-1, and the viral inactivation of various plasma products.

AIDS is only part of the much larger epidemic of HIV-1 infection. For every person who is living with AIDS in the United States, four to five people are infected with HIV-1 but have minimal or no symptoms. They often present to health care providers for problems related to high-risk activity (e.g., IV drug use), unaware they are carrying HIV-1. These encounters provide a critical opportunity to teach about HIV-1 infection.

PATHOPHYSIOLOGY, CLINICAL PRESENTATION, AND COURSE

Pathophysiology

The *human immunodeficiency virus* is an RNA retrovirus that includes a core protein (p24), a reverse transcriptase, an HIV-1 protease, and envelope glycoproteins. Isolates of HIV-1 differ genetically and antigenically, particularly in regard to envelope proteins (a feature that has complicated the development of an effective vaccine).

HIV-1 is transmitted through *sexual contact, parenteral exposure* to blood and selected blood products, and *maternal transmission* (via breast milk and perinatal transmission). Once the virus enters the body, it attaches to the surface of *CD4+ T lymphocytes*. These helper T lymphocytes are the target of HIV-1, by virtue of the affinity of the virus for receptors on their surface. Once attached, the virus enters the lymphocyte and uncoats. Its RNA is transcribed to DNA by reverse transcriptase. The DNA may remain in the cytoplasm or become integrated into the host cell genome, where it can remain latent until some stimulus triggers replication of virus.

Ten billion viral particles are produced in an infected person each day. Most of these viral particles are produced by activated CD4+ lymphocytes, which are killed when the virus enters the lytic stage of infection. These cells are central to maintaining immunocompetence. With damage to the CD4-cell population, patients are at increased risk for clinical manifestations directly associated with the disease, including HIV encephalopathy and HIV-1–associated wasting. As HIV-1 infection progresses, the risks for opportunistic infections and neoplasm increase. Death occurs most frequently because of wasting, opportunistic infection, or neoplasm.

Clinical Presentations and Course

HIV-1 infection in humans is a continuum that can be crudely broken into four phases: (a) primary HIV-1 infection, (b) asymptomatic infection, (c) symptomatic HIV infection, and (d) AIDS. The rate of disease progression varies from person to person and appears to depend on both viral and host factors. In general, the use of antiretroviral therapy and chemoprophylaxis of opportunistic infection have a profound effect on the pace of disease progression.

Primary Infection. The first, brief phase of the illness is a *mononucleosis-like syndrome.* In the initial years of the epidemic, the syndrome was not recognized, but after the development of serologic tests, it became possible to link it to HIV-1. The syndrome consists of fever, sweats, lethargy, malaise, myalgias, arthralgias, headaches, photophobia, diarrhea, sore throat, lymphadenopathy, and a truncal maculopapular rash. It is of sudden onset and lasts 3 to 14 days. More than 50% of individuals infected with HIV-1 experience one or more of these symptoms. Less frequently, neurologic signs and symptoms occur, such as those of meningoencephalitis, myelopathy, peripheral neuropathy, and Guillain-Barré syndrome. The most common neurologic symptoms in primary HIV-1 infection are headache and photophobia. The symptoms that most markedly differentiate seroconversion subjects from control subjects are *swollen lymph nodes*, truncal or

generalized *rash, depression*, irritability, anorexia, *weight loss*, and *retroorbital* pain. Unfortunately, these symptoms are not specific for primary HIV-1 infection.

Asymptomatic Seropositivity. The second phase of HIV-1 infection is the longest of the four phases and also the most variable. It typically lasts *4 to 7 years* and is distinguished by the lack of overt evidence of HIV-1 infection.

Symptomatic Seropositivity (Pre-AIDS). The onset of the third phase of HIV-1 infection ushers in the first physical evidence of immune system dysfunction. *Persistent generalized lymphadenopathy* is often an early sign of this phase. *Localized fungal infections* of the toes, fingernails, and mouth frequently occur. Among women, recalcitrant *vaginal yeast* and *trichomonal infections* often recur. *Oral hairy leukoplakia*, one of the most commonly missed signs of HIV-1 infection, is very prevalent and typically found on the tongue. Cutaneous manifestations of this phase of illness include widespread *warts, molluscum contagiosum*, exacerbations of *psoriasis*, and *seborrheic dermatitis*. Multidermatomal *herpes zoster* and an increased severity or frequency of *herpes simplex* infections can occur. Constitutional symptoms, including *night sweats, weight loss*, and *diarrhea*, are often seen. Without treatment, the duration of this phase is typically 1 to 3 years.

Symptomatic Seropositivity (AIDS) is characterized by significant immune suppression, which leads to the development of disseminated opportunistic infections and unusual malignancies. Pulmonary, gastrointestinal, neurologic, and systemic symptoms are common.

Pneumocystis carinii pneumonia (PCP) is among the most common infections in AIDS patients, with an attack rate of almost 80% in patients not receiving primary prophylaxis (see below). Fever, night sweats, malaise, and weight loss typically precede the onset of pulmonary symptoms by days to weeks. A dry cough may be the first pulmonary manifestation, followed by shortness of breath. Diffuse infiltrates on chest radiographs, a widening alveolar–arteriolar oxygen gradient (>30 mm Hg), and a low partial pressure of oxygen (<50 mm Hg) are associated with reduced survival.

Pulmonary and disseminated forms of invasive fungal infection with *Cryptococcus neoformans, Histoplasma capsulatum*, and *Coccidioides immitis* are other hallmarks of AIDS. Cryptococcal infection occurs throughout the United States and often presents subtly, with headache, fever, and malaise. Altered mentation and stiff neck are absent in most cases. At times, pulmonary complaints dominate the clinical picture of cryptococcal infection. Pulmonary and systemic complaints are prominent in patients with histoplasmosis or coccidioidomycosis. Infiltrates on the chest film of a patient living in an endemic area suggest the diagnosis; splenomegaly can be marked in histoplasmosis.

Mycobacterial infections, both pulmonary and disseminated, are consequences of falling CD4-cell counts. HIV-1–seropositive patients with latent tubercular infection are at increased risk for reactivation and dissemination. Meningeal involvement is the most common form of disseminated disease. Many strains isolated from AIDS patients demonstrate multiple-drug resistance (see Chapter 49). *Mycobacterium avium–intracellulare* infection is an accompaniment of very advanced disease. The clinical presentation is one of wasting, fever, sweats, diarrhea, and weight loss. Blood cultures are often positive.

Recurrent bacterial pneumonia (two or more episodes per year) is a more recently appreciated manifestation of AIDS. The presentations and organisms are typical of bacterial pneumonia, with positive sputum cultures and infiltrates on chest radiograph. Such cases of pneumonia are 20 times more common in HIV-1 patients with low CD4-cell counts (<200/mm^3) than in those with normal counts. The recurrent development of such cases of pneumonia represents significant immunosuppression.

Cytomegalovirus (CMV) infection, often a reactivation of latent disease, is common in AIDS. *Retinitis*, presenting as unilateral visual loss or floaters and, if untreated, progressing to bilateral disease and blindness, afflicts about 5% to 10% of AIDS patients. Exudates and hemorrhages are noted on funduscopic examination. Esophagitis, gastritis, and colitis also may develop.

Enteric infections cause considerable morbidity in AIDS patients and typically present as weight loss, cramping pain, and large-volume diarrhea. *Salmonella, Shigella*, and *Campylobacter* are the leading causes, infection with the latter two more characteristically presenting with bloody diarrhea and leukocytes on Wright's stain of a fecal smear. *Cryptosporidium*, a protozoan, is an important cause of diarrhea in AIDS patients in undeveloped areas.

HIV-1 wasting syndrome is characterized by the profound involuntary loss of more than 10% of body weight in conjunction with either chronic diarrhea (two or more stools per day for more than 1 month) or fever and persistent weakness for a similar period in the absence of another cause.

Neurologic injury from HIV-1 infection ranges from mild *peripheral neuropathy* causing paresthesias to *encephalopathy* with debilitating dementia. The virus appears to be neurotropic, causing significant neurologic injury in up to 30% of AIDS patients. *AIDS dementia complex* results from direct injury to neurons from HIV-1 invasion of the central nervous system (CNS). Early on, there may be only minor impairment of cognitive or motor function, but in later stages, frank dementia and disabling motor disturbances ensue. Neuroimaging studies may show diffuse atrophic changes.

Opportunistic CNS infections also occur. *Toxoplasmosis* is one of the most common. Most *Toxoplasma gondii* disease represents reactivation of latent infection. About one third of those who are seropositive for immunoglobulin G experience reactivation. CNS involvement can cause symptoms both of a mass lesion (discrete deficits, headache) and of encephalitis (fever, altered mental status). The images on scanning by computed tomography (CT) or magnetic resonance imaging (MRI) are characteristic: multiple (more than three) contrast-enhanced mass lesions in the basal ganglia and subcortical white matter.

Syphilis is of increased likelihood in HIV-1 patients with a history of high-risk sexual behavior, and it may take an atypical or accelerated course, including CNS spread.

Malignancies are a consequence of the reduction in cellular immunity. *Kaposi's sarcoma*, non-Hodgkin's lymphoma, and primary CNS lymphoma occur with greatly increased frequency in the setting of HIV-1 infection and serve to define the onset of AIDS. Kaposi's sarcoma is characterized by raised, violaceous, nonblanching plaques or nodules on the skin or mucous membranes. Visceral involvement may occur, presenting as hematemesis, melena, or hematochezia. A mass lesion on a neuroimaging study may represent a *primary CNS lymphoma*, especially in a patient free of the encephalopathic findings that occur with toxoplasmosis of the CNS. Such lymphomas are rare except in the context of HIV-1 infection. The incidence of *cervical dysplasia* is increased 10-fold in HIV-1–seropositive women. The development of *invasive cervical cancer* is indicative of severe immune compromise.

Skin problems in addition to Kaposi's sarcoma are an important source of morbidity. They range from cellulitis to drug eruptions and increase in frequency with worsening of immune function. Drug reactions are particularly common, with trimethoprim/sulfamethoxazole, dapsone/trimethoprim, and aminopenicillins most often implicated.

Prognosis. The prognosis strongly correlates with the CD4-cell count and is inversely related to the HIV load. Asymptomatic HIV-1–seropositive patients with CD4-cell counts above 500/mm^3 and a low viral load may remain otherwise healthy without treatment for many years. However, as HIV-1 infection progresses, patients are at increased risk for clinical manifestations directly associated with the disease (see above). Most frequently, death is caused by opportunistic infection or malignancy. Earlier intervention in HIV-1 infection postpones the onset of AIDS and improves overall survival and quality of life (see below).

DIAGNOSIS

The Diagnosis of HIV-1 Infection is usually made serologically, by the presence of persistent HIV-1 antibody positivity. Alternative diagnostic methods include virus isolation and HIV-1 antigen detection. The very sensitive *ELISA* method (enzyme-linked immunosorbent assay) is used for HIV-1 antibody screening, with positive tests subjected to the more specific *Western blot analysis* for confirmation. The sensitivity and specificity of the ELISA are in the range of 99% for patients at high risk, but the predictive value of a positive test result falls in patients at low risk. Occasionally, it is necessary to attempt direct detection of the virus (with such methods as viral culture, polymerase chain reaction, branched-chain DNA, or p24 antigen) when clinical suspicion is high but standard screening test results are normal.

The Diagnosis of AIDS has little bearing on the clinical management and is useful primarily for historical and epidemiologic reasons. When the HIV epidemic was first recognized, the diagnosis of AIDS was predominantly a clinical one, based on the identification of an *indicator condition*. However, the initial AIDS definition emphasized conditions seen in HIV-1–infected gay men and omitted attention to the CD4-cell count and to presentations in other populations, such as women and heterosexuals. These shortcomings were addressed in the newest CDC surveillance definition of AIDS (see above), which expands the list of indicator conditions to include *pulmonary tuberculosis*, invasive *cervical cancer*, and *recurrent pneumonia* in patients who are HIV-1–seropositive. In addition, the importance of immune status is acknowledged in the these diagnostic criteria, with HIV-1–seropositive patients having a *CD4-cell count* below 200/mm^3 now included among those

considered to have AIDS.

WORKUP

Once a diagnosis of HIV-1 infection is made, the goals of the workup are to identify the stage of illness, determine prognosis, and promptly identify complications of immune incompetence. Progression of immune system damage is a major concern. Patients with falling CD4-cell counts and high viral loads (>100,000 copies per milliliter) are at particularly high risk and should be treated promptly and followed closely.

History

The initial interview of the HIV-1–infected patient should seek information about *infections, malignancies*, and *exposures* that may indicate ongoing immune dysfunction or the potential for future difficulty.

Past Medical History is carefully reviewed for a previous diagnosis of herpetic infections; aseptic meningitis; recurrent sinusitis; skin problems such as folliculitis, staphylococcal infections, psoriasis, molluscum contagiosum, warts, persistent tinea, or seborrhea; recurrent bacterial pneumonia caused by encapsulated organisms (*Haemophilus influenzae*, pneumococci); oral and vaginal candidiasis; abnormal Papanicolaou smear findings; sexually transmitted diseases (if there is a history of syphilis, the details of treatment and serologic titers should be carefully documented); hepatitis B infection or vaccination; hepatitis C infection; tuberculosis (including history of skin testing, exposures, chest radiographs, vaccination, prophylaxis, and treatment); and gastrointestinal infections with parasitic organisms or more common bacterial pathogens. A travel history may be useful in assessing the risk of exposure to histoplasmosis and coccidioidomycosis.

Review of Systems. Because HIV-1 infection is usually a multisystem disease, the review of systems takes on particular importance. It begins with inquiry into *systemic symptoms* (fever, chills, drenching night sweats, fatigue, weight loss), which may be manifestations of acute infection or more advanced disease. *Skin* complaints should be reviewed, particularly reports of violaceous nodules or plaques, pustules, petechiae, groin rashes, or herpetic lesions. Moving to the *HEENT* (head, ears, eyes, nose, throat) review, it is important to ask about sinus pain and any purulent drainage, sore throat, coated tongue, and white patches in the pharynx. Inquiry into *lymphadenopathy* may prove informative.

The *pulmonary* review includes a check for dyspnea, persistent dry or productive cough, and hemoptysis. A nonproductive cough of recent onset in conjunction with dyspnea on exertion should raise suspicion for *Pneumocystis* pneumonia. Patients should be asked about *gastrointestinal* symptoms, especially odynophagia (painful swallowing suggestive of fungal esophagitis), abdominal pain, nausea, vomiting, diarrhea, melena, hematochezia, hematemesis, tenesmus, and perianal pain. Diarrhea and tenesmus suggest large-bowel pathology. Cramping periumbilical pain, diarrhea, and increased flatus point to a small-bowel process. Early satiety, anorexia, and weight loss may be manifestations of gastrointestinal lymphoma. Genitourinary involvement is screened by inquiry into abnormal vaginal bleeding or discharge, dyspareunia, urinary frequency, dysuria, and hematuria.

The *neurologic* review is critical. Unilateral headache becoming more generalized in conjunction with a stiff neck suggests spread of a parameningeal focus of infection into the CNS. New onset of lateralized weakness or numbness, especially if accompanied by a worsening unilateral headache, raises the question of a mass lesion (lymphoma, toxoplasmosis, brain abscess). Monocular visual field disturbances and floaters are characteristic complaints in patients with CMV retinitis. Diplopia and homonymous hemianopsia may indicate a CNS infection or malignancy. Numbness or tingling in the fingers or toes points to a peripheral neuropathy or myelopathy.

Neuropsychiatric difficulties raise the question of AIDS dementia complex. Suggestive symptoms include cognitive problems, difficulty with concentration, memory loss, insomnia, apathy, social isolation, and alterations in mood, especially depression. When accompanied by fever and delirium, they are more likely to be the consequence of an encephalopathy, but such difficulties may also occur as a consequence of a reactive depression. Distinguishing among these conditions can sometimes be difficult and may require neuropsychiatric testing and other diagnostic tests.

Physical Examination

The physical examination is directed toward signs of immunocompromise and its consequences. It includes a careful inspection of the skin, sinuses, eyes, oral cavity, lymph nodes, chest, abdomen, pelvis, and central and peripheral nervous systems. In addition, vital signs should be obtained and carefully recorded. Subtle but persistent unintended weight loss occurs frequently in HIV-1 infection and can be one of the earliest manifestations of disease progression, secondary infection, or malignancy.

Skin is one of the most frequently affected organs. Kaposi's sarcoma (especially prevalent in gay men), warts, molluscum contagiosum, psoriasis, seborrheic dermatitis, and fungal infections of the toes and nails are especially common. A painless, persistent, raised purple lesion, especially if there is more than one such lesion, may be Kaposi's sarcoma and warrants biopsy. Facial seborrhea, scars from recurrent herpetic infections, and premature graying are among the more subtle signs of immunocompromise.

HEENT. The sinuses are noted for tenderness, failure to transilluminate, and purulent discharge. Funduscopic examination may reveal retinal exudates, hemorrhages, or cotton–wool spots suggestive of CMV infection. The exudate is typically pale and associated with hemorrhage; it usually begins peripherally and may be difficult to visualize during routine funduscopic examination.

Careful examination of the oral cavity is essential, with a search for signs of oral hairy leukoplakia, thrush, mucosal petechiae, stomatitis, gingivitis, and Kaposi's sarcoma. Thrush is an important indicator of disease progression. The most common form is *pseudomembranous candidiasis*, removable white plaques on any oral mucosal surface. *Atrophic oral candidiasis* appears as smooth red patches on the hard or soft palate, buccal mucosa, or dorsal surface of the tongue. These may be easily missed without careful inspection. Rarely, candidiasis can occur in a leukoplakia-like form consisting of white lesions that cannot be wiped off but regress with prolonged antifungal therapy. This form of *Candida* infection can easily be confused with oral hairy leukoplakia and is distinguished primarily by its response to therapy (biopsy is rarely warranted). *Angular cheilitis* caused by *Candida* can appear as erythema, cracks, and fissures at the corner of the mouth. This may require the addition of a topical antifungal cream for adequate treatment. Mucosal petechiae can be the sole evidence of HIV-1–associated thrombocytopenia. *Kaposi's sarcoma* often produces oral lesions on the hard and soft palate and gingivae. Aphthous stomatitis may be easily confused with stomatitis associated with herpes simplex or CMV infections. Biopsy may be required to distinguish them. Lymphoma may appear as a mass or ulcer(s), most commonly seen in the peritonsillar region.

Lymph Nodes are checked periodically, as adenopathy may be an important sign of disease progression. If lymphadenopathy occurs in two or more noncontiguous extrainguinal sites and persists for longer than 3 months, and if no cause other than HIV-1 can be found, the condition is referred to as *persistent generalized lymphadenopathy*. Occasionally, *splenomegaly* may be found in association with persistent generalized lymphadenopathy. Asymmetric, large, firm, tender nodes may be evidence of malignancy or secondary infection and often require biopsy.

Chest, Abdomen, Rectum, and Genitalia. The lungs are examined for signs of consolidation, pleural inflammation, and effusion. The heart is checked for murmurs and rubs. The abdomen is noted for enlargement of the liver or spleen and for localized tenderness. Genital and rectal examinations are essential in all patients. Although evidence suggests that Papanicolaou test sensitivity may be reduced among HIV-1–infected women, it is currently recommended that it be performed semiannually because of the greatly increased risk for invasive cervical cancer. Lymphoma, squamous cell carcinoma, CMV infection, and acyclovir-resistant herpes simplex infections are examples of unresponsive anorectal lesions that may require biopsy for diagnosis. Anoscopy or sigmoidoscopy may be necessary to diagnose rectal or colonic lesions or diarrhea.

Neurologic Examination should be conducted regularly and include a careful assessment for meningeal irritation, focal neurologic deficits, and changes in mental status. Evidence for peripheral neuropathy, myelopathy, and myopathy should be sought because these are common and often treatable abnormalities. A detailed mental status examination may aid in the early detection of AIDS dementia complex.

Laboratory Testing

Laboratory testing plays an essential role, not only in workup and monitoring but also in deciding on the nature and timing of therapy. Testing is used to identify those patients who might benefit from special interventions (e.g., hepatitis B vaccine for those who are negative for both hepatitis B surface antibody and hepatitis B core antibody). In other instances, it may reveal hidden medical problems that can be treated (e.g., interferon-a for the treatment of chronic hepatitis C infection). Decisions

regarding the initiation of antiretroviral therapy and PCP prophylaxis are largely based on the results of laboratory tests, especially the CD4-cell count (see below). Increasingly, the effectiveness of antiretroviral therapy is being measured by the CD4-cell count and HIV load.

Initial Testing of the Patient Seropositive for HIV-1. A *complete blood cell count* and *platelet count* are essential (Table 13.1). Anemia of chronic disease, lymphopenia, and thrombocytopenia are common among HIV-1–infected patients, especially those with advanced disease. Idiopathic thrombocytopenia is sometimes seen in the acute phase of HIV-1 infection. Macrocytic anemia occurs in patients receiving zidovudine. Marrow suppression with pancytopenia may develop in the context of invasion by lymphoma or disseminated fungal infection. Proper workup may require measurement of serum iron, ferritin, folate, and vitamin B_{12} concentrations (see Chapter 79). When the cause of anemia is being assessed, it should be recognized that the measurement of mean corpuscular volume may be confounded by the macrocytosis that commonly occurs when patients are taking zidovudine and stavudine.

TEST	INDICATION FOR BASELINE TEST	TEST FREQUENCY
HIV serology	All patients without written documentation of positive serology	Baseline only
CBC count/Hct	All patients	As necessary
Chemistry	All patients	As necessary
CD4+ T-cell count	All patients	Every 3 to 4 months
HIV RNA (viral load)	All patients	Every 1 to 4 months
RPR or VDRL	All patients	Yearly
PPD	All patients without history of (+) PPD, RX treatment or prophylaxis	Consider yearly PPD for those at high risk
Toxoplasma IgG	All patients	As indicated
Varicella IgG	All patients	Baseline only
CMV IgG	All patients	Baseline only
HAA	All patients	Baseline only
HBsAg	All patients	Baseline and as indicated
HBsAb and/or HBcAb	All patients	Baseline
Anti-HCV	All patients	Baseline and as indicated
G-6-PD	Nonwhite patients	Baseline only
Pap smear	All women	Yearly
CXR	All patients	As indicated

CBC, complete blood cell; Hct, hematocrit; RPR, rapid plasma reagin; VDRL, Venereal Disease Research Laboratory; PPD, purified protein derivative; IgG, immune globulin G; CMV, cytomegalovirus; HAA, hepatitis A antibody; HBsAg, hepatitis B surface antigen; HBsAb, hepatitis B surface antibody; HBcAb, hepatitis B core antibody; HCV, hepatitis C virus; G-6-PD, glucose-6-phosphate dehydrogenase; CXR, chest x-ray.

Table 13.1. Laboratory Testing

Before any drug therapies are initiated, baseline *serum chemistries* (electrolytes, blood urea nitrogen, creatinine, transaminase, alkaline phosphatase) may help to identify drug toxicities and comorbid conditions such as HIV- or drug-related renal insufficiency and liver damage associated with alcohol abuse or viral hepatitis.

Serologic testing for syphilis is essential because of its high prevalence among HIV-1–infected individuals. False-positive test results are not uncommon and can be excluded with a confirmatory fluorescein *Treponema* antibody (FTA) test. The natural history of syphilis may be altered by HIV-1 infection, and therefore careful attention to a history and prior treatment for syphilis is essential. If a history of syphilis cannot be documented or if a positive result is accompanied by neurologic signs or symptoms, further workup, including a lumbar puncture, is advocated by most authorities (see Chapter 124 and Chapter 141). Patients who experience therapeutic failure or who cannot receive standard therapy with benzathine penicillin should undergo lumbar puncture also. Interpretation of cerebrospinal fluid results may be difficult, however. Cerebrospinal fluid VDRL (Venereal Disease Research Laboratory) testing is insensitive, and mononuclear pleocytosis and elevated cerebrospinal fluid protein are frequent in HIV infection without neurosyphilis.

Immunoglobulin G serology for *T. gondii* may be helpful in identifying those individuals who would benefit from chemoprophylaxis to prevent reactivation. This prophylaxis is recommended in guidelines on opportunistic infection prevention released by the U.S. Public Health Service and the Infectious Disease Society of America. Estimates have placed the risk for development of toxoplasmic encephalitis in an HIV-infected Toxoplasma-seropositive patient at between 20% and 50%. Seropositive patients should receive prophylaxis against toxoplasmosis when the CD4+-lymphocyte count drops below $100/mm^3$.

Culturing for CMV has little role in managing the HIV-1–seropositive asymptomatic patient. However, CMV serology should be obtained. Patients who are CMV-seronegative should be given CMV-negative or leukocyte-reduced cellular blood products only.

All HIV-1–seropositive patients should have an *intermediate-strength purified protein derivative* (PPD) tuberculin skin test unless they have previously been documented to be PPD-positive, have a history of tuberculosis, or have received the bacille Calmette-Guérin (BCG) vaccine. The test result should be interpreted as positive if the area of induration is *greater than 5 mm* (modified Mantoux test). Routine anergy testing is no longer recommended because of its poor predictive value and because prophylaxis in anergic individuals has been relatively ineffective.

Screening for hepatitis B (see Chapter 57) should be performed to determine the need for immunization. *Hepatitis C screening* may help to identify patients who might benefit from therapy. *Hepatitis A* vaccine can be safely given in HIV-infected patients and should be considered in patients without evidence of prior exposure.

Periodic screening of *vitamin B_{12}* levels should be conducted because vitamin B_{12} deficiency is extremely common, especially among those patients with advanced HIV-1 disease and chronic diarrhea.

Glucose-6-phosphate dehydrogenase (G-6-PD) deficiency is a genetic condition that predisposes individuals to hemolysis when they are exposed to oxidant drugs. Dapsone, primaquine, and sulfonamides are examples of oxidant drugs that are frequently used in HIV-1–infected patients. The most common variants of G-6-PD deficiency occur in two forms. The first, Gd^{A-}, occurs in approximately 10% of black men and 1% to 2% of black women. The second, Gd^{med}, occurs in men from the Mediterranean regions, India, and Southeast Asia. The hemolysis associated with Gd^{med} can be life-threatening, whereas that associated with Gd^{A-} is milder and more self-limited. Individuals at risk should be screened either at baseline or before therapy is initiated with an oxidant drug.

Formal *neuropsychiatric testing* may be needed to document AIDS dementia complex and is best conducted by a technician experienced in the assessment of HIV-1–infected patients.

Women infected with HIV-1 have an elevated risk for pelvic inflammatory disease, *Candida* vaginitis, and cervical dysplasia. This later condition may progress more rapidly as immunodeficiency progresses and can lead to invasive cervical carcinoma. All HIV-1–infected women should have a baseline pelvic examination with Papanicolaou smear. The use of routine colposcopy is controversial, but the test should be performed in women with abnormal Papanicolaou smear results or a history of vaginal condylomata. It should be repeated at least annually in asymptomatic women. More frequent evaluations are recommended in women with abnormalities and with more advanced disease.

Assessing the Degree of Immunocompromise and Prognosis. The *CD4-cell count* is the best single indicator of risk for disease progression. AIDS develops within 1 year in approximately 30% of patients with a CD4-cell count lower than $200/mm^3$ if they are left untreated. AIDS develops within 3 years in 50% of patients with a count between 200 and 400. The risk for development of AIDS in untreated individuals with CD4-cell counts above 400 is 15% within 3 years. The CD4-cell count is used to determine when to initiate antiretroviral therapy and PCP prophylaxis. Finally, the CD4-cell count is useful in assessing the response to antiretroviral therapy. The primary care physician must be aware of factors that can affect the CD4-cell count. These include diurnal variation, use of corticosteroids, intercurrent illness, variations between and within laboratories, coinfection with human T-cell lymphotropic virus type I (HTLV-I), and variation in the components of the white blood cell count. The *CD4 percentage* is less subject to variation than is the absolute CD4 cell count and may be a more suitable measure of immune status. A CD4-cell count greater than 500 is believed to be equivalent to a CD4 percentage greater than 29; a count between 200 and 499 is equivalent to a percentage of 14 to 28, and a count lower than 200 is equivalent to a percentage lower than 14.

Quantitative virology (often referred to as *viral load*) is a critical part of the evaluation of an HIV-infected individual. *Plasma HIV-1 RNA levels* provide complementary prognostic information to the CD4+ count. In addition, they are essential in determining the response to antiretroviral therapy. Viral load assays are of several types and include HIV RNA polymerase chain reaction, branched-chain DNA (HIV bDNA), and the nucleic acid sequence-based amplification (NASBA). Commercially available assays can now detect viral loads as low as 20 to 50 copies per milliliter. In general, viral loads are highest (>100,000 copies per milliliter) during the acute retroviral syndrome and during advanced disease. They are often lowest (100 to 100,000 copies per milliliter) during the asymptomatic phase of HIV infection. Many factors can influence viral loads, including intercurrent illness and recent vaccination. In these circumstances, viral load measurement should be deferred for several weeks or months.

Changes in HIV RNA level at the initiation of therapy correlate strongly with prognosis. A threefold change in viral load is necessary to be clinically significant. A more than 10-fold reduction in RNA level is associated with a significant reduction in risk for disease progression. Failure to obtain such a reduction within 8 weeks of initiation should trigger consideration of modifying the regimen. Viremia should continue to decline and will usually reach its nadir by week 16. The speed of viral load decline is affected by the baseline CD4-cell count, initial viral load, potency of the regimen, medication adherence, prior exposure to antiretrovirals, and the presence of opportunistic infections. These individual differences should be considered when the effect of therapy is being monitored. Optimal antiretroviral therapy will push the viral load below 400 to 500 copies per milliliter by 6 months.

Plasma HIV RNA levels and the CD4-cell count should be measured at the time of diagnosis and every 3 to 4 months thereafter. Less frequent evaluation may be reasonable in those with a high CD4-cell count, whereas more frequent evaluation may be reasonable in those with more advanced disease and in whom therapy is being changed.

Other tests have been studied for value in assessing prognosis (*infectious HIV-1 titers, syncytium-inducing viral phenotype, ratio of CD4 to CD8 lymphocytes*, b_2-microglobulin, neopterin, and HIV *p24 antigen*). None has proved as useful as the CD4+ and HIV-1 RNA determinations.

Diagnosis of Conditions Indicative of AIDS. As noted earlier, the diagnosis of AIDS depends principally on the identification of an indicator condition or on finding in an HIV-1–seropositive patient a CD4-cell count lower than 200. Although clinical findings help in making a presumptive diagnosis of an indicator condition, a definitive diagnosis depends on laboratory confirmation. Diagnostic modalities include histologic or cytologic study, culturing, serologic study, neuroimaging, and endoscopy.

A few comments are warranted. Candidiasis is diagnosed by direct observation or microscopy, not from culture, because *Candida* is a common contaminant. The diagnosis of HIV encephalopathy is one of exclusion and requires examination of cerebrospinal fluid and neuroimaging to rule out other causes. HIV wasting syndrome is another diagnosis of exclusion, and a search for cancer, tuberculosis, cryptosporidiosis, and other specific forms of enteritis is necessary before HIV wasting syndrome can be diagnosed.

PRINCIPLES OF MANAGEMENT

The major components of therapy are vaccination, antiretroviral agents, prophylaxis and treatment of opportunistic infections, and counseling. Each plays a major role. Although the disease remains invariably fatal pending development of curative therapy, a comprehensive and humanely administered treatment program can do much to preserve quality of life and reduce suffering.

Vaccination

An HIV-1–seropositive adult, especially one whose CD4-cell count is above 200/mm^3, should be vaccinated to the degree possible. However, no live-virus vaccines should be used because the patient may already be immunocompromised. All HIV-1–seropositive individuals should receive the *pneumococcal polysaccharide* vaccine, the *influenza vaccine* (yearly), and the hepatitis B vaccine (if not already antibody-positive). In addition, a *tetanus—diphtheria* booster should be given to any patient who has not received one within the last 10 years. The immunogenicity of these vaccines in HIV-1 patients has been called into question, especially in more advanced disease (CD4-cell count < 200/mm^3). Consequently, vaccination should be conducted as early in HIV-1 infection as possible (Table 13.2).

VACCINE	INDICATION	FREQUENCY
Pneumovax	All patients without history of prior vaccination	Consider repeat after 5 to 6 years
Hepatitis A vaccine	All patients negative for HAA, especially those with chronic hepatitis B and hepatitis C infections	One series only
Hepatitis B vaccine	Patients negative for HB$_s$Ab or HB$_c$Ab	One series only
Tetanus booster	Patients without tetanus booster in previous 10 years	Every 10 years
Flu vaccine	All patients as clinically appropriate	Yearly

HAA, hepatitis A antibody; HB$_s$Ab, hepatitis B surface antibody; HB$_c$Ab, hepatitis B core antibody.

Table 13.2. Immunizations

Initial Antiretroviral Therapy

Candidates for Treatment. Antiretrovitral therapy should be initiated in a patient who exhibits any one of the following characteristics: (a) *signs* or *symptoms* that are attributable to HIV-1 infection; (b) an absolute *CD4-cell count below 500/μL*; or (c) *plasma HIV-1 RNA* concentration (viral load) *above 10,000 copies per mL*. For those HIV-1–infected individuals who have no symptoms attributable to HIV-1, have an absolute CD4-cell count above 500/μL, and a plasma HIV-1 RNA concentration below 10,000 copies per milliliter, antiretroviral therapy may be deferred. However, many experienced clinicians would offer treatment to any HIV-1–seropositive patient with *detectable viremia*. If treatment is deferred, the patient should be carefully followed, with reevaluation of plasma HIV-1 RNA concentration and CD4-cell count every 3 to 6 months. Significant increases in plasma HIV-1 RNA concentration or drops in CD4-cell count should precipitate the initiation of antiretroviral therapy.

Some experienced clinicians believe that all HIV-1–seropositive individuals should be offered antiretroviral therapy regardless of plasma HIV-1 RNA concentration or CD4-cell count. If this approach is taken, careful attention must be paid to assisting the patient in maintaining adherence. This can be a particularly difficult problem if the patient feels healthy before therapy is initiated. The problem is further exacerbated by the complicated regimens currently in use. These regimens can involve taking more than 20 pills per day and may cause multiple side effects. Individuals embarking on antiretroviral therapy must understand that adherence to the regimen is essential to the ultimate success of therapy.

Choice of Initial Regimen should be based on the goal of reducing and maintaining the plasma HIV-1 RNA concentration as low as possible. This will forestall the development of viral resistance, drug failure, and disease progression. One should bear in mind that the *higher the plasma HIV-1 RNA* concentration before the initiation of therapy, the more potent the antiretroviral regimen must be to suppress it.

Triple-drug regimens involving two nucleoside analogues and at least one protease inhibitor or efavirenz will most likely be required to suppress very high plasma HIV-1 RNA concentrations (>100,000 copies per milliliter) to undetectable levels (currently, < 400 to 500 copies per milliliter). In tailoring antiretroviral therapy to individual patients, the clinician should consider several factors. Among these are *overlapping toxicities, pharmacokinetic interactions, absence of cross-resistance*, and *drug sequencing* that preserves future antiretroviral options.

The most studied *three-drug regimens* used as initial therapy involve *two nucleoside reverse transcriptase inhibitors* (NRTIs) and either a *non-nucleoside reverse transcriptase inhibitor* (NNRTI) or a *protease inhibitor* (PI) (Table 13.3). If a patient's disease is advanced or the plasma HIV-1 RNA concentration is very elevated, a highly active regimen comprising at least one potent PI or efavirenz should be used. If *lamivudine* is used as one of the NRTIs, it should be part of a regimen that will decrease the plasma HIV-1 RNA concentration to a level below detection. Lamivudine resistance mutations develop quickly in the presence of virus replication to cause significant cross-resistance with other NRTIs, including didanosine and zalcitabine. Similarly, nevirapine, delavirdine, and efavirenz, if used as part of an initial regimen, should be used in combinations that will decrease the plasma HIV-1 RNA concentration below detection. Resistance to these drugs develops quickly if significant viral replication occurs in their presence.

Preferred	Column A (PI or NNRTI)	Column B (NRTI)
	Indinavir	ZDV + ddI
	Nelfinavir	d4T + ddI
	Ritonavir	ZDV + ddC
	Saquinavir-SGC	ZDV + 3TC
	Ritonavir +	d4T + 3TC
	saquinavir-SGC	ddI + 3TC
	Efavirenz	
Alternative	Nevirapine or delavirdine + 2 NRTIs (see above)	
	Abacavir + ZDV + 3TC	
Not generally recommended	2 NRTIs Saquinavir-HGC + 2 NRTIs	
Not recommended	d4T + ZDV ddC + ddI ddC + d4T ddC + 3TC	

PI, protease inhibitor; NRTI, nucleoside reverse transcriptase inhibitor; NNRTI, non-nucleoside reverse transcriptase inhibitor; ZDV, zidovudine; ddI, didanosine; ddC, zalcitabine.

Table 13.3. Recommended Antiretroviral Agents for Treatment of Established HIV Infection

The NRTI abacavir, in combination with zidovudine and lamivudine, can suppress the viral load to undetectable levels in the majority of antiretroviral therapy-naive patients. This regimen spares the patient the initial use of PIs and NNRTIs with their attendant side effects. However, abacavir is associated with a serious hypersensitivity syndrome, and the durability of viral load suppression associated with its use in a triple-NRTI regimen is uncertain. For these reasons, the Panel on Clinical Practices for Treatment of HIV Infection convened by the Department of Health and Human Services and the Henry J. Kaiser Family Foundation has recommended that PI-containing and efavirenz-containing regimens be considered the preferred regimens.

Subsequent Antiretroviral Therapy

Changes in Antiretroviral Therapy may be necessary because of treatment failure, drug toxicity, or nonadherence. Treatment failure occurs when the viral load significantly increases or the desired reduction is not achieved, when the CD4-cell count decreases significantly, or when clinical progression occurs. If a new regimen fails to achieve a threefold to sixfold reduction in viral load by 4 weeks, or less than a 10-fold reduction by 8 weeks, a change in therapy should be considered. If a regimen achieves the 4- and 8-week goals but fails to suppress the viral load to undetectable levels by 4 to 6 months, the patient's regimen should be reevaluated carefully.

Failure may be for several reasons, including viral resistance to one or more antiretroviral agents, altered absorption or metabolism of one or more agents, altered pharmacokinetics resulting from drug interactions, and poor patient adherence to a regimen. Before antiretroviral therapy is changed, it is important to understand the reason(s) for the failure of the current regimen. This understanding will improve the likelihood of success with future regimens.

Table 13.4 provides representative options for subsequent antiretroviral regimens. When a change in antiretrovirals is being considered, a distinction between drug failure and drug toxicity is essential. In the case of drug toxicity, it is appropriate to substitute one or more antiretrovirals of the same potency and from the same class of agents as the agent suspected of causing the toxicity. In the case of drug failure, a detailed history of current and past antiretroviral agents is essential. In this situation, agents with as little overlapping resistance as possible should be sought. In a three-drug regimen, at least two and preferably three new agents should be used. As the patient becomes more "drug-experienced," the task of minimizing overlapping resistance becomes more difficult, and one must rely extensively on plasma viral load and CD4-cell count to inform drug choices.

PRIOR REGIMEN	NEW REGIMEN
2 NRTIs + nelfinavir	2 new NRTIs + RTV; or IDV; or SQV + RTV; or NNRTI + RTV; or NNRTI + IDV; or APV
ritonavir	SQV + RTV; NFV + NNRTI; or NFV + SQV; or APV
indinavir	SQV + RTV; NFV + NNRTI; or NFV + SQV; or APV
saquinavir	RTV + SQV; or NNRTI + IDV
2 NRTIs + NNRTI	2 new NRTs + a protease inhibitor
2 NRTIs	2 new NRTIs + a protease inhibitor 2 new NRTIs + RTV + SQV 1 new NRTI + 1 NNRTI + a protease inhibitor 2 protease inhibitors + NNRTI
1 NRTI	2 new NRTIs + a protease inhibitor 2 new NRTIs + NNRTI 1 new NRTI + 1 NNRTI + protease inhibitor

RTV, ritonavir; IDV, indinavir; SQV, saquinavir; NVP, nevirapine; NFV, nelfinavir; DLV, delavirdine; APV, amprenavir; NRTI, nucleoside reverse transcriptase inhibitor; NNRTI, non-nucleoside reverse transcriptase inhibitor.

Table 13.4. Antiretroviral Options for Patients Who Have Failed Therapy

Treatment interruption before starting a new regimen has been proposed in persons with documented resistant strains (see below). The rationale for a "drug holiday" is that it will allow reemergence of wild-type (nonresistant) virus which will be more responsive to treatment. Despite encouraging virologic data from nonrandomized and randomized small-scale studies of interrupted therapy, there is no evidence of survival benefit from a larger-scale randomized trial of this treatment strategy. In fact, clinical outcomes are worse, with increased rates of infectious complications and reduced CD4 cell counts.

Updated: 09/03/03

Evaluating Drug Resistance. Viral genotyping or phenotyping may prove useful when drug choices are made in initial therapy or treatment failure. However, these technologies have significant technical limitations and are not widely available for clinical use. They assess only the predominant viral quasispecies circulating in plasma. Resistant variants selected by drug pressure may quickly contract to a level below the threshold of detection in plasma when selective pressure is removed. Resistant variants remain and will return to detectable levels quickly if selection pressure is reapplied.

The value of viral resistance testing in the clinical management of HIV infection has yet to be fully established. Each assay and assay service requires standardization and validation. The interpretation of resistance assays requires expert input.

Special Considerations

Several situations warrant specific comment with regard to the use of antiretroviral therapy: primary infection, postexposure prophylaxis, and perinatal transmission.

Primary Infection may represent an opportunity to alter the course of HIV-1 disease significantly for an infected individual. Short-term improvements in viral load and CD4-cell count have been reported when antiretroviral therapy is given during primary infection, but these data are limited. Many experts recommend antiretroviral therapy for all patients who demonstrate laboratory evidence of primary infection. This evidence includes detectable HIV RNA in plasma by either the polymerase chain reaction or the branched-chain DNA method together with a negative or indeterminate result of an HIV antibody test. If a clinical trial for acute infection is unavailable or is declined by the patient, a regimen may be selected from the options available for treating established infection (Table 13.3). This regimen should be maintained indefinitely pending the availability of further information.

Postexposure Prophylaxis. The use of antiretroviral agents to prevent transmission resulting from high-risk exposures in the *occupational setting* has been widely accepted for several years. Guidelines governing the use of these agents for this purpose should be followed. The risk for seroconversion is very low. In a survey of 1,103 health care workers with documented percutaneous exposure, only four (0.36%) had undergone seroconversion, and none of those with nonintact skin or mucous membrane exposure had undergone seroconversion. About one third of exposed persons took zidovudine after exposure; seroconversion occurred in one despite zidovudine prophylaxis. No data from placebo-controlled, randomized trials are available. In their absence, a consensus treatment protocol has been established as part of a multicenter open study. Data are pending.

In the absence of definitive data, the decision to administer antiretroviral prophylaxis must be individualized and shared with the patient. In counseling the patient, one should take into account the severity of the exposure, the very low risk for seroconversion, the fact that such therapy does not provide absolute protection, the high

incidence of drug side effects, and the need for frequent monitoring.

Antiretroviral prophylaxis for *high-risk sexual exposures* is being studied. No guidelines for the use of antiretrovirals in this setting are currently available. However, the CDC is developing recommendations. Information pertaining to the effectiveness, safety, and tolerability of regimens used for postexposure prophylaxis is limited.

Preventing Perinatal Transmission. Zidovudine and nevirapine have been shown to decrease the likelihood of HIV-1 transmission significantly in the perinatal setting. At the present time, no other antiretrovirals have been demonstrated to reduce the likelihood of vertical HIV-1 transmission. Therefore, zidovudine, nevirapine, or both should be included as a component of any antiretroviral regimen used during pregnancy whenever possible.

Opportunistic Infection: Prophylaxis and Treatment

Prophylaxis and prompt treatment of opportunistic infection can significantly lessen disease morbidity and the need for hospitalization. Several of the most common infections will be discussed here. These include PCP, tuberculosis, toxoplasmosis, and candidiasis.

***Pneumocystis carinii.* Pneumonia** is the most common infection in HIV-1–infected adults. Adults with CD4-cell counts below 200 (or <14% of total lymphocytes) or a history of oropharyngeal candidiasis should receive PCP prophylaxis. Several prophylaxis regimens are available. *Trimethoprim/sulfamethoxazole* (TMS) is the preferred agent. One double-strength tablet per day is recommended. However, one single-strength tablet per day is also effective and may be better tolerated. TMS at a dose of one double-strength tablet per day confers cross-protection against *T. gondii* and some common respiratory bacterial pathogens. For most patients, it is well tolerated, but a substantial proportion of patients expereince adverse reactions, primarily fever and rash, so that desensitization or consideration of an alternative means of PCP prophylaxis is necessary. Desensitization to TMS can be employed successfully in up to 70% of patients who experience these reactions.

Dapsone (50 to 100 mg once daily) is an effective prophylactic agent for PCP. This is a very inexpensive drug with a long half-life. Less frequent dosing may be effective, but such dosing schemes may decrease overall adherence.

Aerosolized pentamidine (300 mg once every 4 weeks via a Respirgard II nebulizer) has also been shown to be effective in preventing PCP, although not quite to the same degree as TMS. When breakthroughs occur, the upper lobe is predominantly affected. The dissemination of *Pneumocystis carini* to other tissues has been reported. Individuals with active tuberculosis should not receive aerosolized pentamidine because it greatly increases the risk for tuberculosis among health care providers administering the therapy.

Atovaquone (1,500 mg each day) is comparable to aerosolized pentamidine in effectiveness but is substantially more expensive.

Workup for an HIV-1 patient with a CD4-cell count below 200 and new respiratory symptoms includes a *chest radiograph* and an *induced sputum*. The sputum should be sent for *Gram's stain*, routine *culture, mycobacterial stain* and *culture, fungal wet preparation* and *culture*, and *immunofluorescent stain* for *Pneumocystis carinii*. *Oximetry* and *arterial blood gases* may provide additional information. If the radiograph reveals a bilateral interstitial infiltrate and the sputum Gram's stain is not diagnostic of a specific etiology, the patient should be treated presumptively for PCP pending the results of immunofluorescent stains. If the patient appears clinically stable and is not in respiratory distress, treatment can be initiated on an outpatient basis. Careful follow-up is essential.

Effective *oral therapies* for PCP include *TMS, dapsone/trimethoprim, atovaquone*, and *clindamycin/primaquine*. One of the most effective and easily tolerated of these regimens is dapsone (75 to 100 mg/d in an average-sized adult) combined with trimethoprim (15 mg/kg daily in three or four divided doses). TMS (15 mg/kg daily by trimethoprim content in three or four divided doses) is effective but causes more adverse reactions than does dapsone/trimethoprim. Clindamycin/primaquine may be used in patients who are unable to tolerate dapsone/trimethoprim or TMS. G-6-PD–, Gd^{med}-deficient patients should not receive dapsone, TMS, or primaquine. Effective IV therapies include TMS, trimetrexate, and *pentamidine*.

Oral corticosteroid therapy should be used when a significant alveolar–arterial oxygen gradient (>30 mm Hg) is present, provided it is started within 72 hours of initiating antibiotic treatment. Later therapy has not been shown to improve outcome. If a patient is in respiratory distress or has a significant alveolar–arterial gradient, hospitalization should be considered.

Tuberculosis and Atypical Mycobacteria. All seropositive individuals whose PPD status is unknown should have a *5-TU (tuberculin units) PPD* planted. The test result is considered positive in HIV-1 individuals if *5 mm or more of induration* develops (see Chapter 38). Several regimens may be used for prophylaxis of tuberculosis in this setting. These include *isoniazic* (300 mg each day with 50 mg of pyridoxine for 9 months, or 900 mg with 100 mg of pyridoxine given twice weekly for 9 months) and *rifampin* (600 mg given with 20 mg of pyrazinamide per kilogram daily for 2 months). Many authorities suggest that anergic individuals with a history of PPD positivity also should receive a course of isoniazid.

As noted above, the use of aerosolized pentamidine may induce coughing and thereby facilitate transmission of undiagnosed pulmonary tuberculosis from HIV-1–infected patients to persons sharing the same breathing space during or after treatment. The potential for transmission of tuberculosis depends on the prevalence of tubercular infection in the HIV-1–infected population being served and on such factors as room ventilation, the number of infectious droplet nuclei generated by the patient, and duration of exposure. Specially ventilated facilities are required for the drug to be delivered safely.

The development of *active tuberculosis* in the HIV patient is a problem made even more serious because of the associated risk for multiple *drug-resistant strains*. Such patients require very careful attention to respiratory precautions (see Chapter 49).

Prophylaxis of *Mycobacterium avium* complex (MAC) infection should be instituted for those with CD4-cell counts below 50/mm^3. *Clarithromycin* (500 mg each day) and *azithromycir* (1,200 mg given once each week) are the preferred prophylactic agents. In addition to their prophylactic activity against MAC, clarithromycin and azithromycin may provide protection against respiratory bacterial infections.

Treatment of MAC infection requires multiple drugs. One of the most effective regimens comprises clarithromycin (500 mg given every 12 hours) and ethambutol (15 mg/kg of body weight given daily) with or without rifabutin (300 mg daily). Azithromycin may be substituted for clarithromycin at a dose of 500 to 600 mg daily.

Toxoplasmosis. TMS (*one single-strength tablet each day or one double-strength tablet three times each week*) or *dapsone/pyrimethamine* (50 mg of *dapsone* per day + 50 mg of *pyrimethamine* per week + 25 mg of *folinic acic* per week, or 200 mg of dapsone per week + 75 mg of *pyrimethamine* per week + 25 mg of *folinic acic* per week) appears to provide effective chemoprophylaxis in patients seropositive for *T. gondii* who have CD4-cell counts below 100/mm^3. For those individuals who are not seropositive, thorough cooking of meat and careful hand washing after contact with raw meat should be emphasized. Further, cat owners should clean litter boxes while wearing gloves and practice careful hand washing afterward or have another person perform this chore. Patients who are gardeners should be encouraged to use gloves while enjoying this pastime. Patients with encephalitis require hospitalization for the initiation of sulfadiazine, pyrimethamine, and leukovorin (100- to 200-mg loading dose of *pyrimethamine*, then 50 to 100 mg daily + 10 mg of *folinic acic* daily PO + 4 to 8 g of *sulfadiazine* or *trisulfapyrimidine* daily for at least 6 weeks). Alternative regimens involving the use of *pyrimethamine* and *folinic acic* with either *clindamycin, azithromycin, clarithromycir*, or *atovaquone* can also be used.

Candida infection occurs frequently in HIV-1–infected individuals, especially as the CD4-cell count drops below 200/mm^3. Thrush, esophageal candidiasis, and vaginitis are the most common forms of this infection. Although prophylaxis of thrush is not routinely recommended, occasionally long-term maintenance therapy is required to stem recurrent infections. Topical agents for *oral candidiasis* are effective and well tolerated. One 10-mg *clotrimazole troche* held in the mouth for 15 to 30 minutes three times each day is effective. *Chlorhexidine gluconate* may be useful, especially among patients with significant gingivitis and periodontitis. *Nystatin* is available in either an oral suspension or a pastille. Nystatin oral pastilles (200,000 U, one pastille taken three times each day) or nystatin suspension (100,000 U/mL, swish-and-swallow 15 mL six times a day) can also be used.

Esophageal candidiasis is treated with systemic therapy. *Fluconazole* (200 mg given once daily for 2 to 3 weeks) is one of the most effective therapies. *Itraconazole* (100 to 200 mg given twice daily, or a 100- to 200-mg oral suspension given once daily) may also be used for this purpose. Amphotericin B with or without flucytosine may be required for infections unresponsive to either *fluconazole* or itraconazole.

Vulvovaginal candidiasis is a common problem for HIV-1–infected women. It tends to occur earlier in HIV-1 infection than does oral candidiasis. Again, several agents

are available for *prophylaxis:* intravaginal *miconazole* suppository (200 mg taken for 3 days or 2% cream taken for 7 days), *clotrimazole* (1% cream taken for 7 to 14 days, 100-mg tablets taken daily for 7 days, 100-mg tablets taken twice daily for 3 days, or 500 mg taken once), and *fluconazole* (150-mg tablet given orally once). Maintenance therapy may be required to prevent frequent relapse (100 mg of *ketoconazole* given daily, 50 to 100 mg of *fluconazole* given daily, or 200 mg of *fluconazole* given weekly).

Cytomegalovirus. *Ganciclovir, foscarnet, cidofovir,* and *fomivirsen* are the drugs approved for the treatment of *CMV retinitis. Foscarnet* (*60 mg/kg IV every 8 hours or 90 mg/kg IV every 12 hours for 14 to 21 days*) has been shown to be superior to *ganciclovir* in patients with normal renal function. For patients with impaired renal function, *ganciclovir* (5 mg/kg IV twice daily for 14 to 21 days) is preferred. However, granulocyte counts have to be monitored closely because both cause granulocytopenia. It should be noted that data suggest that alternating or combining *ganciclovir* and *foscarnet* may be less toxic and more active against CMV than giving foscarnet alone. An intraocular *ganciclovir* release device (*Vitrasen*) can also be used for local treatment. *Cidofovir* (5mg/kg IV once weekly for 2 weeks followed by 5 mg/kg IV every 2 weeks; 2 g of probenecid should be given 3 hours before each dose and 1 g PO at 2 and 8 hours after each dose) and *fomivirsen* (330 mg by intravitreal injection on day 1 and day 15, then monthly) may also be used but should not be considered as first-line therapy.

Extraocular CMV disease may be treated with *ganciclovir* and *foscarnet* at doses similar to those used for ocular disease. In general, induction therapy is generally given for a longer period (3 to 6 weeks) in extraocular disease. Maintenance therapy should be considered, especially after reinduction and relapse.

Counseling

Counseling the HIV-1–infected patient involves many aspects, including personal, psychosocial, and financial issues. Assisting patients in understanding and accepting the changes in their sense of self and in life plans and goals is essential to successful care. It is particularly important to educate individuals as much as possible about the disease and its treatment; this helps them regain some sense of control. It is particularly helpful to focus on what patients can do rather than on what is out of their control. Giving accurate information on current estimates of *prognosis* is essential and can be done without destroying hope, especially in view of the advances in therapy and survival.

The *risk for suicide* is increased 30- to 60-fold in HIV-1 patients, especially early in the illness when the diagnosis is first known and in the very late stages of the disease when delirium may be present. Most patients who eventually commit suicide talk of it beforehand to friends and health care workers. Prevention through careful patient preparation at the time of diagnosis and screening for suicidality (see Chapter 227) should be an intrinsic part of the counseling and supportive effort.

It is essential to review *measures for safe sex* with HIV-1–seropositive individuals and their partners. These steps are useful in preventing transmission not only of HIV-1 infection but also of other sexually transmitted diseases. This is extremely important for the HIV-1–infected individual.

Understanding the patient's existing *support network* and helping the patient develop additional supports can be very important. It is often helpful if the patient can link up with infected peers to share experiences and concerns; this helps to minimize isolation, loneliness, and fear.

In many cities, special *community resources* are now available to aid HIV-1–infected patients with legal, social, and financial issues pertaining to the infection. It is important for every physician who cares for such patients to identify these resources.

Finally, it is essential to *discuss death* and *dying* with each patient in an open manner. Often, these issues are shunned by others in the patient's support network. The value of being able to obtain honest and direct answers about death and dying from one's physician cannot be underestimated. During these discussions, the physician and patient should strive to come to a common understanding of the patient's wishes regarding this very important issue.

INDICATIONS FOR ADMISSION AND CONSULTATION

Although outpatient care is preferred for many elements of HIV-1 management, in several instances, prompt hospitalization is essential. The patient with signs or symptoms suggestive of significant pulmonary, CNS, or disseminated infection (especially severe *Pneumocystis* pneumonia, tuberculosis, atypical mycobacterial infection, syphilis, toxoplasmosis, histoplasmosis, coccidioidomycosis, cryptococcosis, or CMV infection) requires prompt hospital admission and infectious disease consultation. Outpatient treatment may be possible later, even for administration of parenteral therapy, but treatment should be initiated in the hospital. Also requiring immediate hospitalization is the suicidal patient, particularly one who admits to having made specific plans for suicide. Urgent psychiatric consultation is essential. When appropriate, referral for *hospice care* should be considered. At this stage of illness, hospital admissions should be kept to a minimum except as needed for purposes of providing comfort.

PART 3 CARDIOVASCULAR PROBLEMS

CHAPTER 14 SCREENING FOR HYPERTENSION

KATHARINE K. TREADWAY

Hypertension can justifiably be considered the most significant condition the practitioner concerned with health maintenance will meet in clinical practice. The size of the affected population is staggering—20% of adults in the United States have systolic pressures greater than 160 mm Hg or diastolic pressures greater than 95 mm Hg. Among the elderly, the prevalence is even greater. Excess morbidity and mortality caused by hypertension have been well documented. Over the past 30 years, efforts to educate both physicians and the general public about the importance of identifying and treating high blood pressure and the improved options for treatment have resulted in improved blood pressure control and a significant decrease in morbidity and mortality from cardiovascular disease and stroke. Despite this, the percentage of Americans who are aware of and who are adequately treated for their hypertension has actually declined during this decade.

Evaluation and management of the identified hypertensive patient are presented in Chapter 19 and Chapter 26. This chapter reviews the epidemiology of high blood pressure, its importance as a risk factor, its measurement, and the evidence for the effectiveness of therapy.

EPIDEMIOLOGY AND RISK FACTORS

Depending on the definition of hypertension used, 15% to 25% of the U.S. population is considered hypertensive. Of those who are hypertensive, approximately 70% fall into the so-called stage I category (see below). Most estimates of the prevalence of hypertension derive from the National Health and Nutrition Examination Surveys of the early 1960s and late 1970s. Subsequent smaller surveys have both substantiated its prevalence and confirmed that age, race, and sex significantly affect prevalence.

Age. Systolic and diastolic blood pressures rise steadily with age into the fifth and sixth decades, when the increase levels off. By then, the prevalence of hypertension approaches 50%. The complication risk also rises steadily with age. The prevalence of hypertension (systolic at least 160 mm Hg or diastolic at least 95 mm Hg) among persons aged 25 to 34 is approximately 5%. By age 55 to 64, it has risen to 35% to 40%. Using the definitions proposed by the Joint National Committee on Detection, Evaluation and Treatment of High Blood Pressure's sixth report, the prevalence is considerably higher.

Gender. Males in all age groups have a higher prevalence of hypertension than females. In the third and fourth decades, it is more than twice as common among men as among women. The ratio decreases with advancing age, so that by age 60 there is only a slight male predominance. Men have substantially higher complication rates than women. The Framingham Study demonstrated that for the major complications of hypertension, risk in mildly hypertensive women equals that of normotensive men. The postulated mechanisms for this reduced risk in women include the beneficial effects of estrogen on vasculature and the different hemodynamic profile of premenopausal hypertensive women, which includes a lower peripheral resistance and higher cardiac output. After menopause, estrogen levels fall, the hemodynamic profile shifts to one of high peripheral resistance and normal cardiac output, and by age 70 the incidences of stroke and coronary disease in women approach those of men.

Race. There is a marked *increase* in prevalence of hypertension among *African-Americans.* Compared with whites, the overall prevalence ratio is 2:1; it is higher in young adults and lower in the elderly. Severe hypertension occurs nearly five times more often than in whites. In addition, the complication rate for any given blood pressure is significantly higher. For example, compared with white hypertensives, African-Americans have an 80% higher mortality from stroke, a 50% higher mortality from heart disease, and a 320% higher incidence of end-stage renal failure. Whether this represents as yet undefined differences in the underlying physiology of hypertension in African-Americans or whether this represents inadequate access to medical care is unclear, although it is likely that both factors play a role.

Obesity. Prevalence increases in obese patients, as does the prevalence of hyperlipidemia and type 2 diabetes mellitus. The association of these three conditions has been attributed to the presence of relative insulin resistance, which may cause hypertension in some patients (see Chapter 19). Data from the Nurses' Study demonstrates that women who gain more than 20 pounds after age 18 have a fivefold increase in the risk of developing hypertension compared with those who did not gain weight. Conversely, women who were at higher body mass index levels at age 18 and lost 5 to 10 pounds had about half the risk of developing hypertension.

Other Risk Factors. Hypertension is more likely to occur in patients with a *positive family history.* It is increasingly clear that hypertension may be caused by a variety of genetic mutations and that there are probably several different genetic forms of hypertension. In addition, there is undoubtedly significant interplay with the environment. *Increased salt intake* correlates with increased prevalence in large populations, though not in individuals. This suggests differing individual susceptibilities to the effects of high salt intake, and indeed there are clearly salt-sensitive hypertensives, although at present we have no simple way of identifying them. An individual's prior or current salt intake, per se, is not a predictor of blood pressure level. *Alcohol* intake in excess of 2 ounces per day is linked to hypertension. The mechanism of *alcohol-induced hypertension* appears to be related to alcohol's ability to stimulate the release of corticotropin-releasing factor from the hypothalamus, which in turn increases central nervous system sympathetic activity and causes a rise in blood pressure. *Sedentary life-style* has been associated with an increase in the risk of developing hypertension. The role of *psychological stress* and its concomitant sympathetic stimulation appears to be variable and possibly a function of underlying differences in susceptibility. *Cigarette smoking*, an important risk factor in its own right, is not positively associated with increased blood pressure, but hypertensive smokers are at significantly greater risk to develop cardiovascular complications than are hypertensive nonsmokers.

HYPERTENSION AS A RISK FACTOR FOR CARDIOVASCULAR MORBIDITY AND MORTALITY

The complications of hypertension may be divided into *hypertensive risks*—those that result directly from the presence of high blood pressure—and *atherosclerotic risks*—those for which hypertension is one of several risk factors. The major hypertensive complications are *stroke, congestive heart failure, renal failure, and left ventricular hypertrophy*. The atherosclerotic complications are coronary artery disease, cerebrovascular disease, and peripheral vascular disease. Although the risk of all these complications rises gradually over all levels of blood pressure, increasing by about 30% for every 10 mm Hg rise in pressure, the risk in a given individual for developing atherosclerotic complications varies enormously, depending on what other risk factors are present. It is important to understand that diastolic and systolic pressures are equally predictive of risk.

Although hypertension remains one of the principal atherosclerotic risk factors for development of coronary artery disease, the additive effects from smoking, hypercholesterolemia, glucose intolerance, and left ventricular hypertrophy are also extremely important (see Chapter 15, Chapter 54, and Chapter 93). For example, the chance of a 40-year-old man with moderate hypertension alone developing ischemic heart disease over an 8-year period is about 5%, but it rises to 70% if all coronary risk factors are present. The Framingham study has also shown hypertension to be the dominant predictor of congestive heart failure, with a sixfold increase in incidence among hypertensives.

NATURAL HISTORY OF HYPERTENSION AND EFFECTIVENESS OF THERAPY

Natural History. With rare exceptions, hypertension is an *asymptomatic disease*. The natural history is one of *insidious* damage that is most often clinically silent for a decade or more. It typically begins between the ages of 35 and 55, often preceded by a period of lability. Those patients with blood pressures at the high end of normal (135 to 140/85 to 90) are far more likely to develop hypertension than those with lower pressures. About 70% of hypertensives will fall into stage I, although this group accounts for something over 50% of the excess cardiovascular mortality attributable to hypertension. About 20% of stage I hypertensives will progress to higher stages if left untreated and about 1% will go on to develop malignant hypertension. About 15% to 30% will become spontaneously normotensive, although we

have no way to identify in which patients this will occur.

Effectiveness of Treatment. Convincing evidence for vigorous *early treatment* of hypertension began to appear 25 years ago with publication of the landmark Veterans Administration Cooperative Study, the first large-scale, placebo-controlled, randomized, prospective study. It involved patients with *moderate to severe hypertension* and found that rates of major nonfatal events and cardiovascular death fell with treatment more than 10-fold among those with severe hypertension and 3-fold among those with moderate pressure elevations. Treatment was most effective in reducing risks of stroke and congestive heart failure.

Later randomized studies expanded these initial findings, and meta-analyses of such studies confirmed the efficacy of treatment and expanded the spectrum of illness to those with mild to moderate hypertension. A meta-analysis of nine observational studies estimated that for each 5-mm Hg increase in blood pressure, the risk of stroke increases approximately 34% and the risk of coronary disease by about 21%. In a companion meta-analysis of 14 randomized controlled trials of antihypertensive therapy, in which blood pressure was lowered in the treatment group by about 5 to 6 mm Hg more than in the control group, the incidence of stroke was reduced by 42% and that of coronary disease by 14%. The reason for the less than predicted benefit in reducing the incidence of coronary events is not clear, although many theories have been proposed. One suggestion, that the trials lasted too short a time to demonstrate full benefit in the reduction of coronary disease, has gained some credence with improved benefit demonstrated in the MRFIT trial after 10 years.

Findings from other studies indicate that benefit from blood pressure reduction increases with severity of blood pressure elevation, African-Americans and those older than 50 years of age benefit most, and young white women benefit least. This difference in benefit can be explained by the lower level of overall cardiovascular risk in young white women. Treating *systolic hypertension* in the elderly significantly lowers the riskof stroke and coronary disease. Finally, lowering blood pressure also reduces the incidence of congestive heart failure and reduces the progression of renal disease.

Although the benefits of treating hypertension appear clear, it is interesting to note that mildly hypertensive patients whose blood pressure spontaneously reverts to normal seem to do even better than those whose pressure is lowered by medication. This finding was first noted in the landmark Australian study of mild hypertensives, in which almost half of the placebo group became spontaneously normotensive over the 5-year period of the study. Such patients had fewer complications than those who achieved a similar level of blood pressure with medication.

In sum, the benefit of lowering blood pressure is real and particularly important as regards incidence of stroke. Reduction in rate of coronary events is also achieved, though to a lesser extent. In most studies, the benefit from treatment of hypertension appears *within 2 to 3 years of initiation of therapy*.

Decision to Treat. The decision to initiate pharmacologic therapy is based on an estimate of *overall cardiovascular risk*. Such an estimate requires consideration not only of blood pressure but also of age, race, sex, smoking, hypercholesterolemia, diabetes, and family history of hypertensive or cardiac complications and the presence or absence of target-organ damage. The costs from medical therapy are weighed against the expected benefits, an especially important determination in young patients with mild uncomplicated disease (see Chapter 26).

SCREENING METHODS

Measurement of Blood Pressure. Blood pressure should be measured at each health encounter. Although the process of identifying patients with hypertension seems relatively straightforward, there are numerous pitfalls and chances for error in measuring blood pressure that can be avoided by proper screening protocol. All personnel responsible for recording blood pressures should be aware of the sources of measurement error. Effective screening technique includes having the patient *rest for 5 minutes* before measurement is made. The pressure should be taken in both arms while the patient is *seated comfortably with back and arm supported. Two or more readings* are taken, separated by 2 minutes. If these readings differ by more than 5 mm Hg, then *additional readings* should be taken. Patients should refrain from smoking or drinking a caffeinated beverage at least 30 minutes before a determination. Note should be made if the patient is cold, anxious, has a full bladder, or has recently exercised, smoked, or had caffeine, because any of these factors may transiently elevate pressure.

Reliable equipment and its proper use are is important. *Mercury bulb manometers* are best; *aneroid manometers*, if used, should be checked and recalibrated regularly. The cuff should be placed as high on the arm as possible and the arm supported and positioned at *heart level* while the pressure is taken. *Cuff size* must be adequate to avoid falsely elevated readings. The *width* of the cuff's inflatable bladder should be greater than *two thirds* the arm width and its *length* greater than *two thirds* the arm *circumference.* Using a standard size cuff in a muscular or obese adult will result in a reading that is as much as 10 mm Hg higher than the true blood pressure. To avoid this error, a large adult-sized cuff should be used in such patients. Although most auscultate using the diaphragm of the stethoscope, the *bell* is recommended for its superior transmission of the low-pitched sounds that characterize the last of the Korotkoff sounds (see Chapter 19).

Systolic pressure is defined as the point at which sound is first heard (Korotkoff 1). *Diastolic pressure* is taken at the point at which sound *disappears* (Korotkoff 5) rather than when it changes in quality (Korotkoff 4). The *averages* of two successive measurements in each arm are recorded. Variability of blood pressure may be related to recent physical activity, emotional state, or body position. Although such factors must be kept in mind, the predictive value of the "casual" blood pressure determination has been validated. Nonetheless, the diagnosis of hypertension must never be made on the basis of a single reading but rather should be based on multiple determinations taken over several visits. A check of the blood pressure should be a routine component of every patient visit, regardless of the presenting complaint (see Chapter 19).

CONCLUSIONS AND RECOMMENDATIONS

- Hypertension is an extremely common condition and the strongest predictor of subsequent cardiovascular and cerebrovascular morbidity and mortality. It is usually asymptomatic, with insidious damage to target organs occurring.
- A large segment of the hypertensive population will benefit from treatment, showing significant reductions in rates of stroke, congestive heart failure, renal failure, and coronary disease. Absolute risk reduction from treatment is a function of pretreatment risk.
- Detection is simple, reliable, and inexpensive. All adults should be screened for hypertension. Its detection and treatment are among the foremost responsibilities of the primary care physician (see also Chapter 19 for diagnostic evaluation and Chapter 26 for treatment).

CHAPTER 15 SCREENING FOR HYPERLIPIDEMIA

GALE S. HAYDOCK, MASON W. FREEMAN

INTRODUCTION

Coronary heart disease (CHD) is the single largest cause of death in American men and women, making identification and treatment of its risk factors a major health care priority. Major independent risk factors include smoking, hypertension, diabetes mellitus, and the common *dyslipidemias* (elevated low-density-lipoprotein [LDL] cholesterol, low high-density-lipoprotein [HDL] cholesterol). Other dyslipidemias that may contribute to risk include hypertriglyceridemia and increased lipoprotein (a) (Lp[a]). Because these risk factors do not completely account for all instances of CHD, the search for additional determinants of risk continues. *C-reactive protein (CRP)*, an acute-phase reactant that increases during inflammation, shows promise in providing substantial predictive value for CHD risk independent of other major CHD risk factors. Elevations in plasma *homocysteine* also appear to confer some independent risk for CHD.

Proper CHD screening is the responsibility of all primary care physicians and requires attention to several questions: Which abnormalities truly increase coronary risk? To what degree will lowering them reduce such risk? How are they best measured? At what age should screening be initiated and for how long? This chapter addresses the CHD risk associated with the dyslipidemias, C-reactive protein, and homocysteine. (See Chapter 14 for discussion of screening for hypertension, Chapter 54 for smoking, and Chapter 93 for diabetes screening.)

DYSLIPIDEMIAS

Twenty percent of all adults older than 20 years of age have a total serum cholesterol concentration in excess of 240 mg/dL, a level associated with an accelerating risk of CHD. Fifty percent of the adult population has total cholesterol levels exceeding 200 mg/dL, the level considered desirable. Patient and professional awareness of the importance of hypercholesterolemia has contributed to a modest (8%) reduction in mean total cholesterol over the past two decades, but the problem remains widespread. Screening for hyperlipidemia is a key element in the primary and secondary prevention of CHD. Proper screening is the responsibility of all primary care physicians and requires attention to several questions: Which lipid abnormalities truly increase coronary risk? To what degree will lowering them reduce such risk? How are they best measured? At what age should screening be initiated and for how long?

RISK FACTORS FOR HYPERLIPIDEMIA

Age. Cholesterol levels increase with age. Total cholesterol increases, on the average, more than 2 mg/dL per year during early adulthood and continues increasing but at a lesser rate until age 65, after which it declines slightly.

Gender. Men have higher total cholesterol levels than women until age 50 and an approximately twofold higher risk of developing CHD. Women carry a higher proportion of cholesterol in the form of HDL cholesterol (primarily HDL $_2$). At the onset of menopause, women lose the protective effect of estrogen, resulting in a net increase in cholesterol and an increased risk of CHD. As women move into their mid-sixties and beyond, their risk of developing CHD approaches that of men of the same age.

Genetic Factors. Primary lipid disorders arising from a *monogenic* (single gene) abnormality account for only a small fraction of patients with hyperlipidemia. These relatively uncommon genetic disorders are, however, frequently responsible for the most severe hyperlipidemias. These are, in turn, associated with the most aggressive forms of coronary artery disease. Because these disorders are more likely to affect the immediate relatives of an affected patient than are complex polygenic conditions, family screening should be performed in the relatives of patients suspected of harboring these genetic mutations.

Diet. A diet high in *saturated fatty acids* raises total and LDL cholesterol. Total and LDL cholesterol are also increased by dietary *cholesterol*, but the effect is smaller than that of saturated fatty acids. *Caloric excess* resulting in obesity has more of an effect on triglycerides than on cholesterol. *Alcohol* has little effect on total cholesterol levels, but it can cause an acute rise in triglycerides among people with hypertriglyceridemia. Moderate alcohol ingestion also causes a rise in HDL levels.

Medications. Antihypertensive agents that adversely affect lipid levels can compromise the effort to reduce CHD risk. *Thiazides* increase LDL cholesterol, at least temporarily, when taken in full doses. The effect is hypothesized to account for the shortfall in reduction in mortality found among hypertensives treated with thiazides (see Chapter 26). *Beta-blockers* cause modest reductions in HDL cholesterol. *Exogenous estrogens* increase HDL$_2$ and can cause extreme triglyceride increases in patients with hypertriglyceridemia. *Corticosteroids* and HIV *protease inhibitors* can also dramatically elevate serum lipids.

Exercise, Weight, Smoking, and Concurrent Diseases. Activity increases HDL cholesterol; inactivity and obesity appear to decrease it. A reduction in HDL cholesterol occurs with *smoking. Diabetes* is associated with elevations in triglycerides, which is frequently accompanied by low HDL cholesterol levels. *Hypothyroidism, nephrotic syndrome, and obstructive liver disease* are important causes of secondary hypercholesterolemia, characterized by increases in total and LDL cholesterol levels.

HYPERLIPIDEMIA AS A RISK FACTOR FOR CORONARY HEART DISEASE

Total Cholesterol. Both epidemiologic and prospective studies have demonstrated that hypercholesterolemia is an independent risk factor for the development of CHD in persons younger than 65 years of age. Coronary risk increases curvilinearly with increasing total cholesterol levels, even within the "normal" range. Over the usually encountered range of total cholesterol values (180 to 300 mg/dL), risk increases by an average of four- to fivefold. Risk begins to accelerate more sharply when the total cholesterol level exceeds 240 mg/dL. Levels lower than 200 mg/dL are considered desirable, although epidemiologic data can still demonstrate an increasing risk for CHD in the interval between 160 and 200 mg/dL.

Low-Density Lipoprotein (LDL) Cholesterol. The positive relationship between total cholesterol and CHD risk derives mainly from the atherogenic LDL cholesterol component. Because the LDL cholesterol accounts for about two thirds of the total cholesterol in the typical patient, the total cholesterol concentration is generally used as a proxy for LDL cholesterol. LDL cholesterol serum levels in excess of 160 mg/dL are associated with significant increases in CHD risk.

Lp(a), consisting of LDL attached to a protein of variable size, called "apoprotein little a," appears in most (but not all) studies to contribute independently of LDL cholesterol to CHD risk. The lack of an accurate inexpensive test, some uncertainty as to the exact risk relationship, and the absence of any studies demonstrating that a reduction in Lp(a) levels results in improve clinical outcomes has kept this marker from being routinely assayed.

High-Density Lipoprotein (HDL) Cholesterol. The relation of the HDL cholesterol level to CHD risk is an inverse one. HDL cholesterol exerts a protective effect that is at least as strong as the atherogenic effect of LDL. For every 10-mg/dL increment in HDL cholesterol concentration, there is a 50% decrease in coronary risk. An HDL cholesterol level lower than 35 mg/dL has come to be recognized as a major independent risk factor for CHD. A level in excess of 60 mg/dL is considered a "negative" risk factor (see Chapter 27). A low HDL cholesterol increases CHD risk across the full range of total and LDL cholesterol concentrations. A patient with a low total cholesterol level is still at increased risk of CHD if HDL cholesterol is low. Conversely, it is possible for a person with an elevated total cholesterol to be at low risk for CHD by virtue of having a very high HDL cholesterol (60 to 100 mg/dL). The determination of a *total-to-HDL cholesterol ratio* helps to distinguish such low-risk individuals from others with elevated total cholesterol. The Framingham Study showed that the ratio was a strong predictor of risk. A ratio of 5 approximates

the average or standard risk, with ratios of 10 and 20 denoting double and triple the risk. A ratio of 4.5 or less is considered desirable.

Subfractions of HDL (e.g., HDL_2, HDL_3) and subcomponents (e.g., *apolipoprotein A1*) also appear protective and inversely predictive of CHD risk. However, they are difficult to measure, and their contribution to estimation of CHD risk does not appear additive to that provided by measurement of the total HDL cholesterol level.

Triglycerides. The importance of *hypertriglyceridemia* to cardiovascular risk remains controversial. In univariate analysis, it is consistently associated with increased CHD risk, but in multivariate analysis, most of this risk is lost when the contribution of HDL cholesterol is factored out. Because high serum levels of triglycerides may causally contribute to lowered HDL levels, one cannot conclude that hypertriglyceridemia is unimportant. Data from the Framingham Heart Study suggest that the high triglyceride/low HDL syndrome is a more important risk factor for women than men, some of which may be due to the association of this lipid profile with insulin resistance or frank glucose intolerance.

Lipid-Related Coronary Heart Disease Risk among the Young and the Elderly. The importance of hypercholesterolemia as a predictor of coronary disease is best established in middle-aged men and postmenopausal women. In the young and the elderly, the relationship is less well established due to a paucity of data.

For young men (under age 35) and premenopausal women, elevated total and LDL cholesterol levels increase *long-term risk* of developing CHD. However, *short-term* CHD risk among those with even moderately high LDL cholesterol levels (160 to 220 mg/dL) but no other CHD risk factors remains relatively low. However, the presence of additional CHD risk factors, particularly diabetes or family history of early CHD, appears to increase short-term risk, as does development of a very high LDL cholesterol level (220 mg/dL).

CHD risk due to hypercholesterolemia in the *elderly* is also incompletely defined. The relative risk of CHD observed in men 60 to 79 years of age with marked hypercholesterolemia is about 1.5. This relative risk is lower than that in comparably hypercholesterolemic patients younger than 60 years of age. The difference is believed to be related to the high prevalence of already established CHD, hypertension, and diabetes in this age group. Among hyperlipidemic elderly patients with established CHD, the relative risk of a new coronary event is just as high as in younger patients. Because the elderly have the highest rates of coronary disease in the population (85% of individuals dying of CHD are 65 years or older), the aggressiveness with which to screen older individuals is a topic of heated debate in the prevention field.

EFFECTIVENESS OF TREATMENT

Nonpharmacologic Measures. Decreases in intake of cholesterol and saturated fat in controlled settings can *reduce total and LDL cholesterol* levels by 30% or more, but this magnitude of reduction is rarely achieved in clinical practice. LDL cholesterol levels are lowered by an average of 10% when reasonably intensive diets are used in the outpatient setting. Dietary measures may also produce a small (approximately 5%) reduction in HDL cholesterol concentration, though the overall total-to-HDL ratio still improves. Weight loss (if obese), aerobic exercise, and smoking cessation can raise the HDL cholesterol level and facilitate the dietary lowering of LDL cholesterol. These measures also reduce CHD risk by decreasing blood pressure and glucose intolerance. Caloric and fat restrictions and control of diabetes lower triglyceride levels, an effect added to by prohibition of alcohol. Reductions in CHD risk follow from cholesterol lowering and amelioration of other risk factors.

Addition of Pharmacologic Measures. Adding drug therapy to a diet and exercise program enhances the lipid-lowering effort. Reductions two to three times greater (25% to 35%) than those achieved by dietary measures alone are attainable and associated with a further lowering of CHD risk. The reduction is most evident among patients with established CHD—a *secondary prevention* effect—with CHD mortality reduced by over 40% and all-cause mortality by 30%. In addition, a halt to *plaque progression* and a modest amount of plaque regression have been demonstrated in patients with established CHD treated aggressively with medical therapy. Pharmacologic therapy for hypercholesterolemic persons without clinically evident CHD (so-called *primary prevention*) also reduces CHD risk. Reductions of approximately 30% in rates of nonfatal infarction, death from CHD, and death from all forms of cardiovascular disease have been achieved in medically treated men and women with moderate increases in their LDL cholesterol levels (LDL levels of 150 to 190 mg/dL). The cardiovascular benefit of these interventions with the HMG CoA reductase inhibitor class of drugs ("statins") has not been associated with any increase in noncardiac deaths (an earlier concern, not borne out in large-scale prospective clinical trials).

SCREENING METHODS

Determinations of total cholesterol, LDL cholesterol, and HDL cholesterol levels would allow reasonable estimates of CHD risk. Decisions about which test(s) to order in screening a particular patient require consideration of test accuracy, cost, availability, significance, and presence of other CHD risk factors.

Measurement of Cholesterol and Choice of Method. The total blood cholesterol is the sum of the cholesterol concentrations contained in the three major circulating lipoproteins (HDL, LDL, and very-low-density lipoproteins [VLDL]). Thus, total cholesterol = LDL cholesterol + HDL cholesterol + VLDL cholesterol. Most laboratories measure total cholesterol and HDL cholesterol directly, calculate the VLDL concentration by dividing the triglyceride concentration by 5 (as long as triglyceride is less than 400 mg/dL), and then mathematically derive the LDL cholesterol concentration.

The accuracy of determinations of total cholesterol and its fractions can vary considerably. The popular *finger-stick method* using a capillary tube and *desktop analyzer* has demonstrated false-negative rates ranging from 12% to 47% for detection of lipid elevations. The best results with finger-stick measurements are for nonfasting total cholesterol, which most closely approximate those obtained by *venous sampling and laboratory processing* (which average 3% to 5% higher). HDL cholesterol measurement by desktop analyzers is less accurate. The finger-stick technology has improved since its inception, but in one recent study, the error rate of a desktop analyzer fell outside of the National Cholesterol Education Program (NCEP) guidelines for three of the four standard lipid measurements. Because this study was conducted in a speciality lipid clinic with experienced technical personnel, the error rates observed may underestimate what would be seen in a busy clinical office practice.

Not all laboratories ensure accuracy of results. Acceptable laboratories are those with instruments calibrated to the standards of the Centers for Disease Control and Prevention, with a margin of error (coefficient of variation) of 3% for a total cholesterol measurement. If finger-stick screening methods reveal a total cholesterol elevation, the determination should be repeated by a proper laboratory before deciding to initiate lipid-lowering therapy (see).

Fasting is unnecessary when screening by measurement of the total cholesterol level, because it is not markedly affected by immediate food intake. However, chronic stress or serious illness might cause the level to fall significantly. Thus, it is best to measure lipid levels in patients when they have recovered from any acute infections, illnesses that results in tissue necrosis, or surgical procedures. A significant drop in total cholesterol and triglyceride levels has been demonstrated when a patient assumes a recumbent position, usually within 5 minutes, and it reaches a maximum of 10% to 12% within 20 to 30 minutes.

Selection of Persons for Screening. The approach to screening lipid levels in patients has been controversial, with the American College of Physicians (ACP) promulgating screening guidelines that differ substantially from those recommended by the NCEP. The differences largely reflect a greater emphasis on cost effectiveness in the ACP guidelines than in those issued by the NCEP. Importantly, both the NCEP guidelines and the ACP recommendations were issued before publication of the most recent statin trials, which show marked reductions in cardiovascular and all-cause mortality and no increase in noncardiovascular disease in hypercholesterolemic patients treated with statins. (Preliminary studies raised concerns about increases in noncardiovascular morbidity and mortality in individuals treated with cholesterol-lowering agents.)

The results of these studies favor the more aggressive screening program suggested by the NCEP. The decision to treat with cholesterol-lowering drugs, however, should still take into consideration the absolute risk for the development of coronary disease that any given patient has. Treating moderately hypercholesterolemic young individuals with costly drugs for several decades before they are statistically likely to experience any CHD events may not be a wise use of health care resources, even if some benefit can be shown. This decision is a matter of judgment and philosophy, and it is likely to be one in which considerable practice variability can be expected. Nevertheless, nonpharmacologic treatments of hyperlipidemia can be both effective and inexpensive and are more likely to be adopted by patients who are aware of their hyperlipidemia.

The *NCEP guidelines* recommended measuring a *total and HDL cholesterol* in all adults 20 years of age and older *every 5 years.* Additional testing is determined by the results of those screens. For those without evidence of CHD, if the total cholesterol is less than 200 mg/dL and the HDL cholesterol is at least 35 mg/dL, the screening is repeated in 5 years. For individuals with total cholesterol levels more than 240 mg/dL or between 200 and 240 with multiple risk factors present, a complete lipoprotein profile is recommended. This includes measurement of triglyceride levels and a calculation of the LDL. NCEP treatment guidelines (see

[27](#)) are then triggered by the LDL value and the presence or absence of risk factors. For those with evidence of CHD, a complete lipoprotein profile is done initially.

The issue of cholesterol screening in the *elderly* also remains somewhat unsettled. It is clearly indicated for those at high risk for CHD (multiple CHD risk factors, established CHD, other clinically evident atherosclerotic disease) who are otherwise well. Screening lower risk healthy persons older than 70 years of age is of unknown value but likely to be beneficial, given the high prevalence of silent CHD in the population. The subgroup analyses that have been done in the over 65 population enrolled in the statin trials demonstrate clear benefits to treatment, although the number of older patients that have been studied remains small. At what point an elderly person is beyond the age where primary prevention of CHD should be considered is a topic that is little informed by any data.

What to Screen. A nonfasting determination of total and HDL cholesterol suffices for patients with no other cardiovascular risk factors. For those with CHD or other CHD risk factors as outlined above, total cholesterol, HDL cholesterol, and serum triglycerides should be measured only after fasting for more than 12 hours. This permits the LDL level to be calculated, if the triglycerides are less than 400 mg/dL, and allows the physician to make any treatment decisions based on the LDL cutpoints contained in the NCEP guidelines.

LDL cholesterol, triglycerides, VLDL cholesterol, and lipoprotein electrophoresis are not indicated for screening purposes. The use of other measurements in assessing risk, such as Lp(a), homocysteine, and C-reactive protein levels (a potential marker of inflammation in the artery wall), are not yet established as worthwhile screening tools in the assessment of patients with CHD.

CONCLUSIONS AND RECOMMENDATIONS

- Hypercholesterolemia is a problem of substantial proportions in the United States and a major risk factor for CHD.
- Elevations in levels of total cholesterol or LDL cholesterol and reduction in HDL cholesterol are strongly positive independent risk factors for the development of CHD in persons younger than 65 years of age.
- Diet, exercise, smoking cessation, and drug therapy are effective measures for treatment of lipid abnormalities associated with CHD risk.
- Reductions in CHD morbidity and mortality have been demonstrated with treatment, particularly in high-risk hyperlipidemic patients such as those with established CHD, but also in hyperlipidemic men and women without clinical evidence of CHD.
- Random serum total and HDL cholesterol measurements should be performed at least every 5 years in persons older than 20 years of age. Those at increased risk of CHD because of smoking, diabetes, hypertension, family history of premature CHD, or symptomatic noncoronary atheromatous disease require more frequent screening.
- Elderly persons are reasonable candidates for cholesterol screening, provided their overall clinical condition would warrant treatment of hypercholesterolemia.
- An HDL cholesterol determination should be part of the screening profile, provided the technology for performing the measurement is available. Results from desktop analyzers using finger-stick blood samples are often erroneous.
- The ratio of total cholesterol to HDL cholesterol should be calculated. A ratio lower than 4.5 is desirable.
- Determination of LDL cholesterol level is not necessary for screening purposes.
- Neither a triglyceride determination nor a lipoprotein electrophoresis is indicated for screening.
- The value of measuring biologically important risk factors such as Lp(a) and certain apolipoproteins is yet to be demonstrated.
- If the finger-stick screening serum total cholesterol is greater than 200 mg/dL, then a repeat determination using venipuncture and laboratory techniques is indicated for confirmation. Further testing and treatment are based on the patient's age and risk factor profile (see [Chapter 27](#)).

C-REACTIVE PROTEIN

CRP is an acute-phase reactant that increases in the setting of inflammation. It activates both complement and endothelial cells. Recent interest in atherosclerosis as an inflammatory process has drawn attention to CRP as a possible marker/risk factor for CHD events. Associations between CRP elevations and cardiovascular events in persons with CHD have been observed, leading some to suggest that screening for CRP might improve determination of CHD risk and outcomes. **Updated: 2/13/03**

Association with Coronary Heart Disease Risk. The most compelling data derive from the Women's Health Study, a large prospective epidemiologic study that found CRP level to be an independent predictor of CHD events that was more powerful than the level of LDL cholesterol. Women in the highest quartile for CRP concentration had a relative risk of 2.3 for a CHD event, compared to a relative risk of 1.5 for women in the highest LDL cholesterol quartile. In addition, CRP appeared to identify a separate population of high-risk persons not identified by LDL cholesterol. On the other hand, the predictive power of CRP diminishes somewhat when other CHD risk factors are taken into account, and CRP elevations are also found in persons with central adiposity and insulin resistance, known CHD risk factors that might be responsible for some of the effects associated with CRP. **Updated: 2/13/03**

Measurement. Because only modest elevations in CRP are associated with substantial increases in CHD risk, it becomes essential to be able to measure subtle elevations in CRP. A new high-sensitivity assay has been validated, providing this capability. **Updated: 2/13/03**

Effectiveness of Treatment. A critical determinant of the validity and utility of a risk factor for screening is evidence of a survival benefit associated with treatment of the risk factor. To date, there are no randomized, prospective studies examining the effect of CRP lowering on CHD risk. In fact, the best means of lowering CRP levels remains unclear. Of interest is the finding that statin drugs appear to be most effective in persons with elevations in CRP, suggesting that their survival benefit might be due in part to CRP reduction. **Updated: 2/13/03**

Selection of Persons to Screen. In the absence of definitive evidence that treatment of CRP elevations reduces CHD risk, there is disagreement as to whether to screen for CRP. Those who are impressed with the available epidemiologic data feel that all adults should be screened. Others want evidence from prospective study of improved outcomes before recommending CRP screening; they suggest for now that available resources be directed at aggressively identifying and better treating the more well-established CHD risk factors. Taking a selective approach, one might reserve CRP measurement for those patients who would undergo a change in therapy based on the degree of risk suggested by the CRP measurement (e.g., the low-to intermediate-risk individual who would be started on aspirin or a statin if the CRP measurement suggested heightened risk). **Updated: 2/13/03**

Conclusions and Recommendations

- CRP appears to be an independent risk factor for CHD events, particularly in women. **Updated: 2/13/03**
- The association between CHD risk and CRP elevation in women is strong and of greater magnitude than the association between LDL cholesterol elevation and CHD event risk. **Updated: 2/13/03**
- There are no definitive data from long-term randomized clinical trials proving that lowering of CRP reduces risk of CHD events. The best way to reduce CRP is not even clear. **Updated: 2/13/03**
- Pending definitive evidence of benefit, CRP screening might be applied selectively in instances where the results will change management. If measured, the high-sensitivity assay should be used. **Updated: 2/13/03**

Homocysteine. The lay press has given much attention to elevations in the amino acid homocysteine as a risk factor for CHD. Children who are homozygous for homocysteinuria develop premature atherosclerotic disease, and early retrospective case-control studies suggested substantially enhanced risk of CHD events in adults with abnormally high plasma levels. **Updated: 2/13/03**

Association with Coronary Heart Disease Risk. Compared to early retrospective data, metaanalyses combining data from prospective studies confirmed an enhanced CHD risk, but although the risk was significant and independent of other CHD risk factors, it was substantially less than initially suggested by retrospective studies. After correcting for other CHD risk factors, metaanalysis found an 11% reduction in CHD risk associated with a 25% reduction in homocysteine level; stroke risk was reduced 19%. Genetic studies of persons with the TT polymorphism (C to T substitution) show a 25% increase in homocysteine and a 16% increase in CHD risk. **Updated: 2/13/03**

Measurement. Relatively inexpensive measurement of plasma homocysteine is becoming available; accuracy is facilitated by fasting, and sensitivity is enhanced by methionine loading, which stresses the involved enzyme deficiency (tetrahydrofolate reductase). **Updated: 2/13/03**

Effectiveness of Treatment. Folic acid supplementation with or without vitamins B$_6$ and B$_{12}$ will lower homocysteine levels by nearly 25% in 2 to 6 weeks, even in persons who are not deficient in these vitamins. The higher the pretreatment homocysteine level and the lower the folate stores, the greater the reduction in homocysteine. Despite the effectiveness of treatment in lowering homocysteine, it remains to be proven whether decreasing homocysteine elevations will reduce the frequency of adverse cardiovascular events. Prospective, randomized, controlled trials are underway to answer the question. **Updated: 2/13/03**

Patient Selection. Pending definitive evidence of benefit, widespread screening is not warranted, but in some situations measurement of homocysteine may deserve consideration. For example, young adults with a strongly positive family history of CHD, especially in the absence of known CHD risk factors, and those with premature vascular disease may be reasonable candidates for screening and treatment if elevations are found. Many physicians currently screen for and treat CHD patients with homocysteine elevations—even moderate ones—because treatment is safe and simple. **Updated: 2/13/03**

Conclusions and Recommendations

- Elevations in homocysteine are associated with a statistically significant but modest increase in risk of CHD events. **Updated: 2/13/03**
- Folic acid supplementation is capable of reducing elevations in homocysteine, but there is no evidence yet from prospective randomized trials that reduction in homocysteine elevation reduces CHD risk. **Updated: 2/13/03**
- Widespread screening is not warranted at this time, but selective screening may be worth consideration when there is a strong family history of CHD, onset of CHD is premature, or in the case of a patient with CHD but no identifiable risk factors. **Updated: 2/13/03**

CHAPTER 16 BACTERIAL ENDOCARDITIS PROPHYLAXIS

Once universally fatal, bacterial endocarditis remains a serious disease, with a mortality rate of about 25 percent. The pathogenesis of endocarditis suggests that individual infections might be prevented by judicious use of prophylactic antibiotics, yet the incidence of this infection has not changed much despite the widespread availability of antibiotics. Recent data even question the effectiveness of prophylaxis, at least among patients undergoing dental procedures. The primary care provider must understand the evidence for benefit and accurately assess individual risk in order to properly apply recommendations for prophylaxis. Patient education is essential to ensure compliance.

EPIDEMIOLOGY AND RISK FACTORS

During the past several decades, there has been a shift in the incidence of endocarditis to older age groups; the current mean age is about 50 years. Men predominate in those over 50; under 50, the gender ratio is more nearly equal.

Risk Factors. Individual risk of endocarditis is typically viewed as a function of cardiac and procedural risk factors (see Table 16.1, Table 16.2 and Table 16.3). However, up to 30% of cases of endocarditis occur in the absence of underlying heart disease, and spontaneous transient bacteremia confers greater cumulative risk among susceptible individuals than do procedures. Clearly, all individuals have some finite risk of developing endocarditis. Because of the difficulty in predicting who is most susceptible and when, it has been estimated that no more than 6% of endocarditis cases can be prevented. Nonetheless, the morbidity and mortality of endocarditis are sufficient justification to advocate preventive measures for patients at substantial risk.

1. High Risk
   a. Prosthetic heart valve(s)
   b. History of endocarditis
2. Moderate Risk
   a. Rheumatic or other acquired valvular disease
   b. Congenital heart disease (excluding atrial septal defect of the secundum type)
   c. Idiopathic hypertrophic subaortic stenosis
3. Probable Moderate Risk
   a. Mitral valve prolapse
   b. Undiagnosed murmurs

Table 16.1. Cardiac Risk Factors for Endocarditis

EVENT	INSTANCES IN WHICH BACTEREMIA OCCURS (%)
Dental extraction	75
Tooth brushing, flossing, or irrigation	
Normal gingiva	20
Gingivitis	50
Bronchoscopy	
Fiberoptic	<1
Rigid	15
Fiberoptic endoscopy	10
Sigmoidoscopy	5
Barium enema	10
Liver biopsy	5
Transurethral resection of prostate	
Sterile urine	10
Infected urine	50

Table 16.2. Common Events Predisposing to Bacteremia

Respiratory tract
   Tonsillectomy and/or adenoidectomy
   Surgical operations that involve respiratory mucosa
   Bronchoscopy with a rigid bronchoscope
Gastrointestinal tract
   Sclerotherapy for esophageal varices
   Esophageal stricture dilation
   Endoscopic retrograde cholangiography with biliary obstruction
   Biliary tract surgery
   Surgical operations that involve intestinal mucosa
Genitourinary tract
   Prostatic surgery
   Cystoscopy
   Urethral dilation

Table 16.3. Other Events and Procedures

Cardiac. In the preantibiotic era, chronic rheumatic heart disease was the underlying lesion in up to 90% of endocarditis cases. Now prosthetic cardiac valves, previous endocarditis (recurrence rate as high as 10%), complex congenital heart disease, and surgically constructed pulmonary shunts are the high-risk cardiac lesions (see Table 16.1). Moderate risk is associated with other cardiac anomalies (see Table 16.2). However, as noted, endocarditis can occur without known predisposing cardiac disease. Prosthetic-valve endocarditis may be early, usually associated with surgery and most often involving nosocomial pathogens (eg, staphylococci). Late disease occurs after procedures that induce bacteremia and typically involves bacteria of low virulence that are rarely able to infect damaged natural valves. Prosthetic valve endocarditis is a serious condition; overall mortality is substantial, even with antibiotics and valve replacement.

Procedural. Data on incidence of bacteremia with procedures are fragmentary at best, but risk appears greatest with dental procedures. Tooth extraction and periodontal surgery have incidence rates of about 50 percent; other dental procedures approach that figure. Endocarditis risk is minimal with coronary artery bypass graft surgery or placement of pacemakers or implanted defibrillators. Some nondental procedures also have a substantial incidence of subsequent bacteremia, but others have little (see Table 16.2, Table 16.3).

NATURAL HISTORY OF ENDOCARDITIS AND EFFECTIVENESS OF THERAPY

Natural History. Untreated endocarditis is uniformly fatal. Current mortality rates are approximately 10 percent with natural valves and 25 percent to 65 percent with

prosthetic valves. Death often follows congestive heart failure, arterial emboli, myocardial infarction, myocardial abscesses, or other complications.

Effectiveness of Therapy. The best estimates of protective efficacy for antibiotic therapy derive from case-control studies and range from 48% to 91%. There are no data from prospective trials, in part because of the very large number of patients needed and difficulties in identifying patients at risk and detecting transient bacteremias. Most recommendations for prophylactic antibiotic regimens are based primarily on experience with experimental animal models.

RISK OF PROPHYLACTIC THERAPY

For penicillin prophylaxis, the risk of serious reaction is very small in patients without previous allergy or a history of rheumatic fever–about 1 to 4 per 100,000. The risk of death caused by serious penicillin reaction has been estimated at 1 to 2 per 100,000 patients receiving the drug. Less information is available concerning risks associated with other prophylactic antibiotics, including amoxicillin, which is now recommended because it is better absorbed from the gastrointestinal tract and provides higher and more sustained serum levels. Surveys have identified very few serious reactions to other oral regimens, including clindamycin. Even with parenteral regimens including aminoglycosides, there is little toxicity when the drug is given for the brief period necessary for adequate prophylaxis.

IDENTIFYING PATIENTS AT RISK

An individual's risk of procedure-related endocarditis can be estimated by checking for important heart disease (see Table 16.1) and taking into account the likelihood of a procedure-related bacteremia (see Table 16.2, Table 16.3). A history of congenital or rheumatic heart disease and presence of a murmur indicative of hemodynamically significant disease indicate substantial risk. Echocardiographic documentation of hypertrophic cardiomyopathy or the presence of valve calcification can also be considered an indication for prophylaxis.

The most difficult cases are those where risk appears to be intermediate, as with mitral valve prolapse or with an isolated systolic murmur without a helpful history or other cardiac findings (see Chapter 21). Bacterial endocarditis prophylaxis for this group is controversial. Risk-benefit analyses suggest that expected morbidity and mortality associated with penicillin therapy outweigh the benefits of prevention. Nevertheless, many clinicians continue to recommend prophylaxis. The American Heart Association currently recommends prophylaxis for patients with mitral valve prolapse only if there is evidence of significant valvular regurgitation.

Endocarditis prophylaxis is recommended for those in the high and moderate-risk categories (see Table 16.1). It is not recommended for those in the negligible-risk category (no greater risk than the general population). It should be kept in mind that the absolute risk of endocarditis, even for the high-risk patient is extremely low (eg, <1 case per 1000 tooth extractions).

CONCLUSIONS AND RECOMMENDATIONS

Clinical effectiveness of endocarditis prophylaxis is difficult to demonstrate definitively. However, when the serious morbidity and mortality associated with the disease are weighed against the small risk associated with prophylaxis, vigorous preventive efforts have been considered justified. Identifiable risk varies with the type of heart abnormality and the event responsible for bacteremia, as summarized in Table 16.1, Table 16.2, and Table 16.3.

Consensus recommendations for prophylactic regimens have been revised to maximize compliance and efficacy (see Table 16.4 and Table 16.5). The absence of evidence for an association between dental procedures and subsequent endocarditis will likely stimulate reconsideration of these recommendations.

Table 16.4. Prophylactic Regimens for Dental, Oral, Respiratory Tract, or Esophageal Procedures

Table 16.5. Prophylactic Regimens for Genitourinary Gastrointestinal (Excluding Esophageal) Procedures

As in all preventive efforts, patient education is extremely important. All patients with identifiable risk should be urged to maintain a high level of oral health to minimize the potential for recurrent bacteremia. Patients receiving rheumatic fever prophylaxis must understand that their continuous therapy will not protect them from endocarditis.

CHAPTER 17 RHEUMATIC FEVER PROPHYLAXIS

Despite a decline in incidence that began before the availability of antibiotics, rheumatic fever and rheumatic heart disease remain significant causes of preventable morbidity. Localized resurgences occurred in the United States during the early 1990s and equally affected adults and children and the well-to-do and the disadvantaged. Primary prevention depends on appropriate diagnosis and effective treatment of group A streptococcal pharyngitis (see Chapter 220). Vaccination against streptococcal infection may be possible in the future, but current preventive measures depend on discriminating antibiotic use.

The prophylactic use of antibiotics has been shown to be effective for primary prevention during epidemics among closed populations. The major role of antibiotic prophylaxis, however, is in prevention of second attacks. The risk of recurrence after streptococcal infection is especially high in patients with evidence of carditis. Continuous streptococcal prophylaxis in patients with prior rheumatic fever is the major means of preventing the cardiac sequelae of rheumatic fever recurrences. It is the task of the primary physician to identify patients who would benefit from such prophylaxis and to provide the instruction necessary for long-term adherence.

EPIDEMIOLOGY AND RISK FACTORS

The epidemiology of rheumatic fever parallels that of streptococcal infection. Rare in children younger than 5 years of age, it is most common in older children and adolescents. Incidence decreases after adolescence; cases after age 40 are very rare. There is no clear predilection for either sex.

Although a genetic predisposition has not been proven, an association between certain human leukocyte antigens and rheumatic diseases has been identified, at least among white patients. Heterogeneity in the immune response to a specific streptococcal cell-wall antigen, the group A carbohydrate, has been demonstrated, but predictors of the hyperimmune response associated with the clinical sequelae of rheumatic fever have not been identified.

Racial differences in the incidence of rheumatic fever exist but disappear when socioeconomic status is considered; crowded living conditions is an important variable. Crowding may also explain the high incidence in cold climates and during winter months in temperate climates.

All demographic risk factors are heavily outweighed by a previous history of rheumatic fever. The likelihood of an attack after streptococcal infection is at least five times higher among individuals with previous rheumatic fever.

NATURAL HISTORY OF RHEUMATIC FEVER AND EFFECTIVENESS OF THERAPY

Rheumatic fever follows between 0.5% and 3.0% of ineffectively treated cases of group A streptococcal upper respiratory infections.Diagnosis and appropriate antibiotic therapy will prevent rheumatic fever in the individual case, but such efforts cannot be expected to eliminate rheumatic disease because of the high proportion of streptococcal infections that are subclinical. Approximately one third of patients with primary rheumatic fever have no history of preceding respiratory infections. Another one third have symptoms but do not seek medical care. The remainder are ineffectively diagnosed or treated.

Among all patients with group A streptococcal infection and a history of previous rheumatic fever, the recurrence rate is 15%. More specific rates can be estimated for subgroups depending on the number of previous rheumatic attacks, the interval since the last attack, and whether or not there was evidence of carditis. Specific attack rates are summarized in Table 17.1.

	RECURRENCES OF STREPTOCOCCAL INFECTION (%)
Interval Since Onset of Last Rheumatic Episode	
Up to 2 yr	26
2–5 yr	15
5 yr and over	10
Number of Previous Attacks of Rheumatic Fever	
2 or more	27
1	14
Rheumatic Heart Disease	
Not present	13
Present	26

Modified from Spagnuolo M, Pasternack B, Taranta A, et al. Risk of rheumatic fever recurrences after streptococcal infections. N Engl J Med 1971;285:641.

Table 17.1. Risk of Recurrent Rheumatic Fever After Group A Streptococcal Infection

Because of these high secondary attack rates and the ubiquity of the streptococcus, *continuous* antibiotic prophylaxis of streptococcal infection is the only feasible method of preventing rheumatic fever recurrences. Three antibiotic regimens have gained general acceptance:

1. Benzathine penicillin G, 1,200,000 units IM every 3 or 4 weeks;
2. Sulfadiazine, 1 g/d PO (500 mg for patients weighing less than 60 pounds);
3. Penicillin G, 250 mg PO twice a day.

Although the effectiveness of erythromycin (250 mg PO twice a day) has not been studied, it is recommended for the rare patient allergic to both penicillin and sulfonamides. The classic study comparing the effectiveness of these three regimens in preventing streptococcal infection and rheumatic fever is summarized in Table 17.2. Some reports suggest that failure rates may be higher when benzathine penicillin injections are administered every 4 weeks rather than every 3. Because adherence is more difficult with the greater frequency, some have suggested doses of 1,800,000 units or even 2,400,000 units depending on weight, but further study is needed.

Table 17.2. Prophylaxis and Attack Rates of Streptococcal Infection and Rheumatic Fever Recurrences

There are no firm guidelines regarding the duration of continuous antibiotic prophylaxis after an episode of rheumatic fever. Factors that influence the likelihood of rheumatic recurrence after infection have already been reviewed. Within limits, the physician can estimate the risk of exposure of a particular patient to streptococcal infection. For example, parents of young children, teachers and other school personnel, health care providers, and military personnel are at high risk.

RISKS OF ANTIBIOTIC PROPHYLAXIS

The risks of penicillin administration are discussed in Chapter 16 on endocarditis prophylaxis. It should be emphasized that, in a large series, reactions after parenteral administration were no more common than those after oral therapy.

CONCLUSIONS AND RECOMMENDATIONS

- Primary prevention of rheumatic fever depends on accurate diagnosis and treatment of symptomatic streptococcal upper respiratory infections. Prevention of rheumatic fever recurrences depends on continuous streptococcal prophylaxis of the patients at risk.
- Injections of benzathine penicillin G (1,200,000 units IM) every 3 or 4 weeks provide the most effective prophylaxis and are recommended in patients with a high risk of both streptococcal exposure and a rheumatic recurrence after infection. Acceptable oral regimens in patients at lower risk include sulfadiazine, 1 g/d PO; *or* penicillin G, 250 mg PO twice daily; *or* erythromycin, 250 mg PO twice daily (in patients allergic to both penicillin and sulfa drugs).
- The duration of prophylaxis should be based on the risk incurred by the particular patient.
- All patients with rheumatic fever should be treated until age 25 or for 5 years after an episode (whichever is longer). In those with two or more previous attacks or with rheumatic heart disease, therapy should be continued until age 40 or for 10 years after the last episode. Prophylaxis in patients with rheumatic heart disease at high risk of streptococcal exposure should be continued indefinitely.

CHAPTER 18 EXERCISE FOR PREVENTION OF CARDIOVASCULAR DISEASE

HARVEY B. SIMON

When performed regularly and properly, exercise has a powerful protective effect against coronary artery disease, effective for both primary prevention and secondary prevention. Exercise also provides significant benefits for many of the chronic diseases that affect American society, including hypertension, stroke, type 2 diabetes, osteoporosis, and common cancers (e.g., colon, breast, female reproductive tract). Despite these benefits, only about 22% of American adults exercise at recommended levels. Sedentary living imposes a relative risk of dying from coronary artery disease of 1.9. The magnitude of this excess relative risk approaches that of smoking (2.5), elevated cholesterol (2.4), and hypertension (2.1). Because sedentary living is to two to three times more prevalent than any of these other risk factors, it can be argued that physical inactivity is the single largest contributor to the epidemic of coronary artery disease. About 250,000 excess deaths in the United States each year can be attributed to lack of exercise.

The primary care physician can have a powerful motivating effect on patients by educating them about the benefits and approaches to exercise. One needs to identify those patients at risk for exercise-induced complications and prescribe a personalized exercise program that is safe and effective. Also important is identification, initial treatment, and appropriate referral of exercise-related problems.

PHYSIOLOGY AND CLINICAL EFFECTS OF EXERCISE

Physiology

Physical work may involve either *aerobic* or *anaerobic* metabolism, and it may rely on either isotonic or isometric muscular activity. Energy must be generated continuously during exercise, because the total amount of stored ATP in muscles can sustain only 10 seconds of maximal exertion. The production of new ATP requires metabolism of muscle glycogen. The availability of oxygen determines whether this metabolism will be aerobic or anaerobic. When oxygen supply is adequate, metabolism is aerobic and glycogen is completely metabolized to pyruvate and then to water and CO_2 through the Krebs cycle.

With increasing exercise intensity, the ability of the lungs to take up oxygen and of the heart and blood vessels to deliver it to muscle cells is exceeded, and metabolism becomes anaerobic. The costs of anaerobic metabolism are substantial. Anaerobic metabolism is inefficient; it generates only one third as much energy from each gram of glycogen, and it increases production of lactic acid, resulting in muscle cramps, fatigue, and dyspnea. Lactic acid is buffered by bicarbonate, resulting in increased CO_2 production and hyperventilation. Clinically, an abrupt rise in respiratory rate indicates that the anaerobic threshold has been crossed. Endurance training can be expected to increase the anaerobic threshold, thus allowing more work to be performed under favorable aerobic conditions.

Aerobic and Anaerobic Exercise. The goal of training is to improve cardiovascular function and muscular efficiency. The type of exercise is critical. Although maximal exertion (used in anaerobic training) is beneficial to certain competitive athletes, the cornerstone of training for fitness is endurance or *aerobic exercise* using large muscle groups in continuous rhythmic activity for prolonged periods. *Jogging and brisk walking* are ideal for this. Other good training activities include *bicycling, swimming, cross-country skiing, rowing*, and *rope jumping*. These activities provide *isotonic exercise* whereby skeletal muscle fibers shorten in length with little change in tension. Heart rate and cardiac output increase, but peripheral vascular resistance falls.

In contrast, sports that depend on very brief bursts of intense activity, such as weight lifting, provide *isometric exercise* in which muscle tension increases with little change in fiber length. Such exercise produces a marked increase in peripheral vascular resistance and blood pressure with little increase in cardiac output. Aerobic power does not increase with isometric exercising, and the hypertensive response can be hazardous to patients with cardiovascular disease. Because arm work has a greater tendency to produce tachycardia and hypertension than does an equivalent degree of leg work, it is particularly important to limit the resistance level in arm exercises for patients with hypertension or heart disease.

Sports that allow prolonged periods of inactivity, such as baseball or golf, are poor for cardiopulmonary conditioning. Similarly, although activities providing sustained but gentle muscular effort, such as yoga, can be important parts of a fitness program because they are excellent for promoting flexibility and strength, they are poor tools for attaining cardiopulmonary fitness.

Effects of Exercise

The effects of regular exercise can be classified in terms of cardiovascular, musculoskeletal, metabolic, and psychological functions. Regular endurance-type exercise improves cardiovascular performance and tends to lower blood pressure, body fat, weight, and serum triglycerides while elevating serum high-density lipoproteins. Physical fitness may also assist in the psychological response to stress.

Cardiovascular. The most thoroughly documented results of aerobic exercise concern changes in cardiovascular performance. Exercise requires an increase in the body's oxygen consumption, which is made possible by increased oxygen uptake by pulmonary ventilation, increased oxygen delivery by the heart and the peripheral circulation, and increased oxygen extraction by muscle. Endurance training enhances the efficiency of these processes by both central and peripheral mechanisms. At rest and at submaximal work loads, the fit individual has a slower heart rate than does the untrained person. Stroke volume is increased so that cardiac output for a given work load is unchanged. Although the achievable maximum heart rate is not increased by training, the maximum cardiac output and maximum oxygen consumption are greatly enhanced so that the well-trained individuals can both attain higher work loads and sustain them for longer periods before becoming exhausted.

Although there is little firm evidence that exercise increases myocardial oxygen supply or produces collateral vascularization in humans, *myocardial oxygen demand* for a given work load *decreases*. This diminution in myocardial oxygen consumption is made possible by the lower heart rate and lower systolic blood pressure that accompany exercise in the fit individual. This can be of particular benefit to the patient with angina, as this "double product" of heart rate × blood pressure determines the angina threshold (see Chapter 30). In addition, animal studies have demonstrated increased coronary artery cross-sectional area, increased myocardial capillary density, and myocardial hypertrophy in rats and dogs forced to exercise.

The peripheral effects of repetitive isotonic exercise are also of great importance in endurance training. *Capillary blood flow* to muscle is increased. Muscle fibers increase in volume, and muscle strength and endurance are enhanced. Muscle mitochondria increase in size and number, and respiratory enzymes increase. As a result, muscle oxygen extraction is improved. Training also improves neuromuscular coordination and musculoskeletal efficiency.

Another important cardiovascular effect of exercise is on *blood pressure*. Systolic pressure normally increases during aerobic exercise, but this rise tends to be slightly less in the fit individual. More important, total peripheral resistance decreases as a result of improved muscle blood flow and decreased circulating catecholamine levels. The net result in trained individuals is lower blood pressure, both during exercise and at rest. Because this effect is actually more prominent in hypertensive subjects, endurance training can be an important nonpharmacologic treatment for the control of mild to moderate hypertension (see Chapter 26).

Less well-established cardiovascular benefits of exercise training include a possible *diminution of arrhythmias*, perhaps because of lower catecholamine levels. In addition, exercise increases *fibrinolytic activity* and decreases platelet adhesiveness; these hematologic effects may, to some degree, protect against atherogenesis. In these areas, too, the data are preliminary. The effects on cardiovascular morbidity and mortality can be marked (see below).

Metabolic. The metabolic benefits of exercise are well documented. *Weight control* is an important motivating factor for many runners. An average jogger can be expected to consume about 600 calories in an hour of running. Other endurance activities have similar effects (Table 18.1). Although exercise alone will produce only

a slow reduction in total body weight, the percentage of body fat decreases more rapidly, resulting in visible increases in muscle tone. Perhaps most important, fit people often become motivated to adhere to dietary patterns that will permit sustained weight control.

Table 18.1. Approximate Metabolic Expenditures Associated with Selected Activities[a]

Another metabolic effect of great interest is that of regular exercise on the blood lipids. In many runners, serum *triglyceride* levels fall dramatically without changes in the dietary intake of fats or carbohydrates. The total *cholesterol* level changes less predictably, but *high-density lipoprotein* levels are reliably increased by aerobic exercise, and these higher levels correlate with a lower risk for coronary artery disease (see Chapter 15).

Several population studies demonstrate that sedentary living increases the risk of developing *glucose intolerance* and *type 2 diabetes* and that good cardiorespiratory fitness reduces risk. The risk associated with lack of exercise appears independent of other known risk factors.

Psychological. Most individuals who engage in regular exercise develop an *improved self-image*. This can be of great importance in the rehabilitation of patients with ischemic heart disease (see Chapter 31) and can also be used to help motivate healthy individuals to modify other risk factors by following a prudent diet and discontinuing smoking. The recreational aspects of exercise tend to lessen anxiety and depression. Running is being studied as a tool for the treatment of depression, and early results in small groups of patients are encouraging. Nevertheless, the so-called runner's high proves elusive or illusionary for many joggers. Although exercise has many psychological benefits, it is hardly a panacea. Patients can be encouraged to exercise for both psychological and physical gains, but they must have realistic expectations.

Morbidity and Mortality. Because of its amelioration of many cardiovascular risk factors, it would seem reasonable to expect regular exercise to *reduce risk of cardiovascular morbidity and mortality*. Although there are no data from prospective, randomized, controlled studies to allow a definitive conclusion about cause and effect, numerous observational and epidemiologic studies carefully quantifying exercise, documenting cardiovascular fitness, and controlling for most confounding factors demonstrate an inverse relationship between amount of physical activity and cardiovascular morbidity and mortality. However, such studies cannot rule out the possibility that *genetic factors* and *self-selection* might account for some of the benefit observed, that is, if healthy people tend to exercise more, then the reduced mortality in active people may related to underlying factors rather than to the exercise per se.

The best *evidence* against genetic factors and self-selection as the predominant causes for the observed benefit of exercise derive from epidemiologic studies. The Finnish Twin Cohort study revealed a reduction in mortality risk of 34% for occasional exercisers and of 56% for conditioned exercisers compared with their genetically identical twins who were sedentary. In a study of Harvard alumni that included those who participated in varsity sports, sedentary men were at a 64% higher risk for a first myocardial infarction than were classmates who expended at least 2,000 kcal/wk in exercise. Varsity sports participation (a marker of initial fitness and genetic endowment) conferred no protective effect unless exercise was continued in later years.

Maintaining a physically active life-style can be expected to reduce the risk of myocardial infarction by 35% to 70%. Whereas exercise is most effective when commenced early in life, physical activity confers benefit even if initiated later in life. In the Harvard alumni study, men who began to exercise in middle age enjoyed a 23% reduction in mortality compared with their peers who remained sedentary. British investigators noted that the initiation of even light to moderate exercise can reduce all cause mortality by 45%, even after adjusting for potential confounders. Among adult residents of Kings County, Washington, gardening for more than 60 minutes a week was associated with a 68% lower risk of primary cardiac arrests and walking with a 73% risk reduction as compared with sedentary individuals. Among elderly men, walking more than 2 miles a day reduces the mortality rate by nearly 50% compared with those who walk less than 1 mile per day.

Most data regarding the benefits of exercise pertain to men. The best data pertaining to the effects of exercise for primary prevention of coronary events in women derive from the Nurses' Health Study, involving over 72,000 female nurses aged 40 to 65 years who were free of coronary disease and followed for 8 years. There were 645 coronary events (death or nonfatal infarction), with an inversely progressive relationship found between amount of exercise (expressed as energy expenditure)and age-adjusted relative risk of coronary events. Compared with those in the lowest exercise quintile, the range of relative risk was 0.77 to 0.46, with the later figure for those in the highest exercise quintile. Those who engaged in moderate exercise (walking 20 min/mile for 3 or more hours per week) had the same degree of risk reduction (about 35%) as those who engaged in more vigorous forms of exercise. Persons who were previously sedentary and became active in middle adulthood reduced their relative risk.

Although these studies concentrate on the role of exercise in the *primary prevention* of cardiovascular disease, attention is also being directed to the role of physical training in the treatment of patients with established atherosclerotic heart disease (*secondary prevention*). Independent meta-analyses of prospective trials of exercise in the treatment of coronary artery disease demonstrated a 20% to 25% decrease in overall mortality in the exercise group; fatal reinfarction and total cardiovascular deaths were also significantly reduced in the exercise group, but nonfatal reinfarctions were no different in the exercise and control groups.

Other Benefits. Although the greatest protective effect of exercise is on the cardiovascular system, reducing the risk of heart attack, sudden cardiac death, stroke, and hypertension, there are other important benefits of habitual exercise. Women who begin exercising in early adulthood experience nearly a 50% reduction in their lifetime risk of *breast and reproductive cancer*. Physically active men have a significantly lower risk of *colon cancer*. Exercise increases bone density, helping to prevent *osteoporosis*. Patients with *chronic obstructive lung disease* and *peripheral vascular disease* report symptomatic and functional improvements.

MEDICAL SCREENING OF POTENTIAL EXERCISERS

Medical screening of the prospective participant and prescription of an appropriate exercise program are essential for the person who has been inactive. In addition, we recommend that all adults planning to engage in vigorous activity (including young persons who want to participate in competitive athletics) are screened for underlying heart disease before beginning. The goal is to reduce the risk of sudden cardiac death. Any decision to restrict a young person from engaging in competitive sports or other vigorous activity should be based on firm evidence, because of the potentially devastating social and psychological impacts the restriction may have. A cardiac consultation is warranted for young persons the primary care physician deems in need of restriction.

The initial screening effort does not need to entail elaborate laboratory testing, but a careful and detailed *cardiovascular history* and *physical examination* are essential. The value of the *resting electrocardiogram* (ECG) for detection of coronary disease in asymptomatic healthy persons is nil, but the test is warranted in asymptomatic young persons who plan to engage in competitive athletics for its ability to detect conduction, rhythm, voltage, and repolarization anomalies that might be tip-offs to important underlying myocardial disease. Even *exercise stress testing* for detection of silent coronary disease is of limited utility in healthy asymptomatic persons but should be considered in those with coronary risk factors (see below).

What to Look For

Silent coronary disease is obviously the major concern for men over the age of 45 years and for menopausal women seeking to start an exercise program (see Chapter 30). When evaluating younger persons who seek to engage in competitive athletics, it is important to check not only for the *major valvular diseases* (e.g., *aortic stenosis, mitral stenosis*, and *mitral valve prolapse*, see Chapter 21 and Chapter 33) and rhythm disturbances (see Chapter 25), but also for *hypertrophic*

cardiomyopathy and *arrhythmogenic right ventricular cardiomyopathy*, two uncommon often unsuspected conditions that are important causes of sudden death in competitive athletes. The presence of any one of these conditions may be relatively silent or heralded by such findings as palpitations on exertion, syncope or near syncope, lightheadedness, exertional dyspnea chest discomfort, a family history of heart disease or of sudden cardiac death, voltage and ST- and T-wave abnormalities on ECG, and atrial or ventricular premature beats or frank dysrhythmias. A high index of suspicion is warranted.

Hypertrophic cardiomyopathy may be mistaken for the "*athlete's heart*," seen in persons who engage in strenuous anaerobic exercise. However, a history of effort syncope or near syncope, a family history of cardiac sudden death, a systolic heart murmur that increases with maneuvers that decrease left ventricular volume (see Chapter 21), and marked increase in voltages, prominent Q waves, and deep negative T-waves on resting ECG should make one suspicious of hypertrophic disease. Cardiac ultrasound is required. Diagnostic findings differentiating this condition from athlete's heart include asymmetric wall thickening, involvement of the right and left ventricular, total wall thickness greater than 13 mm, and outflow tract obstruction. Heavy exertion should be restricted and a cardiac consultation obtained.

Arrhythmogenic right ventricular cardiomyopathy is rare but as noted above has been found to be an important cause of arrhythmogenic death in younger persons who engage in competitive sports. Suggestive findings include a family history of sudden cardiac death, palpitations on exertion, inverted T-waves in the right precordial leads on ECG, and ventricular premature beats with a left-bundle-branch pattern.

Anomalous origin of coronary artery is another leading cause of sudden death in athletes. It is typically asymptomatic and difficult to detect premorbidly.

History. The first step in medical screening is obtaining a detailed personal and family history. Each patient should be carefully questioned about symptoms that suggest cardiovascular disease, including chest pain, palpitations, dyspnea, undue fatigue, syncope, and claudication. It is very important to review health habits in detail, with special attention to previous exercise patterns, smoking, diet, and the use of oral contraceptive agents. Of particular importance in the family history is the presence of coronary heart disease, peripheral vascular disease, hypertension, stroke, diabetes, or sudden death.

Physical Examination. A complete physical examination is also vital to the medical screening of the prospective exerciser. Height and weight should be recorded, and it may be useful to calculate the body mass index or to measure the percent body fat (see Chapter 10). The blood pressure is taken at rest with thepatient supine and standing, and the heart rate and pressure are recorded after mild exercise (stair climbing or sit-ups are satisfactory for this purpose). The chest is examined for rales, wheezes, and rhonchi and the heart for cardiomegaly, gallops, murmurs, and rhythm disturbances. The peripheral pulses and abdomen should be palpated to exclude atherosclerotic disease and an aortic aneurysm. The musculoskeletal system should be evaluated both to exclude significant pathology and to determine whether specific flexibility or strengthening exercises are required as part of the training program.

Laboratory Studies. Several laboratory studies are helpful in the screening process. Screening for atherosclerotic risk factors is essential (glucose, lipid profile). Also useful are checks of serum hemoglobin and creatinine. For patients older than 40 years of age (especially those with cardiac risk factors or a family history of heart disease), a *resting ECG* is helpful to check for ischemia, left ventricular hypertrophy, and disturbances of rate and rhythm. Young persons who are going to engage in competitive athletics and who have a history of heart murmur, palpitations, dyspnea, undue fatigue, syncope, lightheadedness, or a family history of sudden death, premature heart disease, or dysrhythmias might also benefit from a resting ECG.

If any of these screening procedures discloses evidence suggesting heart disease, then *exercise stress testing* is mandatory before an exercise program is initiated. Even if preliminary screening reveals no evidence of heart disease, stress testing may be helpful for asymptomatic patients with multiple cardiac risk factors, especially if they have been sedentary. Some argue that stress testing may be a prudent precursor in men older than 50 years of age and in women older than 60 years of age who are considering a vigorous exercise program, even if they are asymptomatic and apparently healthy, because atherosclerotic heart disease is so prevalent in our society. However, it must be remembered that stress testing has a very low predictive value in persons with a low pretest probability of coronary artery disease (see Chapter 36). In persons with a history of palpitations or symptoms of lightheadedness, stress testing and *Holter monitoring* may be useful for uncovering exercise-induced arrhythmias and hypotension. Other uses of stress testing are to evaluate the individual's exercise capacity and establish the maximal and target heart rates for use in the exercise prescription. *Echocardiography* is indicated if there is a heart murmur on physical examination (see Chapter 21).

In special cases, additional studies may be desirable, such as forced expiratory volume in 1 second, vital capacity, and arterial blood gases in patients with subjective dyspnea or suspected pulmonary disease. Specialized ergometric testing can determine maximal oxygen consumption, total work capacity, and other physiologic parameters.

Classification. Medical screening and exercise testing allow the physician to assign each patient to one of three categories:

1. *No restrictions, no supervision*: Individuals with normal studies who can undertake an exercise program without medical supervision. Even in these healthy people, individualized exercise prescriptions and guidance regarding training techniques and safety precautions will be of great value.
2. *Some restrictions, some supervision*: Patients with ischemic heart disease, moderate hypertension, or moderate chronic obstructive lung disease will benefit from graded exercise programs, but they should be referred to a specialized exercise rehabilitation program that can provide medical supervision and facilities for emergency treatment. However, if structured rehabilitation is not available, milder forms of exercise without medical supervision can still be recommended (e.g., walking, stationary bicycling) with appropriate precautions.
3. *Marked restrictions or exclusion, marked supervision*: Physical exertion is contraindicated in the presence of uncontrolled congestive heart failure, ventricular irritability, uncontrolled hypertension, unstable diabetes, or uncontrolled epilepsy, although patients with these conditions can sometimes be enrolled in supervised programs if they respond to medical therapy. Patients with left ventricular or aortic aneurysms or hemodynamically significant aortic valve disease should be excluded from exercise programs.

EXERCISE PRESCRIPTION

Role of the Primary Physician. People can exercise for recreation, for health, or for fitness and sports competition. The primary care physician has an important role in encouraging and counseling exercise. The objective is to help the patient find a form and amount of exercise that will be safe, beneficial, enjoyable, and carried out over a prolonged period of time. Imposing a program of exercise is much less effective in achieving sustained compliance than finding out what the patient is willing and interested in doing. Helping the patient to incorporate an exercise program into a busy life-style is critical. Whereas formal workouts are essential for optimal fitness and physical performance, modest levels of physical activity during daily life have important health benefits (see above). Life-style interventions appear to be as effective as formal exercise programs of similar intensity in improving cardiovascular fitness, blood pressure, and body fat composition.

Primary care physicians should encourage all patients who are capable of physical activity to exercise nearly every day; simply walking for 30 to 45 minutes can reduce cardiovascular risk significantly. For patients who are interested and capable, the physician should be prepared to prescribe a program of fitness training.

Fitness Program. The basic elements include frequency, intensity, and duration of exercise.

A *frequency* of three exercise sessions per week are required to develop and maintain fitness, and five sessions per week probably provide near maximum benefit. Hence, the exercise prescription should call for at least three workouts each week. Many individuals prefer a routine of daily activity; this is an excellent program, but it is advisable to schedule easier and harder workouts on alternate days to prevent injuries and allow the muscles to recover.

The *intensity and duration* of training are closely related. Equal degrees of fitness can be attained through less intense exercise sustained over a longer period or through more vigorous effort for shorter periods. Maximum cardiopulmonary fitness can be attained by 15 to 60 minutes of continuous aerobic exercises that are strenuous enough to raise the heart rate to 60% to 80% of maximum or the oxygen uptake to 50% to 85% of maximum. However, as pointed out by the results of theNurses' Health Study, maximum reductions in coronary risk need do not necessarily require attainment of maximum cardiopulmonary fitness. Moderate degrees of exercise appear to provide the same degree of protection as vigorous activity, at least in middle-aged women.

Optimal fitness goals must be attained very slowly and gradually, and the physician's exercise prescription should provide a practical means of attaining them. Both the starting point and the rate of progression depend on the health, age, and fitness of the participant. As a rule of thumb, the beginner should plan to exercise aerobically for 10 to 12 minutes at a pace sufficient to increase heart rate to 60% to 80% of maximum without producing breathlessness.

Each aerobic workout session begins with a 5- to 10-minute *warm-up period*. At the beginning of exercise, even the well-conditioned athlete experiences some degree of dyspnea due to anaerobic metabolism. It takes 45 to 90 seconds for cardiac output to increase enough to meet the new work load and provide the "second wind." A

warm-up period will minimize this initial anaerobic period and also allow muscles to loosen and stretch out, which prevents many injuries. For the runner, the warm-up period should consist of stretching exercise, calisthenics, and a gradual progression from walking to slow jogging to running.

The actual *training period* should initially consist of a total of 10 to 12 minutes of exercise. At first, it is best to alternate periods of effort with periods of recovery. This is easily accomplished by alternating full intensity exercise with low intensity exercise. For example, an unfit or older individual might alternate 1 minute of full exercising with 1 minute of gentle exercise, repeating this cycle 10 to 12 times during each training day. When this can be accomplished with comfort—perhaps at the end of 10 to 20 sessions over 2 to 3 weeks—the schedule can be advanced to 2 minutes of full exercise alternating with 2 minutes of gentle exercise, with six cycles in each session. After this is mastered, the exercise ritual can be extended to 3 or 4 minutes with only 1 or 2 minutes of rest for three or four cycles and then to two 6-minute runs with 1 or 2 minutes of walking in between. By the end of 1 or 2 months, most individuals can expect to be able to exercise for 10 to 20 minutes continuously.

Although the young and athletic person will progress more rapidly than the older or unfit one, it is important to urge restraint. One of the most common causes of orthopedic injuries is attempting too much too quickly. Once a base of 10 to 20 minutes of exercise is well established, further progress can be encouraged. It is reasonable to increase time or distance by a rate of about 10% per week. This can be accomplished by extending one or two sessions while preserving some short distance days or by gradually extending each session. At the end of 4 to 6 months, 3 to 4 miles of jogging or equivalent exercise 3 to 5 days per week will provide maximum conditioning. This level must be maintained to sustain the cardiopulmonary benefits of exercise. Feelings of accomplishment and well-being usually provide motivation for sustained participation, often at even higher levels. As little as 20 minutes of aerobic exercise three times per week is beneficial, but 3 to 4 hours of exercise per week provides the maximum longevity benefits.

In addition to the duration of exercise, the *intensity or pace* of exercise requires consideration. The most precise readily available measure of intensity is the *heart rate*. Patients should work at a pace sufficient to raise the pulse to 60% to 80% of maximum. If exercise testing has been performed, an observed maximal heart rate can be used for this calculation. In the absence of such data, the maximal heart rate can be estimated for healthy individuals by subtracting the age from 220. As a rough guide, the target of 60% to 80% of this maximum translates to 130 to 150 beats per minute for younger persons and to 110 to 125 beats per minute for older ones. Patients can be taught to count their carotid or radial pulse just before and immediately after exercise and to adjust their pace to attain and maintain the target heart rate. It can be very helpful to have patients keep a daily record of these figures together with the time and approximate distance covered. As training progresses, a more rapid pace will be required to achieve the target heart rate.

Many people find it difficult or unpleasant to take their pulse. For such persons, intensity of effort can be roughly gauged by the "*talking*" *pace*—the intensity sufficient to feel one is working hard while still able to talk to a companion without feeling dyspneic.

The *cool-down period* completes the exercise prescription. A period of 5 to 10 minutes of walking and stretching exercises is desirable. This prevents the marked vasodilatation for dissipation of heat from causing hypotension and hypoperfusion. Very hot or very cold showers should be avoided.

PATIENT EDUCATION

Motivating the Patient. Patient need to know that next to smoking, hypertension, and hypercholesterolemia, inactivity is one of the most important treatable cardiac risk factors. Many do not appreciate that exercise not only can help them to look, feel, and work better, but it can reduce overall coronary morbidity and mortality. Also helpful is emphasizing that even modest amounts of activity (including informal exercise such as gardening) can provide substantial health benefits and that moderate exercise (e.g., walking at a moderate pace) can be as effective in reducing coronary risk as vigorous activity. This helps patients find enjoyable activities that can be incorporated into their daily life and facilitates motivation. The goal is to have them take up and sustain a program of endurance-type activity. Most important to success is choosing a form of exercise that is enjoyable and readily incorporated into daily living.

Focusing on Safety. Exercise is not without risk, and patients need to know what to look for and how to respond. There is no question that exercise can precipitate cardiac arrhythmias and myocardial ischemia in persons with underlying *heart disease*. Sudden death is a tragic, though infrequent, complication of exercise. Careful medical screening of potential exercisers (see above) and design of an appropriate individualized exercise prescription are essential to patient safety. In addition, detailed review of cardiac warning signs (chest pressure, dizziness, lightheadedness, dyspnea, palpitations, unusual fatigue, nausea, diaphoresis) is critical along with advice to stop exercising immediately if such symptoms develop. One must be sure the patient will not continue exercising or rationalize the symptoms away by misattributing them to such harmless causes as "indigestion" or "gas." Meticulous supervision of high-risk individuals and use of closely controlled conditioning programs have enabled survivors of myocardial infarctions to engage safely in aerobic exercise, even marathon running.

Some exercisers encounter exercise-induced *asthma*, particularly during cold weather. Advising use of a face mask that warms inspired air often suffices; sometimes prophylactic treatment with inhaled cromolyn, albuterol, or montelukast is necessary and helpful (see Chapter 48). Extreme environmental conditions may also produce thermal stress ranging from frostbite to heat stroke. Here too, prevention is the best therapy. The physician should be able to advise the exerciser about appropriate fluid intake, clothing, acclimatization, and safe duration of exposure and exercise. Similar advice prevents dehydration and electrolyte depletion.

Musculoskeletal injuries are very common and result from overuse, inflexibility, and muscle imbalance (see Chapter 152 and Chapter 154). Overuse is prevented by gradual increases in exercise; inflexibility and imbalance are avoided by stretching and strengthening (see below). Providing advice about equipment and technique can also help lessen the risk of injury (see below).

PRACTICAL ADVICE FOR THE BEGINNING EXERCISER

Food and Fluid Intake. It is best to avoid exercise within 2 hours of a substantial meal. Despite many claims to the contrary, no specific dietary programs are required for exercise. The obese person should restrict calories to reduce, whereas the lean individual may require increased caloric intake to maintain weight. Competitive athletes believe that increased carbohydrate intake during the 3 days before a competitive endurance event helps improve performance, and there is some experimental evidence suggesting that such "carbohydrate loading" does increase muscle glycogen content. Adequate fluid intake is essential, particularly in warm weather, because the sensation of thirst lags behind volume depletion. It is best to begin drinking small amounts before thirst becomes overt. Water is excellent, though some athletes prefer balanced electrolyte solutions or even carbonated beverages.

Climate. Thermal stress presents a potentially serious threat. When confronted with an abrupt change in climate, the exerciser should sharply reduce distance and speed for several days until acclimatization is achieved. In warm humid weather, outdoor exercise should be confined to early morning or evening hours or shady locations, distances and speed should be reduced, fluids should be taken at frequent intervals during the run, and clothing should be light colored and lightweight. Environmental temperatures between 50°F and 60°F are ideal for exercising in shorts and T shirts. Between 40°F and 50°F, a warmup suit is generally sufficient; below 40°F, gloves or mittens and a hat are important. Multiple layers of thin flexible clothing are better than a single bulky garment. Woolen fabrics are ideal, but a soft cotton layer should be next to the skin. An extra layer of thermal underwear is vital for temperatures below 30°F, and if winds are strong or temperatures drop below 15°F, an additional layer such as a turtleneck, extra shorts, and possibly a ski mask are required. Again, distances should be reduced in bitter cold, and it is particularly important to avoid wet conditions, which can lead to frostbite, especially of the feet.

Air pollutants may cause irritation of the upper and lower respiratory tract, and carbon monoxide can impair oxygenation and precipitate angina. One should avoid jogging or biking on heavily traveled roads, during rush hours, and on days when temperature inversions increase air pollution.

Safety. Safety is of utmost importance. The runner and walker should run facing the flow of cars. Sidewalks are preferred; although country roads are appealing, it is desirable to stay with a companion in isolated areas in case of injury. Daytime exercise is safer both because one is more visible to cars and can see road hazards more easily. Bright-colored clothing should be encouraged, and at night reflectorized vests are mandatory. Dogs are best avoided by means of an impromptu detour, but if this is not possible, they can generally be intimidated by a firm command to "go home" or by the threat of a stick or stone.

Equipment. One of the advantages of jogging and walking is that elaborate equipment is not required; however, good athletic *shoes* are essential. Many excellent shoes are available; the choice should be dictated by fit, comfort, and support rather than by endorsements or ratings. The toe box should provide enough room for dorsiflexion during take-off, the sole should be flexible and provide adequate cushioning, and the heel should be fairly snug without exerting pressure on the Achilles tendon. Most good athletic shoes are costly but are durable and useful for reducing the risk of injury. Good shoes are important; other items ranging from stopwatches to designer sweat suits are optional to say the least.

Orthotics and other orthopedic devices are sometimes helpful for refractory problems. Patients with overuse injuries who fail to limit their activity may require a splint or cast to enforce inactivity, even if immobilization is not actually necessary for healing. The use of such devices requires referral to an orthopedist or podiatrist skilled in treating runners' musculoskeletal problems.

Stretching. Aerobic exercise programs may produce asymmetric muscular development. In runners, the calf, hamstring, and Achilles tendon can become overdeveloped and/or shortened and tight. Hill running and sprinting may produce similar effects on the quadriceps and hip flexors. A regular program of stretching exercises is essential to promote flexibility and balanced muscular development. These exercises are ideal for the warm-up and cool-down periods before and after exercise.

Stretching routines are almost as numerous and varied as runners themselves. Four exercises are of particular value: the Achilles and soleus stretch (Fig. 18.1), the hamstring stretch (Fig. 18.2), the quadriceps stretch (Fig. 18.3), and the hip and side stretch (Fig. 18.4).

FIG. 18.1. Calf, Achilles, and soleus stretch. Stand 3 feet from a wall with one foot forward, leaning forward to support your upper body by resting your forearms against the wall. Bend the forward leg at the knee. Keep the rear leg straight with the heel on the floor, and slowly press your hips forward until you feel the calf stretch. Hold for 15 seconds. Relax and then repeat with the rear knee slightly bent so that you feel the Achilles stretch. Repeat with the other leg forward.

FIG. 18.2. Hamstring stretch. Rest one leg on a sturdy table or desk. Keeping both legs straight, slowly bend forward at the waist so that you feel the hamstring stretch. Hold for 30 seconds. Repeat with the other leg up.

FIG. 18.3. Quadriceps stretch. Stand at arm's length from a wall with your feet parallel to the wall. Rest your hand on the wall for support. Hold your ankle in your free hand, and pull the foot back and up until the heel touches the buttocks, while leaning slightly forward from the waist. Repeat with the other leg.

FIG. 18.4. Hip and side stretch. Sit on the floor and spread your legs as far apart as possible. With your legs and back straight, bend forward from the waist until you feel a stretch at the inner thighs. Hold for 20 seconds. Relax, then twist at the waist, and lean to touch your right hand to your left foot. Hold for 20 seconds. Repeat on the other side.

With increased training, more stretching will be necessary. In addition to flexibility, balanced muscular strength can be important. Bent-knee situps are particularly valuable in strengthening abdominal muscles and preventing "side stitches." Upper extremity strength is surprisingly important; push-ups are the simplest upper extremity exercise. For older persons, low-resistance high-repetition weight training is extremely helpful for maintaining muscle mass and bone density during the aging progress.

Exercise is not a panacea, but it has many cardiopulmonary, metabolic, and psychological benefits. The physician has a crucial role in motivating, screening, and preventing problems. Periodic return visits may be necessary for dealing with various running-related problems. These visits afford the opportunity for the physician to

counsel patience and persistence. Joggers who get through the difficult 2 or 3 months at the beginning of training are likely to develop running habits that are both enjoyable and healthful.

RECOMMENDATIONS

- Encourage all persons to engage regularly in physical activity that provides aerobic exercise.
- Help the individual choose an activity program that is medically appropriate, enjoyable, and readily incorporated into daily living. The program does not need to be one of formal exercise; even gardening and modest daily informal activity can provide a survival benefit. Life-style interventions appear to be as effective as formal exercise programs of similar intensity in improving cardiovascular fitness, blood pressure, and body fat composition.
- For the person who is not interested in structured training, design a program of life-style change that provides regular aerobic activity (e.g., walking more, riding less; climbing stairs instead of taking elevators).
- For individuals interested in a formal fitness program, screen first for underlying cardiopulmonary disease, predominantly by a careful history and physical examination. Those with risk factors, symptoms, or signs of heart disease are candidates for additional cardiac studies to help determine the safe limits of their exercise program.
- For persons medically appropriate for fitness training, prescribe a program of aerobic exercise, three times per week. Start with 5 minutes for warm up, 10 to 12 minutes for exercise, and 5 minutes for cooling down. As a rule of thumb, the beginner should plan to exercise aerobically for 10 to 12 minutes at a pace sufficient to increase heart rate to 60% to 80% of maximum without producing breathlessness.
- Design the program so that the optimal fitness goals are attained very slowly and gradually. The intensity target should be at a comfortable level (e.g., the "talking" pace—the intensity sufficient to feel one is working hard while still able to talk to a companion without feeling dyspneic).
- Increase intensity gently and duration gradually (e.g., by 10% each week). Avoid too much too soon. Set both the starting point and the rate of progression according to the health, age, and fitness of the participant.
- Set for those who desire maximum cardiopulmonary fitness a goal of exercising continuously for 15 to 60 minutes, performing aerobic exercises that are strenuous enough to raise the heart rate to 80% of maximum (maximum rate in beats per minute = [220 − age] × 0.8). Equal degrees of fitness can be attained through less intense exercise sustained over a longer period or through more vigorous effort for shorter periods.
- Consider a program of moderate exercise for those who desire a near maximum reduction in risk of coronary disease without achieving maximum cardiopulmonary fitness. For example, recommend for middle-aged women a program of walking at a moderate pace (20 min/mile) for 3 or more hours a week. One does not need to prescribe vigorous exercise to maximize coronary risk reduction. Those who have not been active previously should be encouraged to begin a program of moderate exercise, with walking an excellent and practical suggestion.
- For persons engaged in a program of fitness training, recommend a minimum of three sessions per week to develop and maintain fitness; recommend five sessions per week for those interested in maximum benefit.
- For those who prefer a routine of daily activity, recommend easier and harder workouts on alternate days to prevent injuries and allow the muscles to recover.
- Review cardiac warning signs (chest pressure, dizziness, lightheadedness, dyspnea, palpitations, unusual fatigue, nausea, diaphoresis). Teach all exercisers to stop activity immediately if such symptoms develop and call for assistance.

CHAPTER 19 EVALUATION OF HYPERTENSION

KATHARINE K. TREADWAY

High blood pressure, if unrecognized or untreated, significantly increases the morbidity and mortality associated with coronary disease, heart failure, renal failure, and stroke. Risk further increases dramatically in the presence of smoking, glucose intolerance, hyperlipidemia, left ventricular hypertrophy (LVH), male gender, African-American race, or increasing age. Treatment of hypertension—even if only partial—can greatly reduce its morbidity and mortality risks.

Upon encountering blood pressure elevation, the first priority for the primary physician is to *confirm the diagnosis*. After confirmation, the evaluation focuses on three major tasks. The first is to rule out any *secondary causes*. Although about 95% of patients have primary disease (no clearly definable underlying cause), a search for a secondary etiology is important, because if such a cause is present, treatment will need to be etiologic to be effective. The second is to assess the *severity of disease*, because risk and type of treatment program derive from the degree of pressure elevation and amount of target-organ (end-organ) damage. The third is to identify any concurrent *cardiovascular risk factors*, because their presence will affect the threshold for initiating therapy and the nature of the treatment program. As of yet, attempts to determine the principal underlying pathophysiology have proven elusive, though when it becomes feasible to do so, the results should facilitate diagnosis and further rationalize treatment.

DEFINITION AND CLASSIFICATION OF HYPERTENSION

Definition. The definition of hypertension is arbitrary (it even varies from country to country). Actuarial data have shown that morbidity and mortality related to complications of hypertension increase linearly with increasing levels of either systolic (SBP) or diastolic blood pressure (DBP). Hence, no critical level of blood pressure exists beyond which risk becomes highly magnified. Most definitions of hypertension refer to a level of blood pressure associated with a substantial risk of complications. A major consensus report, the Sixth Report of the Joint National Committee on Detection, Evaluation, and Treatment of High Blood Pressure (JNC VI) recommends a *SBP greater than or equal to 140 mm Hg and a DBP of 90 mm Hg or more* for the definition of hypertension.

The definition of hypertension must be *individualized* for each patient. The diagnosis derives not only from the absolute level of blood pressure but also from the presence or absence of other *cardiovascular risk factors*. Factors besides hypertension identified by the Framingham study as significant contributors to cardiovascular risk include cigarette smoking, elevated serum cholesterol, glucose intolerance, and electrocardiographic evidence of LVH with strain. In addition, African-American race, male gender, and age greater than 50 need to be taken into account. The patient with borderline hypertension, a moderately elevated serum cholesterol level, and a history ofsmoking has a fivefold higher risk of incurring cardiovascular disease than the patient with borderline hypertension alone.

Classification. The JNC VI recommendations include eliminating the traditional designations of "*mild*," "*moderate*," and "*severe*" hypertension to avoid the misleading notion than mild hypertension is not a significant health risk. Instead, they designate three stages:

- *Stage I*—DBP 90 to 99 mm, SBP 140 to 159 mm;
- *Stage I*—DBP 100 to 109 mm, SBP 160 to 179 mm;
- *Stage III*—DBP more than 110 mm, SBP more than 180 mm.

In addition, a "high-normal" category (DBP 85 to 89, SBP 135 to 139) is designated to highlight the increased risk of developing sustained hypertension in this group (Table 19.1).

Table 19.1. Classification of Blood Pressure for Adults Aged 18 Years and Older [a]

PATHOPHYSIOLOGY AND CLINICAL PRESENTATION

Pathophysiology

Control of blood pressure and the pathophysiology of hypertension are still incompletely understood. It has become increasingly clear that hypertension is a polygenic disorder with probable variable penetrance and phenotype in which environment may play a modifying role. Thus, it represents a complex interaction of multiple genetic and environmental factors playing varyingly significant roles in particular patients. Because there is a strong familial predisposition to hypertension, much of the pathophysiology is likely to be an expression of inherited defects in the regulation of blood pressure. There are probably several mechanistic subtypes of "primary" hypertension. It is also likely that several abnormal mechanisms are present in any one individual. It is unlikely that single gene mutations will be found to be responsible except in rare instances. As of yet, it is usually not possible to identify specific etiologic mechanisms in a given case. Nonetheless, several elements deserve elaboration and provide a rational basis for evaluation and therapy.

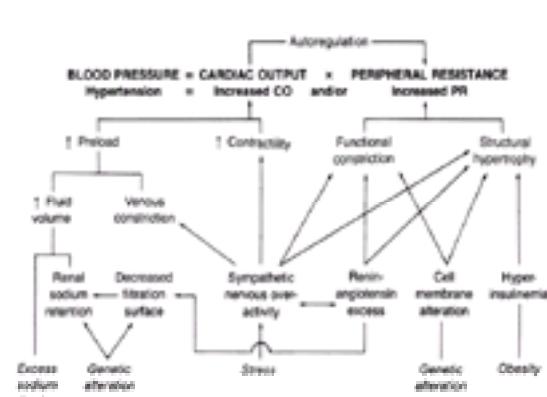
Primary determinants of blood pressure are *cardiac output* and *peripheral resistance*. Each is affected by a variety of factors, which, in turn, have multiple control points (Fig. 19.1).


FIG. 19.1. Factors involved in control of blood pressure. (From Kaplan NM. Clinical hypertension, 5th ed. Baltimore: William & Wilkins, 1990:57, with permission.)

Sodium. Several lines of evidence continue to implicate sodium. Population studies demonstrate a relationship between high blood pressure and high sodium intake. In cultures where salt intake is low, hypertension is exceedingly rare. When members of those same cultures migrate into cultures in which salt intake is high, approximately 25% to 30% will develop hypertension. Sodium restriction, as well as use of diuretics, has long been known to reduce blood pressure in a subset of hypertensives. However, sodium intake is a poor predictor of hypertension in a given individual, suggesting that susceptibility depends on many other factors, probably both genetic and environmental. It is postulated that many hypertensives have an inherited defect in the ability of the kidney to excrete excess sodium. This leads to an increase in intravascular volume that is corrected by an as yet unidentified factor—the putative "natriuretic hormone"—that inhibits the Na^+/K^+-ATPase pump. The net result is an increase in intracellular sodium, which raises *free intracellular calcium*. The rise in intracellular calcium heightens vascular tone and elevates blood pressure. Natriuresis is effected at the cost of a higher resting pressure. Additionally, in salt-sensitive patients, a high sodium intake has been associated with higher levels of norepinephrine and an increased responsiveness to norepinephrine.

Catecholamines. Catecholamines affect blood pressure regulation both centrally via the vasomotor centers in the brain and peripherally through the action of the sympathetic nervous system. Catecholamines elevate blood pressure both by increasing peripheral resistance and increasing cardiac output. Sympathetic hyperactivity has been suggested as playing a primary role in the development of hypertension in some patients. *Pheochromocytoma* provides a model for secondary hypertension based on excessive catecholamines. Studies on patients with borderline hypertension have allowed clear identification of subgroups in which a defect in autonomic nervous system controls exists, resulting in excessive sympathetic and reduced parasympathetic activity. An exaggerated pressor response to external stressful stimuli has been demonstrated in some hypertensive patients and in their normotensive offspring. Also described are "hyperkinetic" hypertensives, who are generally young and present with tachycardia and elevated cardiac output. Their hypertension may reflect the interaction of an underlying predisposition and various environmental stimuli.

Renin-Angiotensin System. Renin is secreted by the juxtaglomerular apparatus in response to a number of stimuli, including a decrease in intravascular volume, decreased perfusion pressure, b-adrenergic stimulation, and hypokalemia. Renin acts on angiotensinogen (a decapeptide produced in the liver) to form *angiotensin I*, a substance with no known biologic activity. Angiotensin I is converted in the lung to *angiotensin II* by *angiotensin-converting enzyme*. Angiotensin II is a potent vasoconstrictor that also acts on the adrenal cortex to release aldosterone, which increases sodium and water reabsorption in the distal tubule of the nephron.

Renin production is inversely proportional to effective blood volume. Anything that increases effective blood volume suppresses renin and anything that decreases effective blood volume stimulates renin. For example, in *primary hyperaldosteronism*, autonomous production of the salt-retaining hormone aldosterone by an adrenal adenoma results in intravascular volume expansion and renin suppression. Conversely, in *renal artery stenosis*, decreased renal perfusion on the affected side is perceived by that kidney as decreased effective blood volume. In renin studies of patients with primary hypertension, about 15% have a high renin, the remainder showing normal or low levels. It is still not clear how much of a role this system plays in the pathogenesis of primary hypertension. One theory suggests that in patients with hypertension, a "normal" renin may in fact be inappropriately high due to a relative insensitivity to the adrenal cortical effects of angiotensin II. In addition, in about 50% of hypertensives with normal or elevated renin levels, there is a defect in the normal modulation of responsiveness to angiotensin II based on sodium intake, so-called nonmodulators. In these patients, the defect can be reversed by the use of angiotensin-converting enzyme inhibitors.

At present, we have no way to identify such patients, but this offers a glimpse of the potential of eventually being able to accurately diagnose the underlying etiology of hypertension in a given patient and adjust therapy specifically. Finally, there are local renin-angiotensin systems within the brain, heart, kidney, and placenta. It is possible that locally derived angiotensin II may play a significant role in the development of hypertension and in some of its consequences.

Insulin. The increased frequency of hypertension in patients with type II diabetes has stimulated search for a common mechanistic link. Elevations in serum insulin have been found capable of increasing plasma catecholamines and stimulating sodium reabsorption in the kidney, both of which are capable of raising blood pressure. In addition, insulin enhances the pressor responses to angiotensin II and serves as a potent growth factor for vascular smooth muscle, which could lead to hypertrophy and increased peripheral resistance. Insulin levels are higher in obese nondiabetic hypertensives than in their normotensive counterparts, suggesting a mechanism linking obesity with hypertension. Relative insulin resistance has also been identified in nonobese hypertensive patients and in nonhypertensive nonobese offspring of hypertensive parents, suggesting that elevated insulin levels may occur as part of a genetic defect and are not necessarily secondary to obesity.

Calcium. Increased intracellular calcium appears to increase vascular tone. Alteration in calcium binding at the cellular level may lead to increased levels of free intracellular calcium with a resultant increase in vascular tone.

Alteration of Cell Membrane Function. A variety of abnormalities in cellular sodium transport has been demonstrated to occur in some hypertensive patients. These include the Na^+-Li^+ countertransport system, the Na^+-H^+ exchange, the Na^+-K^+ ATPase pump and the Na^+-K^+-C^- cotransport systems, among many others. The result of these abnormal transport systems is to increase intracellular sodium.

Clinical Presentations

Primary or "essential" hypertension accounts for at least 95% of cases. Onset is usually between ages 30 and 50, except for *isolated systolic hypertension*, which is typically a disease of the elderly. Often, a family history of hypertension can be elicited. For 80% of patients, the onset is gradual and the severity mild. Patients with uncomplicated disease are asymptomatic. Although some patients report fatigue, headache, lightheadedness, flushing, or epistaxis, the correlation between symptoms and blood pressure is poor, except in patients with dangerous elevations in pressure. The rare syndrome of *hypertensive encephalopathy* occurs in the setting of malignant hypertension, where DBP rises rapidly above 130 mm Hg, accompanied by symptoms and signs of increased intracranial pressure (restlessness, confusion, somnolence, blurred vision, nausea, vomiting, blurred disc margins, retinal hemorrhages) and heart failure (dyspnea, rales, third heart sound).

Most patients remain asymptomatic unless end-organ damage develops, causing symptoms of congestive failure, renal failure, cerebrovascular insufficiency, peripheral vascular disease, or ischemic heart disease.

Labile hypertension is blood pressure that intermittently rises above the normal levels for each given age group and sex. Established hypertension has been shown to develop more commonly in such patients.

"White-coat hypertension" is a term used to describe blood pressure elevations that occur in the doctor's office but not in the home or work environment. The condition is seen in both hypertensive and normotensive patients. Persons who manifest this condition typically have SBP and DBP at least 10 mm Hg greater in the office than at home but do not have greater blood pressure reactivity in the ambulatory setting. They tend to be older and are more likely to receive more antihypertensive medication than their peers, because they seem to be refractory.

Pseudohypertension occurs in elderly persons with very stiff brachial arteries secondary to fibrosis and atherosclerotic change. The vessel walls resist compression by the blood pressure cuff, resulting in sphygmomanometer readings for systolic pressure that markedly exceed the true intraarterial pressure and may simulate very high levels of hypertension. Suggestive clinical findings that differentiate this form of pressure elevation from true systolic hypertension of the elderly include absence of target organ changes (no signs of retinopathy, ventricular hypertrophy, nephropathy) despite the marked elevation in blood pressure. *Osler's maneuver* (inflating the cuff above the measured SBP and seeing if a nonpulsatile radial artery can be palpated) is purported to be helpful in confirming the condition, but its efficacy is unproven.

Pseudorefractory hypertension, a form of apparently refractory disease, has been described in patients who manifest a marked vasoconstrictor response to blood pressure determinations performed with an arm cuff. Their predominant elevation is in DBP, compared with the white-coat hypertensive, who responds with a rise in SBP. Such patients are apt to be mistaken for truly refractory hypertensives because pressures may remain elevated both in the office and at home. The tipoff to this condition is the absence of end-organ damage (e.g., normal fundi, normal cardiac ultrasound) despite apparent persistence of hypertension.

Secondary hypertension has a definable etiology (Table 19.2), occurs within a wide age range, and is often abrupt in onset and severe in magnitude; family history

is commonly negative. Certain forms of secondary hypertension may be heralded by specific symptoms. For example, leg claudication may be a manifestation of *coarctation* of the aorta, causing lower extremity ischemia. The patient with *Cushing's syndrome* may complain of hirsutism or easy bruising. Almost all patients with *pheochromocytoma* report paroxysms of excessive perspiration, headaches, or palpitations; about half have sustained hypertension in addition to the paroxysmal symptoms. Hypokalemia ensues from *primary aldosteronism* and may trigger muscle cramps, weakness, and polyuria.

Table 19.2. Primary versus Secondary Hypertension: Specific Screening Protocols

DIFFERENTIAL DIAGNOSIS

About 95% of new hypertensive patients encountered in primary care practice have primary or essential disease. Secondary causes account for the remainder, with one large study showing renal failure accounting for 2.4%, renovascular disease for 1.0%, primary aldosteronism for 1.0%, drugs for 0.8%, pheochromocytoma for 0.2%, and Cushing's syndrome for 0.1%. Coarctation of the aorta is usually detected earlier in life and rarely presents as unexplained adult-onset hypertension ( ).

Table 19.3. Clinical Features Suggestive of Renal Artery Stenosis

WORKUP

As noted earlier, the goals of the evaluation include firmly establishing the diagnosis; ruling out secondary causes; and determining the severity of the pressure elevation, the degree of target-organ damage, and the degree of overall cardiovascular risk.

Establishing the Diagnosis

Use of proper technique for measurement of the blood pressure is essential (see Chapter 14 and below). Except in patients with severely elevated blood pressure, the diagnosis of hypertension should almost always be based on *multiple determinations* of blood pressure, preferably not only on different visits but by different personnel and in different settings. As noted above, there is a tendency for blood pressures to be higher whentaken by a physician than when taken by a nurse or other medical worker. Repeating the blood pressure at the end of the visit can also be informative, because pressures are likely to be less elevated at the end of a visit than at the beginning. Studies comparing the correlation of LVH with pressures obtained in the physician's office, at home, and at work show that *work-site readings* correlate best with degree of LDH.

Teaching the patient to check one's pressure at home and at work can greatly facilitate diagnosis and management, but *home determinations* should be viewed as an adjunct, not as a replacement for office-based measurements. Home determinations are diagnostically useful when there is concern the office reading might represent "white-coat" hypertension caused by patient anxiety. Home determinations are usually lower than those obtained in the office. Readings in excess of 138/85 mm Hg are considered elevated. If home determinations are to be undertaken, the patient's technique and equipment should be checked and calibrated during an office visit, comparing their readings taken in the office with those obtained by the physician using a mercury bulb manometer. In general, the mechanical aneroid manometers are simple, inexpensive, and accurate but need to be checked frequently. Finger monitors are convenient and easy to use, but they are not accurate and not recommended. If home monitoring proves to be sufficiently accurate, one can consider using such determinations to facilitate management (see Chapter 26).

When there is a marked discrepancy between home and office pressures or a wide variation in pressures obtained throughout the day, *24-hour ambulatory monitoring* may be useful, though usually it is unnecessary and quite expensive. Such monitoring appears to be the most accurate way to assess blood pressure, with no regression to the mean and better correlation with left ventricular mass than casual blood pressures. Under study conditions, patients who undergo ambulatory monitoring and adjustment of therapy based on its findings need less intensive therapy, but costs are not reduced due to the expense of the monitoring. It is still not clear how to best use this information in a cost-effective manner other than to resolve discrepancies in readings if they occur.

Conducting the Basic Workup

The basic diagnostic evaluation consists of ruling out *secondary causes* and determining the severity of the pressure elevation, the degree of *target-organ damage*, and the presence of *cardiovascular risk factors*.

History. It is best to begin by eliciting the patient's hypertensive history: date of onset or last previously normal blood pressure, level at time of onset, any medications taken, and response to therapy. Such information facilitates determination of etiology and helps guide workup. For example, sudden onset at a young age, very high pressure, no family history, and refractoriness to treatment suggest a secondary cause (see below). In addition, the history is checked for contributing factors, such as prior *renal disease*, *salt* and *alcohol excess*, and recent *weight* gain. Noting any associated modifiable cardiovascular risk factors (*smoking, hypercholesterolemia, diabetes, and obesity*) facilitates assessment of total coronary risk. Evidence of cardiovascular and neurologic complications such as a history of prior myocardial infarction or stroke and symptoms suggestive of angina, congestive heart failure, claudication, or transient ischemic attacks should be sought. It is important to inquire about the use of medications that may exacerbate hypertension such as amphetamines, oral contraceptives, corticosteroids, thyroid hormone (in excess), over-the-counter sympathomimetic decongestants, and, in the elderly, chronic use of nonsteroidal antiinflammatory agents. In addition, excessive alcohol use and cocaine abuse may elevate blood pressure.

Awareness of the *symptoms* associated with *secondary etiologies* is essential. Complaints such as hirsutism, easy bruising, paroxysms of palpitations and sweats, weakness, muscle cramps, and leg claudication should all suggest a secondary form of hypertension. Other clues to a secondary cause—especially renovascular

disease—are onset at the extremes of age, rapid and severe course, and refractoriness to medication (see below).

Physical Examination. Coffee intake and smoking should be halted at least 30 minutes before taking the pressure. Blood pressure is properly measured in *both arms* while the patient is seated comfortably and after resting for 5 minutes. The cuff should be placed on the bared upper arm, which is supported by the examiner at heart level. The Korotkoff sounds are best listened for by using the stethoscope *bell* rather than the diaphragm; the bell better transmits the low-pitched sounds of diastole. The average of two successive measurements in each arm is recorded. *Diastolic pressure* is taken at the point at which *sound disappears* (Korotkoff 5) rather than when it changes in quality (Korotkoff 4). *Cuff size* must be adequate to avoid falsely elevated readings (cuff width greater than two thirds of arm width, length of inflatable portion greater than two thirds of arm circumference). In the elderly, the pressure should also be taken standing to detect any postural changes. Any *auscultatory gap* (loss and reappearance of the Korotkoff sounds) should be noted because it correlates with arterial stiffness and carotid atherosclerosis, known predictors of prognosis.

The remainder of the examination focuses on *weight* and *pulse* measurements; the *skin* for stigmata of Cushing's syndrome, chronic renal failure, or neurofibromatosis; *fundoscopy* for arteriolar narrowing, increased vascular tortuosity, arteriovenous nicking, or hemorrhages; the *thyroid* for enlargement or nodularity; *carotid pulses* for bruits or diminution of pulse; *lungs* for signs of heart failure; *heart* for left ventricular lift and S_4 and S_3 heart sounds; *peripheral vasculature* for pulses, bruits, and abnormalities in bilateral arm and leg pressure measurements and simultaneous radial and femoral pulse palpation; *abdomen* for masses and bruits; and the *neurologic exam* for focal deficits.

Basic Laboratory Studies. The laboratory evaluation of high blood pressure has three purposes: to ascertain the degree of end-organ damage resulting from hypertension, to identify patients at high risk for the development of cardiovascular complications, and to screen for secondary possibly reversible forms of the disease. Despite the wide array of sophisticated diagnostic techniques now readily available, there is increasing evidence that the diagnosis of secondary hypertension can be made accurately and economically by the alert physician on the basis of a careful history, a physical examination, and only a few simple diagnostic tests. Extensive laboratory evaluation of patients with high blood pressure is unwarranted.

The basic laboratory investigation of hypertension for detection of secondary causes and end-organ damage and for determination of cardiovascular risk needs to include little more than a *complete blood count, urinalysis, blood urea nitrogen, creatinine, potassium, calcium (with albumin), fasting blood sugar, total and high-density lipoprotein cholesterol, and electrocardiogram* (ECG). The urinalysis provides evidence of primary renal disease. The extent of renal compromise due to renal disease or secondary to the hypertension itself is indicated by the blood urea nitrogen, creatinine, and urinalysis. Fasting blood sugar, serum cholesterol, and ECG supply data regarding cardiovascular risk and presence of left atrial enlargement and ventricular hypertrophy. Serum potassium is a valuable screening test for primary aldosteronism and should be known before diuretic therapy is instituted. Total cost of these determinations is reasonable. In most patients, evaluation can and should stop here.

More extensive routine laboratory evaluation of patients with high blood pressure has come under a great deal of criticism. The yield in the absence of clinical evidence for a secondary cause is low, and such testing is not cost effective. It was hoped that *renin profiling* would help identify the underlying pathophysiology in patients with primary disease, guide workup for secondary causes, and rationalize selection of therapy. However, the renin assay continues to suffer from difficulties with accuracy and reliability, except in certain research laboratories. Moreover, most hypertensives have normal renin levels, undermining the value of widespread testing. Finally, when renin profiling has been used to guide choice of therapy, benefit has been hard to demonstrate.

Echocardiography for detection of LVH has been useful in research studies, with presence of LVH associated with an increased risk of cardiovascular complications. However, its routine use rarely adds much to the assessment, except in the setting of refractory hypertension where definitive evidence of end-organ hypertrophy helps one distinguish between true and apparent refractoriness to therapy (see [Chapter 26](#)). When the need to search for LVH is less pressing (e.g., in the patient with newly encountered blood pressure elevation), the ECG can provide a reasonable though less sensitive estimate. Of interest, however, is the finding from the Framingham data that the presence of LVH on ECG confers higher risk than that found only on echocardiogram.

Evaluation of Suspected Secondary Causes of Hypertension

Patients at somewhat higher risk for *secondary hypertension* include those with abrupt onset (especially if female and younger than 35 years of age, without a family history of hypertension, or older than age 50 and with evidence of diffuse atherosclerosis), with severe hypertension (DBP more than 120 mm Hg), or with failure to respond to maximum medical therapy despite full compliance. Fortunately, in most patients at high risk for secondary hypertension, a specific diagnosis will be suggested by history and physical examination, supplemented by a few well-chosen laboratory studies ([Table 19.1](#)).

Cushing's syndrome is often heralded by its characteristic clinical features (e.g., truncal obesity, facial plethora, violaceous abdominal striae, proximal muscle thinning and weakness, "buffalo hump"), but the presentation may be more subtle. The initial test of choice is the 24-hour *urinary free cortisol*. A finding in excess of 250 µg/d is virtually diagnostic; a level above the upper limit of normal (65 µg/d) in a person with characteristic clinical features strongly supports the diagnosis, but a reading below it rules out the condition. Persons with suspected disease need an assessment of corticotropin (ACTH) dependence, which can be performed by simultaneous late p.m. determinations of *plasma ACTH* and *cortisol*. An elevated cortisol and an inappropriately normal or elevated ACTH indicates an ACTH-producing source; an elevated cortisol and a suppressed ACTH level (less than 5 pg/mL) suggests an autonomous adrenal or ectopic source. Alternatively, an overnight 1 mg *dexamethasone suppression test* can be performed (1 mg is taken at midnight and an 8 a.m. plasma cortisol is obtained). A cortisol level more than 5 µg/dL is suggestive of an autonomous gland, but false-positives are common (due to obesity, stress, depression, alcohol excess).

Coarctation of the aorta is suggested by the presence of reduced pulses in the lower extremities in a person with elevated arm pressures. The suspicion is enhanced by finding reduced blood pressure measurements in the lower extremities and a delay in pulse transmission on simultaneous palpation of radial and femoral pulses. In severe cases, a flow murmur may be audible over the anterior chest or back. A chest radiograph may show rib notching. Confirmation can be obtained by echocardiography or chest computed tomography (CT).

Pheochromocytoma is suggested by a story of *paroxysmal sympathetic discharge* (sweats, palpitations, tachycardia). The *24-hour urine* assay for *catecholamines*, *VMA*, or *metanephrines* is a sensitive screening test for pheochromocytoma, especially when collected the same day that the patient reports symptoms and processed using the more sensitive liquid chromatography assay. Two normal 24-hour urines performed while the patient is symptomatic virtually rules out the diagnosis. Two positive urines have a high predictive value for the presence of pheochromocytoma. Methyldopa can falsely elevate metanephrines. Although *combination studies* are often ordered (i.e., urinary catecholamines plus metanephrines or VMA), they add little to the power of testing because their sensitivities and specificities are nearly identical. *Plasma* determinations of *catecholamines* and *metanephrines* are available and touted as more sensitive and specific, but sensitivity and specificity are not yet well established. If urinary screening for pheochromocytoma is positive, then one can proceed to *CT of the adrenal glands*—sensitivity is about 90% for lesions larger than 1 cm in diameter. Use of the CT should be limited to patients whose urines test positive and should never be used as a screening test for pheochromocytoma, because innocent adrenal masses having nothing to do with hypertension are common.

Primary hyperaldosteronism is usually suggested by otherwise unexplained *hypokalemia* or excessive potassium requirements in a person taking diuretics. Untreated hypertensive patients with primary hyperaldosteronism demonstrate an inappropriately high ratio (more than 20) of *plasma aldosterone* to *plasma renin*. Measuring the ratio is a reasonable screening test for suspected primary hyperaldosteronism. Confirmation requires measurements of aldosterone secretion in the setting of sodium loading and sodium depletion, which are best performed by referral to an endocrinologist.

Renovascular hypertension should be considered when blood pressure elevation is of new onset, hard to control, or associated with worsening renal function (see [Table 19.3](#)). The definitive test remains *renal arteriography* in combination with *renal-vein renin* determinations. Angiographic study with renin sampling not only identifies the anatomic and physiologic impairments, but also allows for immediate therapeutic angioplasty. However, the study has several disadvantages, including its invasiveness, risk of embolic complications, high expense, and risk of dye-induced renal injury. These risks necessitate careful case selection. The best noninvasive approach(es) to screening for hemodynamically significant renal artery stenosis continue to be explored.

A potentially useful *clinical prediction* rule was developed for screening those with drug-resistant disease or rising serum creatinine during ACE-inhibitor therapy. Using multivariate analysis, key clinical features predictive of renal artery stenosis in such patients were identified (see [Table 19.3](#)). Sensitivity and specificity for this prediction rule are about 70% and 90% respectively.

The *captopril renal scan* (using radionuclide scintigraphy performed 1 hour after a dose of captopril) is another means of screening. Captopril enhances differences in glomerular filtration between normal and hypoperfused kidneys. While the test shows adequate specificity (.90 to .95), it is expensive and its sensitivity is

disappointing (.6 to .7). Sensitivity is especially impaired by the scan's nondiagnostic readings in the setting of bilateral stenosis and stenosis-related complications, such as azotemia or a small poorly functioning kidney. *Magnetic resonance angiography (MRA)* offers a more sensitive and very specific contrast-free noninvasive means of identifying anatomically significant renal artery stenosis (sensitivity approaches 90%, specificity over 95%); however, the test is extremely expensive and, unlike captopril scanning, does not provide physiologic information.

The ultimate contributions to blood pressure control of prediction rules and these noninvasive studies singly or collectively remain to be determined. The literature should be followed for emerging data. Prediction rules have been used successfully to determine response to treatment. The younger the patient, the more recent the onset of hypertension, and the lower the systolic pressure, the greater the probability of response to revascularization for renal artery disease.

Risk Stratification

Incorporating the findings of the workup for cardiovascular risk factors, clinically overt cardiovascular disease, and target-organ damage into a risk profile helps to guide therapy (see Chapter 26). The most important factors predicting cardiovascular risk include the presence of *diabetes mellitus, clinical cardiovascular disease*, and *target-organ damage*. Damage to target organs (manifested by hypertensive retinopathic changes, signs of LVH with remodeling, and proteinuria or renal insufficiency) indicates significant risk of subsequent cardiovascular morbidity and mortality. Similarly, manifestations of overt cardiovascular disease (e.g., angina, claudication, congestive heart failure, stroke, carotid bruit) portend poor outcome if hypertension remains untreated. The JNC VI identifies three risk categories of increasing severity (A, B, and C) based on these determinants that can be used to guide clinical decision making:

- *Risk Group A* (no additional risk): No cardiovascular risk factors; no clinical cardiovascular disease or target-organ damage;
- *Risk Group E* (moderate addition risk): At least one risk factor, not including diabetes, clinical cardiovascular disease, or target-organ disease;
- *Risk Group C* (marked additional risk): Clinical cardiovascular disease or target-organ disease or diabetes, with or without other risk factors.

Combining these risk categories with the stage of hypertension provides a rational guide to the urgency of therapy and the intensity of the treatment program (see Chapter 26).

RECOMMENDATIONS

- Upon encountering blood pressure elevation, *confirm the diagnosis* but do not test for underlying pathophysiology (except in cases of suspected secondary hypertension), because such testing is not yet sufficiently accurate to aid in clinical decision making.
- Check for and rule out any clinically suggested *secondary causes*.
- Assess the *severity* of the blood pressure elevation.
- Identify any *target-organ (end-organ) damage*.
- Identify any and all concurrent *cardiovascular risk factors*, including clinically overt cardiovascular disease.
- Combine these risk determinations into an *overall estimate of cardiovascular risk*.

CHAPTER 20 EVALUATION OF CHEST PAIN

The patient who presents with chest pain in the outpatient setting poses a diagnostic challenge. The spectrum of diagnostic possibilities ranges from life-threatening cardiac, pulmonary, and aortic etiologies to esophageal and musculoskeletal causes. Harmless conditions may mimic more serious disease. Atypical chest pain can be especially problematic. The primary physician must be skilled in quickly and accurately differentiating the patient who requires immediate hospitalization from the person who can be safely evaluated in the outpatient setting. Initial decision making depends predominantly on a careful assessment of the history supplemented, when possible, by checking for a few key physical and electrocardiographic findings. Further testing must be selected judiciously to avoid generating false-positive results.

PATHOPHYSIOLOGY AND CLINICAL PRESENTATION

Chest pain may arise from chest wall, intrathoracic, abdominal, or even psychophysiologic sources.

Chest Wall. Pain originating in the chest wall is usually due to musculoskeletal pathology, although occasionally nerve injury is responsible. Typically, the pain can be pinpointed by the patient, being somatic in nature. It is aggravated by deep inspiration, cough, direct palpation, and movement. Common sites of involvement are the costochondral and chondrosternal junctions. Duration ranges from a few seconds to several days and quality from sharp to dull or aching. Sometimes the patient complains of tightness. Vigorous and unaccustomed exertion can lead to muscular and ligamentous strain, which may account for some cases. Others are due to *costochondritis* (Tietze's syndrome), which is an inflammatory condition that causes localized swelling, erythema, warmth, and tenderness at the costochondral or chondrosternal junction. *Rib fracture* may produce a similar picture, although location is different, and there is a history of antecedent trauma or metastatic cancer. Of interest, there is an increased frequency of musculoskeletal pain in patients with angina, which causes a potentially confusing clinical presentation.

Nerve injury due to a recrudescence of *herpes zoster* infection can be very painful, with a dermatomal distribution being characteristic. The pain may precede the typical rash (prosaically described as "dew drops on a rose petal"; see Chapter 193) by 3 to 5 days. Neurologic complaints range from hypoesthesia to dysesthesia and hyperesthesia. In the elderly, the pain may persist for months, long after the rash resolves.

Nerve injury from *cervical root compression* (see Chapter 148) due to cervical spine disease or a *thoracic outlet syndrome* can produce pain in the chest and upper arm, superficially resembling angina. In the outlet syndrome, a cervical rib may compress part of the brachial plexus, resulting in motor and sensory deficits in an ulnar distribution at the same time that there is discomfort in the chest and upper arm (see Chapter 167).

Lungs and Pleura. *Inflammation or distention of the pleura* produces true "pleuritic pain," which is worsened by deep inspiration and cough but relatively unaffected by movement or palpation. A host of causes can trigger the inflammatory process, including infection, pulmonary infarction, neoplasm, uremia, and connective tissue disease. The more florid the inflammation, the greater the pain. An infectious origin is more likely to cause pain than is a low-grade serositis associated with connective tissue disease. Stretching of the pleura after a *spontaneous pneumothorax* results in acute onset of pleuritic pain and dyspnea. The condition occurs in young persons and those with emphysema, in which there can be rupture of a bleb. If the pneumothorax is large, deviation of the trachea may be observed.

Pleurodynia is a self-limited source of pleuritic pain, most common in children and young adults and associated with a respiratory viral infection, such as that due to coxsackie virus B. A typical viral syndrome precedes the acute onset of chest pain. Chest pain in the setting of a viral upper respiratory infection may also occur from cough-initiated injury to the chest wall or from bronchospasm. Young healthy persons sometimes note a sudden sharp pleuritic episode relieved by taking a deep breath, referred to as the *precordial-catch syndrome*. Its mechanism is unclear, but a transient folding of the pleura on itself is hypothesized.

Most diseases of the *pulmonary parenchyma* do not cause chest pain unless they extend to a pain-sensitive structure (e.g., vessel wall, pleura). Consequently, the chest pain occurring in the context of *pneumonia, pulmonary tuberculosis,* or *pulmonary embolization* will be pleuritic and represent extensive disease. It is estimated that fewer than 10% of embolic episodes trigger chest pain. The most common manifestations of embolization are dyspnea, tachypnea, and tachycardia, which are nearly universal but may be short-lived. Pleural rub, effusion, fever, and hemoptysis suggest the presence of pulmonary infarction and pleural reaction.

Heart and Pericardium. *Coronary artery disease* impairing myocardial blood supply and presenting as *angina pectoris* is the most important cardiac source of chest pain. Coronary perfusion may be similarly compromised by critical *aortic stenosis* leading to angina (see Chapter 33). The classic hallmarks of angina are its sudden onset with exertion, emotional stress, or eating (usually a very large meal) and its relief within minutes by rest or nitroglycerin. Patients usually describe their chest pain as a squeezing, heaviness, or pressure, although it may be burning or sharp. The quality of the pain is not diagnostic, and many patients state the sensation is more a "discomfort" than a true pain. Radiation to the jaw, neck, shoulder, arm, back, or upper abdomen is common and may present in the absence of chest symptoms. At times, the arm is reported to feel numb or tingling. Autonomic epiphenomena such as diaphoresis and nausea may accompany the episode, as may dyspnea if there is transient pump failure or marked anxiety. Episodes last 2 to 20 minutes. Prompt response to nitroglycerin is characteristic; relief is usually obtained within 5 minutes.

Gender and racial differences in presentation have been explored. The clinical presentation of myocardial ischemia in *women*, particularly women under the age of 60 years, can differ from that in men. Chest pain is more likely to be absent or atypical (see below) and may be overshadowed by exertional fatigue, shortness of breath, diaphoresis, arm tingling, jaw discomfort, nausea, or other epiphenomena of ischemia that are easy to dismiss as "noncardiac." Diabetes mellitus is a major risk factor for early onset of ischemic heart disease in women. As regards the effect of race on presentation, acute chest pain presentations appear to be similar among whites and African-Americans.

Unstable angina is one of the *acute coronary syndromes*, along with *non–Q wave myocardial infarction and Q-wave myocardial infarction.* All are important causes of coronary chest pain and result from acute plaque rupture that triggers platelet activation, thrombin clot formation, and active vasoconstriction. The clinical presentations of unstable angina include onset of new chest pain within the past 2 months severe enough to inhibit activity; established angina now increasing in frequency, severity, and duration (*crescendo angina*) and occurring with progressively less provocation; and development of *rest pain* or *nocturnal angina* in a person with a previously stable anginal pattern. Immediate mortality risk is high (up to 4%) but declines after 1 to 2 weeks. Clinical features associated with greatest risk include rest pain in excess of 20 minutes, signs of pump failure (hypotension, rales, S_3), new or worsening mitral regurgitation, and 1 mm or more of ST segment change with pain.

Women with unstable angina are less likely than men to present with acute ST segment elevation indicative of vessel-occluding infarction. Compared with men presenting with unstable angina, they are older; more likely to have diabetes, hypertension, and prior heart failure; and typically present hours later into the episode.

Myocardial infarction is typically heralded by chest pain exceeding that of unstable angina, but the presentation is often more subtle or even silent, particularly in diabetics, the elderly, and women. Bad prognostic signs include heart failure, hypotension, mitral regurgitation, ST segment elevation, and a new left bundle branch block. Onset of *postinfarction angina* is also associated with high risk.

Variant angina, as originally described by Prinzmetal, refers to anginal pain occurring exclusively at rest in conjunction with transient ST segment elevation on electrocardiogram (ECG). Classically, this syndrome was associated with coronary artery spasm at the site of high-grade proximal fixed stenosis. However, other forms of coronary disease may produce a similar clinical picture, and coronary vasospasm may present in ways other than Prinzmetal's description. *Cocaine abuse* can trigger ischemia by precipitating coronary vasoconstriction, increasing myocardial oxygen demand, and enhancing platelet aggregation. It may present as angina in a young person with no other coronary heart disease (CHD) risk factors.

Atypical angina (atypical chest pain) is a term used to denote angina-like chest pain that differs in location, quality, or other characteristics from more typical angina

yet is still suggestive by virtue of similar precipitants, timing, or other features. Some define the term more precisely, indicating presence of any two of angina's three cardinal features (substernal location, exercise precipitation, prompt relief by rest or nitroglycerine). As many as 50% of such patients who come to angiography prove to have coronary disease. Among the remainder, there appear to be increased incidences of panic disorder, major depression, esophageal disease, and coronary microcirculatory dysfunction. The mechanisms for many of these causes are not well understood, but recent interest has focused on the coronary microcirculation. *Coronary microvascular dysfunction* has been noted, characterized by abnormal responses to autonomic and biochemical stimuli. Normally, vasodilatory endothelial stimuli such as acetylcholine fail to lower arterial resistance. These patients exhibit increased microvascular resistance and reductions in perfusion. Such microvascular dysfunction has been found with increased frequency among patients with atypical angina who exhibit an ischemic response to exercise stress testing yet have entirely normal coronary angiograms. The terms "*microvascular angina*" and "*syndrome X*" have been applied to such persons. The significance of these findings is still is unclear and requires much more study, but they suggest a possible explanation for the chest pain of patients with *hypertrophic cardiomyopathy*.

Mitral valve prolapse is notorious for its association with atypical chest pain. The commonly held view of a link between the two has been challenged by recent studies controlling more stringently for selection bias. Some argue the apparent association is due to an increased frequency of underlying psychopathology, such as panic disorder (see below), that may trigger chest pain. Symptoms of autonomic dysfunction (e.g., palpitations, sweating, dizziness) may sometimes accompany the chest pain and simulate an ischemic attack.

Pericarditis may present with pleuritic pain, resulting from spread of the inflammatory process from the relatively insensitive pericardium to the adjacent pain-sensitive parietal pleura. The pain is sharp, aggravated by respiratory activity, and sometimes precipitated by swallowing if the posterior aspect of the heart is involved. When the diaphragmatic surface of the pericardium is involved, pain will be referred to the tip of the shoulder. Change in position may alter the pain. Patients often note lessening of pain on sitting up and leaning forward. Pericarditis can also produce a second type of pain that mimics angina. Its most diagnostic physical finding is a two- or three-component friction rub.

A vexing pericardial problem is the development of chest pain after coronary bypass surgery. The return of typical angina raises the specter of graft occlusion, but pleuritic pain suggests the *postpericardiotomy syndrome*.

Aorta. *Aortic dissection* is a must-not-miss cause of chest pain. Almost invariably (70% to 90% of cases), it begins with sudden onset of severe chest or interscapular pain, maximal from the start, and tearing or ripping in quality. If it begins in the chest, it may radiate to the interscapular region, neck, jaw, lower back, or even down into the legs. Associated symptoms include neurologic deficits from cutoff of blood supply to the brain, spinal cord, or limb. Loss or diminution of a major peripheral pulse is a key physical finding, as are new onset of aortic insufficiency and pericardial tamponade due to dissection into the aortic root.

Esophagus. Esophageal pain can be the great mimicker of anginal chest pain, producing chest discomfort that can resemble angina in quality, location, radiation, and even precipitants (e.g., exposure to cold, exertion). Unlike angina, esophageal chest pain is more likely to persist as a dull sensation for several hours after an acute attack and may occur with swallowing. The pain sometimes radiates to the interscapular region. The chest pain may occur spontaneously or in the context of meals or *acid reflux* (manifested by retrosternal burning that may be brought on by a large meal, lying down, or bending over and relieved by antacids). Some patients report *dysphagia* as an accompanying symptom. In some instances, studies of esophageal function reveal *motor dysfunction* (e.g., nonpropulsive contractions or "spasm") and acid reflux from the stomach. Nitrates and calcium-channel blockers may provide relief in such cases, as they do for angina. Some patients with atypical chest pain and normal coronary angiograms manifest both esophageal spasm and microcirculatory dysfunction, raising the intriguing possibility of a generalized disorder of smooth muscle reactivity.

About half of patients with noncardiac (i.e., angiogram-negative) angina-like chest pain report no concurrent dysphagia or heartburn and manifest no signs of reflux or motor dysfunction on detailed esophageal testing. In the past, such chest pain was labeled as "*noncardiac chest pain of unknown etiology*"; however, controlled studies using impedance planimetry reveal esophageal *hypersensitivity, hyperreactivity, and stiffness* in a large proportion of previously undiagnosed patients. These findings suggest a *sensory* or "*nociceptive*" etiology to much noncardiac chest pain. It appears that, in such patients, normal degrees of esophageal distention result in exaggerated perceptions of pain and in hyperreactivity.

Other Gastrointestinal Tract Sources. An attack of acute *cholecystitis* may resemble angina by producing substernal discomfort that responds to nitrates, which reduce cystic duct spasm. On rare occasions, *pancreatitis or peptic ulcer* disease produces substernal chest pain. Even a patient with gaseous distention of the bowel in the area of the splenic flexure may complain of precordial discomfort.

Psyche. Dramatic chest pain presentations are common among patients with underlying psychopathology. In addition to presentations that may be clinically indistinguishable from angina, patients with *anxiety* or *depression* often describe feelings of chest heaviness or tightness that can last for hours to days, unrelated to exertion and unrelieved by rest. In patients with anxiety disorders, this sensation may be accompanied by a feeling of inability to take in a deep breath. When there is associated hyperventilation, the resulting hypocapnia leaves the patient lightheaded and the extremities tingling.

Cardiac neurosis may lead to reports of chest pain mimicking angina. At other times, the patient misinterprets a noncardiac chest sensation. Patients with a *personality disorder* and *somatization* may describe almost any form of chest pain, including some suggestive of angina. A life-long pattern of multiple refractory bodily complaints is characteristic (see Chapter 230). *Malingering* represents a conscious effort to feign illness for secondary gain. The hallmark is inconsistency of the story. Although other forms of psychogenic chest pain may bring secondary benefits to the patient, there is no premeditated attempt to deceive.

Patients with atypical chest pain related to an underlying depression or panic disorder tend to be younger, more often female, more apt to have a higher number of accompanying autonomic symptoms, more bothered by phobias, and more likely to describe an atypical form of chest pain than those with chest pain and a positive coronary angiogram.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of chest pain can be organized along anatomic lines, as outlined in Table 20.1. Must-not-miss diagnoses include CHD, critical aortic stenosis, aortic dissection, pneumothorax, cholecystitis, pericarditis, and pleuritis from pneumonia, embolization, or cancer. Underdiagnosis and delay in diagnosis of CHD is a problem in women under the age of 60 years, because their clinical presentations may be atypical or ignored. A high index of suspicion is warranted in such persons, especially when there is preexisting diabetes, a major risk factor for early development of CHD in women. Underdiagnosis of CHD is also a problem for African-Americans presenting with chest pain.

Table 20.1. Differential Diagnosis of Chest Pain

WORKUP

The first priority is to determine the *need for emergent hospitalization.* This requires estimating the likelihood of myocardial ischemia, aortic dissection, and pulmonary embolization, conditions that place the patient at high risk for a potentially life-threatening complication. Timeliness of the assessment is of the utmost importance,

because outcome often depends on prompt intervention. In many instances, the decision to immediately hospitalize will need to be made by history alone, often on the basis of a telephone call by the patient. Delaying hospitalization is a major cause of poor outcome. Delays tend to be particularly prevalent among women and African-Americans. Postmenopausal women presenting with ischemic chest pain are one third less likely to be admitted to the hospital than men with the same degree of cardiac risk.

An efficient triage strategy for initial decision making is one that determines and stratifies chest pain risk on the basis of presenting history supplemented by physical examination, ECG, and on occasion chest x-ray (if available and deemed necessary). Predictions of risk based on this approach have proven to be extremely powerful and can be used to determine who will benefit most from prompt hospitalization and aggressive testing. Extensively testing low-probability patients for ischemia, dissection, and embolization is not only wasteful, it leads to a high false-alarm rate with its attendant adverse consequences. Although there may be psychological pressure to proceed to elaborate diagnostic studies in all patients with chest pain, only those with at least a modest pretest probability (e.g., at least 20%) of serious pathology benefit from such testing (see Chapter 2). The provision of meaningful reassurance does not usually require exhaustive testing, but it is aided by a careful clinical assessment (see Patient Education, below).

History

Estimating Probability of Coronary Disease by History. A careful chest pain description is critical. The prevalence of angiographically confirmed CHD approaches 90% in persons with a classic story for angina (see above). Prevalence declines to less than 15% in those coming to catheterization who have nonanginal chest pain. In the Framingham study, patients presenting with new onset of definite angina had a relative risk of a coronary event over 2 years of 3.7 for men and 5.9 for women. Relative risk fell for those with possible angina to 3.0 for men and 2.9 for women and to 1.3 for men and 0.8 for women with nonanginal chest pain.

Among the features of the chest pain description with the greatest discriminant value are its *timing* in relation to *precipitating* and *alleviating factors*. Quality, location, radiation, and intensity of pain are notoriously nonspecific. Precordial pain radiating down the left arm can occur with almost any cause of chest pain. A common pitfall in taking the history is to provide classic descriptions of chest pain to the patient who cannot give a quick crisp account of his or her chest pain. Under the duress of the physician's interrogation, the patient may agree to one of these neat descriptions, leading to a false-positive diagnosis. The initial vagueness may have been more useful.

Past medical history is reviewed for major *cardiac risk factors* (e.g., hypertension, diabetes, smoking, hypercholesterolemia, and obesity). Inquiry into cocaine use is essential, especially in young persons presenting with ischemia-like chest pain. *Family history* is checked for *premature coronary disease*. Note is also taken of patient *age and gender*. Postmenopausal women with coronary artery disease have an especially poor prognosis. Awareness of the potential biasing effects of gender and race on clinical thinking is critical to avoiding them. Race and gender have been found to be independent determinants of how patients are assessed. Because there are no differences in acute chest pain presentations among whites and African-Americans, the chest pain presentation can be evaluated without need to adjust for race. However, differences in CHD presentation between sexes need to be kept in mind. Women are often underdiagnosed, in part because the story may be atypical or vague (e.g., exertional fatigue, arm tingling, nausea, shortness of breath). A high index of suspicion for CHD is required in women under the age of 60 years presenting with chest pain, especially if they have preexisting diabetes (which negates the beneficial effects of estrogen).

Checking for an Acute Coronary Syndrome. Any person with angina-like pain and cardiac risk factors should be asked if the pain is of *greater than 20 minutes'* duration, *crescendo* in pattern, now occurring at *rest* or at *night* and with exertion, of *new onset* (especially if severe enough to limit activity), or associated with *dyspnea*. An answer of "yes" to any of these questions on telephone triage should prompt immediate hospitalization by ambulance, because risk of an acute coronary syndrome is sufficiently high and time is of the utmost importance. If evaluated in the office, the patient needs only a brief physical examination and ECG (only if immediately available; see below) to complete the initial assessment.

Consideration of Noncardiac Etiologies in Persons with Angina-like Pain. Some elements of the history suggestive of coronary disease are also important for the other causes they suggest. *Pain brought on by exertion and relieved by rest* is certainly indicative of angina, but psychogenic disease and even esophageal spasm may behave in similar fashion, necessitating at least consideration of these alternative diagnoses. A check for anxiety, depression, panic episodes, headache, nervousness, weakness, fatigue, and life-long history of multiple bodily complaints may help identify a psychogenic origin. Heartburn, dysphagia, symptoms associated with meals, and an absence of CHD risk factors raise the possibility of esophageal disease. Recurrent episodes that last hours to days provide further evidence of a noncardiac origin. *Prompt response to nitroglycerin* is another characteristic feature of CHD, but esophageal spasm, coronary microvascular disease, cystic duct spasm, and even some psychogenic etiologies may also respond to nitrates. *Chest pain brought on by eating* may be due to angina, but in the absence of other risk factors for CHD, one needs to consider gastroesophageal or pancreaticobiliary pathology. As noted earlier, response to nitroglycerin is not necessarily helpful in differentiation.

Checking for Aortic Dissection. Attention to onset, radiation, and associated symptoms are critical for early identification of aortic dissection. One checks for *sudden* onset; *maximum* intensity from the start (often described as a catastrophic presentation of tearing or searing pain); radiation into the *interscapular* region, *jaw*, neck, or down into the lower back or legs; and any accompanying *new neurologic deficit or syncopal episode*. Such a presentation should strongly suggest acute dissection of the thoracic aorta and warrant consideration of immediate hospitalization. Past medical history is reviewed for atherosclerotic risk factors, existing vascular disease, blunt trauma to the chest, and connective tissue disease (e.g., Marfan's syndrome). Although many less serious conditions can cause chest pain that radiates into the back (esophageal pathology being the most common), the seriousness of aortic dissection mandates a careful review of the history and risk factors. Seventy percent to 90% of cases exhibit the characteristically dramatic presentation, but 10% to 30% are more subtle in their manifestations, necessitating a high index of suspicion for the condition.

Evaluating Pleuritic Pain. *Pain worsened by deep inspiration or cough* is a hallmark of pleural irritation, but such pain is also suggestive of pericarditis and chest wall pathology. Even aortic dissection may cause pain worsened by movement due to respiration. Focal *chest wall tenderness* worsened by movement quickly narrows the differential to a chest wall origin. In the absence of focal chest wall pain, one needs to search promptly for evidence of intrathoracic pathology. Inquiry is needed into fever, cough, sputum production, tuberculosis exposure, hemoptysis, smoking, HIV exposure or high-risk behavior, unilateral leg edema, calf tenderness, shortness of breath, past history of embolization, recent orthopedic surgery, and oral contraceptive use. Pneumothorax should come to mind when pleuritic pain is *sudden* in onset and accompanied by *dyspnea* in a young patient with a previous history of pneumothorax or when the patient has long-standing bullous emphysema. Precordial-catch syndrome is suggested by brief self-limited episodes in an otherwise healthy young person. Pleuritic pain worsened by turning but relieved by *sitting up and leaning forward* is indicative of pericarditis, which can be further assessed by physical examination. Attention to *the context* of the patient's pleuritic pain often suggests the diagnosis. Onset in a person with known metastatic cancer may be due to a pathologic fracture, pleural metastasis, or pulmonary embolization. The same pain in an otherwise healthy young person with new onset of a dry cough, low-grade fever, and myalgias is consistent with viral-induced pleurodynia and muscle soreness from coughing. A critical task is *estimating the pretest probability of pulmonary embolization*, which is aided by attention to key historical features and presence of risk factors (Table 20.2).

Table 20.2. Estimating Clinical Pretest Probability of Pulmonary Embolization

Physical Examination

In cases of acute chest pain where the history is very suggestive of unstable angina, pulmonary embolization, or aortic dissection, the decision to immediately hospitalize can be made on the basis of history alone. There is no reason to delay admission. In the setting of less acute chest pain or a more ambiguous story, the physical examination can provide important evidence pertinent to the differential diagnosis and the assessment of risk.

General appearance and vital signs can be telling. Tachypnea and tachycardia in a person with acute pleuritic pain are suggestive of pulmonary embolization, whereas an anxious, sighing, hyperventilating individual who complains of constant chest tightness is likely to be suffering from an anxiety disorder. Blood pressure is noted for elevation (an important risk factor for cardiovascular disease), for hypotension (a bad prognostic sign in acute coronary syndromes), and for asymmetry (a sign of aortic dissection). The *skin* is noted for cyanosis, herpetic rash, pallor, jaundice, and xanthomata. Examination of the *fundi* may provide evidence of atherosclerotic, diabetic, or hypertensive disease. The *carotid pulse* is palpated for delay in upstroke, suggesting hemodynamically significant aortic stenosis, and checked for its loss in the person with possible aortic dissection. The *jugular venous pressure* is noted; it may be transiently elevated during an ischemic episode or newly elevated from acute right heart strain due to acute pulmonary embolization.

The *chest wall* is examined carefully in the person reporting "pleuritic" pain, beginning with inspection for signs of trauma and the *rash of herpes zoster* and palpation for swelling and focal tenderness. If pain is elicited, it is important to be sure the pain on palpation is identical to the patient's presenting complaint. One should next listen to the *lungs for a pleural friction rub* during inspiration and expiration and note any signs of consolidation or effusion. *Hyperresonance*, absent breath sounds, and *tracheal deviation* suggest a significant pneumothorax that requires immediate attention. Checking for *rales* (crackles) in the patient with angina assesses the possibility of ischemic left ventricular dysfunction (another sign of pump failure and poor prognosis).

On examination of the *heart*, the left ventricular impulse is observed and noted for signs of hypertrophy (indicative of significant aortic stenosis, long-standing hypertension, or a hypertrophic cardiomyopathy). Signs of ischemic myocardial dysfunction, such as *loss of physiologic splitting* of the second heart sound, development of an S_4, and presence of an S_3 are sought; they may be transient, occurring only during chest pain, but their presence suggests considerable myocardium at risk. Listening for the *systolic ejection murmur* of aortic stenosis should not be forgotten in the patient with angina nor should the *systolic regurgitant murmur* of mitral regurgitation due to papillary muscle ischemia. If the chest pain is pleuritic, then carefully listening for the two- to three-component *pericardial friction rub* is indicated. Although the relation between mitral valve prolapse and chest pain is questionable, listening briefly for a mid-systolic click and late systolic murmur completes the examination.

The *abdomen* is checked for epigastric and right upper quadrant tenderness (especially when evidence suggests gastric or hepatobiliary disease) and for masses (particularly an abdominal aneurysm in the context of suspected dissection). The *legs* require careful examination for unilateral edema and other signs of phlebitis (see Chapter 22), a potential source of pulmonary embolization in the person presenting with pleuritic pain. All *peripheral pulses* are checked, noting any absences and evidence of acute ischemia, which might occur with an aortic dissection. The *spine* is palpated for areas of tenderness along the cervical and thoracic segments, and the *neurologic* examination needs to include a check for new focal deficits, another possible clue to dissection.

Laboratory Studies

Outpatient Testing versus Immediate Hospitalization. Although laboratory studies can be helpful, *one should not delay the decision to urgently hospitalize when the clinical picture suggests unstable angina or pulmonary embolization.* In fact, any delay brought about by taking time to obtain a "nice-to-have" but not essential diagnostic study in the office could be life threatening. Only those studies that are essential to immediate decision making should be considered. Even an ECG may be superfluous in the face of a reasonable story for unstable angina, because a normal study would not change the decision to hospitalize immediately.

Whom to Test. For patients who are deemed appropriate for outpatient evaluation, test selection should focus on conditions for which there is *at least a low-intermediate pretest probability* (e.g., more than 20%). Using such a probability threshold minimizes the risk of generating an unacceptably high proportion of false-positive results (see Chapter 2), which can lead to unwarranted disability and unnecessary invasive interventions. Because physician responses to the chest pain presentation sometimes differ by patient gender or race, it is important to keep the possibility of bias in mind so that the diagnostic assessment is not unduly influenced by it. African-American women are 60% less likely to be referred for cardiac catheterization than white men with the same pretest risk of coronary disease.

Suspected Coronary Heart Disease. The approach to laboratory workup for coronary disease is determined by the condition's pretest probability and an appreciation for the sensitivity, specificity, and cost of available tests (see Table 20.3).

TEST TYPE	SENSITIVITY	SPECIFICITY	SENSITIVITY FOR THREE-VESSEL/LEFT MAIN DISEASE	RELATIVE COST
Electrocardiographic	0.68	0.77	0.86	1.0
Echocardiographic	0.76	0.88	0.94	2.5
Thallium imaging, planar only	0.79	0.73	1.00	2.0
SPECT scanning	0.88	0.77	0.98	4.0
PET scanning	0.91	0.82	?	14.0

SPECT, single-photon emission computed tomography; PET, positron emission tomography.

From Garber AM, Solomon NA. Cost-effectiveness of alternative test strategies for the diagnosis of coronary artery disease. Ann Intern Med 1999; 130:719, with permission.

Table 20.3. Sensitivity, Specificity, and Costs of Stress Tests for the Detection of Coronary Disease

Clinically High Probability—Unstable Angina. As noted above, the very-high-probability patient (multiple CHD risk factors, history very suggestive of *unstable angina*) requires *immediate hospitalization* without delay. Additional outpatient testing is unwarranted. Once the patient arrives in the emergency room, a *resting ECG* is critical to initial decision making, used in most critical pathways for optimal emergency room triage of chest pain patients. Any ST- or T-wave changes indicative of ischemia are an indication for prompt consideration of therapy, be it thrombolytic or revascularization. Proceeding directly to *coronary angiography* is more cost effective than stress testing in such very-high-probability patients.

A normal ECG is not by itself sufficient evidence for discharge of the high-probability patient, but a shortened period of observation (e.g., 6 hours) followed by *stress testing* is being applied in some centers to safely minimize length of stay for patients with no ECG changes and normal serum levels of myocardial *creatine phosphokinase and troponin I*. Exclusionary criteria for early stress testing include ongoing chest pain, signs of heart failure, and elevations in creatine phosphokinase or troponin levels. Considerable debate continues as to the most cost-effective approach to initial inpatient evaluation of such patients.

Clinically High Probability—Stable Angina. The patient with CHD risk factors and a clinical presentation that is classic for *stable angina* does not need any testing to establish the diagnosis of coronary disease (the pretest probability is already in excess of 90%). Rather, the role of testing is to *estimate prognosis and stratify risk*, which inform selection of initial treatment (i.e., revascularization vs. medical therapy; see Chapter 30). A well-recognized prognostic determinant is *amount of myocardium at risk*, which can be assessed by electrocardiographic, radionuclide, or echocardiographic stress testing (see below and Chapter 30 and Chapter 36). A less well-recognized risk factor is prior silent myocardial infarction, which may be detected by *resting ECG* (new Q waves or new ST- or T-wave changes since last ECG) or *cardiac ultrasound* (segmental wall akinesis). Postinfarction angina is a sign of potentially severe coronary disease, especially in persons with prior silent infarction (16-fold increase in mortality risk).

Clinically Intermediate Probability—Unstable Angina. The initial approach to this patient is the same as for the high-probability patient (i.e., immediate emergency room assessment; see above).

Clinically Intermediate Probability—Stable Angina. Patients in this category typically have a single cardiac risk factor and give a history of atypical chest pain that

is noncrescendo in pattern. In such persons, a *resting ECG* may be helpful, but nonemergent *stress testing* is needed if the resting ECG is nondiagnostic. Several modalities are available for stress testing (see also Chapter 36).

Exercise electrocardiography provides excellent sensitivity and specificity for detection of high-risk coronary disease (i.e., left main, left main equivalent, or three-vessel disease) at low cost, but false-positives occur in younger women, sensitivity is lower in the setting of less serious forms of coronary disease, and the test cannot be interpreted adequately unless the resting ECG is normal.

Stress echocardiography can be performed by bicycle exercise or dobutamine stimulation; cost is somewhat higher than with ECG, but sensitivity and specificity are better.

Radionuclide imaging with thallium or technetium sestamibi uses planar scanning and, more recently, *single-photon emission computed tomography* (SPECT), which enhances sensitivity and specificity by providing three-dimensional views. It can be performed by treadmill exercising or adenosine injection, which causes a steal phenomenon and enhances differences in uptake. Increased sensitivity is achieved with radionuclide imaging but at increased cost. *Positron emission tomography* (PET) is the most sensitive and specific of tests for coronary insufficiency but also the most expensive and still limited in availability. *Ambulatory electrocardiographic monitoring* is not recommended because specificity is low and the false-positive rate is high.

Sensitivity for detection of coronary disease ranges from 0.68 for ECG to 0.91 for PET. All are very sensitive for detection of left main, left main equivalent, and three-vessel coronary disease, with sensitivities ranging from 0.86 for ECG stress testing to 0.98 for SPECT. Electrocardiographic stress testing is by far the lowest in *cost* but also slightly less sensitive and specific than other modalities. Cost-effectiveness analyses identify ECG and echocardiographic stress testing as the most cost effective for diagnosis of coronary disease in chest pain patients with an intermediate pretest probability of coronary disease. SPECT may also be cost effective in settings where its cost is lower than average. The increased sensitivity and specificity associated with PET scanning are insufficient at the present time to overcome its very high cost (see Chapter 36).

Clinically Low Probability. The patient with clearly nonanginal chest pain, no CHD risk factors and a normal cardiac examination has such a low probability of CHD that testing is likely to generate only negative or false-positive results and excessive medical bills. Even a CHD test with high sensitivity and specificity will perform poorly and produce an excessive proportion of false-positive results if applied to a person with a very low pretest probability of CHD (see Chapter 2 and Chapter 36).

Occasionally, a *resting ECG* is obtained to reassure the very anxious low-risk patient. Performing this low-cost test has been found to speed resumption of normal activity in the overly concerned patient without greatly increasing cost. This approach should not be used unless there is strong patient need for some "objective" reassurance and the patient is warned beforehand that a positive result is most likely to be a false-positive. As lay knowledge of testing modalities for coronary disease increases, requests among low-risk patients for stress testing are likely to escalate but should be rebuffed because such testing will only increase cost without improving diagnostic accuracy.

Suspected Esophageal Disease. The obvious case of esophageal disease (retrosternal burning, difficulty swallowing) requires no testing unless symptoms are refractory, in which case a search for malignancy is indicated (see Chapter 60). More problematic diagnostically is the patient with angina-like pain, a normal cardiac evaluation (including angiography), and no esophageal symptoms. As many as 20% of patients with pain suspicious enough to warrant coronary angiography have been shown to have esophageal disorders. A convincing diagnosis of esophageal disease might save the patient a cardiac catheterization.

A host of provocative tests and esophageal function studies are available, including *manometry*, 24-hour *pH monitoring, edrophonium* provocation, and *acid perfusion* (see Chapter 60 for details). Although initial reports promoted their usefulness in the evaluation of chest pain, more carefully controlled study has failed to detect differences in esophageal function, either between periods of pain and no pain or between asymptomatic healthy control subjects and patients. In about 25% of patients, edrophonium chloride or acid provocation will trigger pain in patients and not in control subjects, but there is no difference in motor response. Either motor dysfunction is not the etiology in most esophageal cases or the tests of motor function are not very good. In either case, there seems to be little rational for their routine application. Recent reports suggest that measuring the response to *esophageal distention* better differentiates patients from control subjects. Distention testing is still a research tool and not available for clinical use, but the future trend in diagnosis of esophageal chest pain is likely to be toward identification of altered nociception and a heightened sensory response.

Pleuritic Chest Pain—Suspected Pulmonary Embolization. Just as for coronary disease, cost-effective test selection for embolization requires attention to its *pretest probability*. A validated model developed by Canadian investigators for estimating pretest probability uses *history and physical examination* supplemented by *chest x-ray and ECG* (Table 20.2). The most frequent radiographic finding in cases of embolization is a unilateral effusion. The utility of an ECG in patients with suspected embolus is marginal. The electrocardiographic findings of acute right heart strain ($S_1Q_3T_3$) are helpful if present, but sensitivity is low and a normal ECG certainly does not rule out the diagnosis. The most common electrocardiographic abnormality is inverted T waves in leads *V1-4* (representing posterior ischemia due to right coronary artery compression from right heart overload). *Arterial blood gases* are insensitive and often of little help in identifying patients with pulmonary emboli, but *arterial oxygen saturation* can add to the estimate of pretest probability.

Pulmonary Angiography. This study remains the gold standard for diagnosis of pulmonary embolism and should be used when definitive diagnosis is essential, urgent, and not available from noninvasive testing. Angiography without prior scanning is urged by some experts, especially if the risk of anticoagulant therapy is high for the patient and a definitive diagnosis is needed before commencing treatment. Nonetheless, rational use of noninvasive approaches to testing can greatly reduce the need for invasive study in most instances.

Ventilation-Perfusion Scanning. The test is widely used in patients with suspected embolization. As demonstrated in the landmark Prospective Investigation of Pulmonary Embolism Diagnosis (PIOPED), a normal or nearly normal scan in a patient with a low pretest clinical probability of embolization effectively rules out the diagnosis (negative predictive value, 96%). Likewise, a "high-probability" scan rules in the diagnosis if the patient has a high pretest probability (positive predictive value, 96%). Ventilation-perfusion (V/Q) scanning by itself can reduce the need for angiography in the 40% of cases where the pretest probabilities are strong and the scan results are concordant with these probabilities.

Unfortunately, the V/Q scans of a large proportion of patients produce either equivocal results or findings that are discordant with pretest probabilities. High false-positive rates are especially prevalent in those with preexisting lung disease and in the elderly. The addition of ventilation scanning has not solved the problem of false-positives. In the PIOPED, 40% of patients with a "low-probability" scan and a high pretest probability proved to have pulmonary embolization by angiography. Forty-four percent of patients with a high-probability scan and a low pretest probability had no embolization by angiography. The largest single group of patients were those with scans of "intermediate" probability, in whom embolization could be neither ruled in or out. These high rates of false-positives and false-negatives among selected groups of patients and the large number of indeterminate scans reflect shortcomings in the sensitivity and specificity of the test. Assuming any abnormality on scan to be a positive test, sensitivity would still be only about 90% and specificity just 10%. V/Q scanning remains widely used as a screening test for pulmonary embolism, but additional testing is needed in many patients.

D-Dimer Testing. This test provides a promising approach to noninvasive screening for pulmonary embolism. D-dimer is a degradation product of cross-linked fibrin. Its formation occurs in the context of ongoing thrombosis and fibrinolysis, making its measurement a potentially sensitive indicator of active venous thrombosis and thromboembolization. Reports of sensitivity in the setting of pulmonary embolism range from 85% to 100%, depending on the assay used. Specificity is not high (40% to 68%); D-dimer acts as an acute phase reactant and its levels rise in response to any event that induces fibrinolysis, such as inflammation, cancer, or trauma. Because D-dimer testing lacks specificity, confirmatory testing is needed when a result is "positive" (i.e., more than 0.5 µg/dL).

These characteristics make the D-dimer test most useful for ruling out pulmonary embolization, especially in chest pain patients with a low pretest probability. In such patients, the negative predictive value of a normal D-dimer level (less than 0.5 µg/dL) is 99%, effectively ruling out embolization and obviating the need for V/Q scanning or venous ultrasound testing. The test is also useful as a supplementary test in persons with a moderate pretest probability of embolization who have a nondiagnostic V/Q scan. A normal D-dimer in this setting provides a negative predictive value of 95%; if there is also a negative venous ultrasound, the negative predictive value of a normal D-dimer approaches 100%.

The original ELISA assay required testing on plasma and took 3 to 4 hours. Newer assays provide nearly equivalent sensitivity and can be performed in minutes on whole blood. Of concern are reports of unsatisfactory performance of the whole blood assay in cancer patients, where a negative result has not been found to reliably exclude DVT.

Venous Ultrasound of the Lower Extremities. Compression venous ultrasound provides some of the specificity lacking in V/Q scanning and D-dimer testing. Venous ultrasound is very specific and sensitive for detection of symptomatic deep vein thrombosis in the proximal veins (sensitivity 95%, specificity 96%). Because almost all pulmonary thromboemboli originate from the deep proximal veins of the legs, venous ultrasound has been proposed as a means to improve noninvasive diagnosis of embolization. However, the sensitivity of a single study is limited, because up to 40% of patients with embolism have no deductible clot remaining in the proximal venous system after initial embolization. To overcome this limitation, serial studies are done over 1 to 2 weeks. In most instances, a clot needs to reform in the leg before reembolization. Thus, sensitivity of the test for risk of embolization can be greatly enhanced by performing serial ultrasound studies. Even if the diagnosis of embolism cannot be confirmed initially, the risk of reembolization can be estimated by serial study. Using serial ultrasound in conjunction with V/Q scanning and pretest probability for embolism, Canadian investigators made an accurate diagnosis in over 96% of cases for suspected embolism; the false-negative rate was only 0.6%, with angiography needed in only 3.7% of cases.

Application of serial ultrasound has been found especially useful in patients with a moderate pretest probability and indeterminate V/Q scan findings. In this setting, a normal serial ultrasound rules out the diagnosis or at least obviates the need for immediate anticoagulation or angiography; a positive study rules it in, again obviating the need for angiography. Ultrasound in combination with D-dimer determination has been found effective in excluding embolism in patients with a low clinical suspicion for embolism.

Helical (Spiral) Computed Tomography. This new technology is designed to detect emboli-induced pulmonary filling defects by means of a two-dimensional volumetric image of the lung. Although rapid to perform (about 30 seconds), the test requires intravenous contrast and is expensive. Some have proposed it as an alternative to V/Q scanning or angiography. Although helical computed tomography (CT) test shows promise for use in the evaluation of patients with poor pulmonary reserve who have a nondiagnostic lung scan plus a negative venous ultrasound and in those with a very high pretest probability, available data are inadequate to determine what the best application(s) of this technology may be and how it may contribute to diagnosis and decision making. Prospective trials are needed.

Approach to Testing. Pretest probability of pulmonary embolization should be used to guide test selection (Table 20.2).

Low pretest probability patients can be screened by application of a sensitive noninvasive test such as D-dimer assay or V/Q scan, with selection dependent on availability and local expertise. A completely normal V/Q scan or D-dimer study rules out clinically significant pulmonary embolism in low-probability patients (negative predictive value well in excess of 95% in major prospective studies). A normal D-dimer can obviate the need for the more expensive V/Q scan. A nondiagnostic V/Q scan or a D-dimer level more than 0.5 µg/dL necessitates additional testing, such as venous Doppler ultrasound; if the initial ultrasound is negative and the patient is in no cardiopulmonary distress, then withholding anticoagulation and testing serially is a reasonable strategy.

High pretest probability patients should be admitted and have anticoagulation started pending the results of testing. V/Q scanning can then proceed, followed by ultrasound if the result is indeterminate. If ultrasound is positive, the diagnosis is confirmed; if negative or equivocal, then angiography is indicated, because noninvasive testing remains insufficiently sensitive at this time to rule out embolization in a patient with a high pretest probability.

Intermediate pretest probability patients should start with a V/Q scan. A normal V/Q scan rules out the diagnosis. An indeterminate V/Q result does not and should be followed by venous ultrasound and D-dimer testing, which if negative rules out embolism. If D-dimer testing is not available, then serial ultrasound testing is a reasonable substitute to ensure absence of DVT and risk of embolization.

Pleuritic Chest Pain—Suspected Pulmonary Infection and Other Nonembolic Etiologies. The *chest x-ray* is the initial test of choice. Pneumococcal pneumonia and tuberculosis often present with acute pleuritic chest pain and may be mistaken clinically for pulmonary embolism. Consequently, any patient with pleuritic pain, sputum production, and an infiltrate of chest film should also have both *Gram's and acid-fast stains* made. A pleural effusion may also be detected on chest film. Any nonloculated pleural effusion of unknown etiology should be tapped, gram-stained, cultured, examined microscopically, and sent for cell count, glucose, lactic dehydrogenase, and protein determinations (see Chapter 43). *Suspicion of pneumothorax* is also an indication for a chest film, but if radiography is not immediately available and the patient is in respiratory distress, decompression should not be delayed.

When *pericarditis* is under consideration, an ECG is essential. However, the ECG changes of early repolarization, a harmless finding seen in young men, may closely resemble those of acute pericarditis. The presence of concave ST segment elevations in both limb and precordial leads and the presence of PR segment depressions in the precordial leads, if they occur in the limb leads, distinguish pericarditis from early repolarization. *Cardiac ultrasonography* may reveal a pericardial effusion. An antinuclear antibody, blood urea nitrogen, and tuberculin skin test are indicated when the cause of pericarditis is not readily evident.

Suspected Aortic Dissection. A *chest x-ray*, which may demonstrate a widened mediastinum (especially in traumatic aortic rupture), is sometimes performed for screening purposes, but if dissection is truly suspected on clinical grounds, then emergency admission for aortic angiography is indicated. Delaying admission to obtain a chest film is unwise. Patients with traumatic aortic dissection may also be well served by *transesophageal ultrasonography* preferred to *transthoracic ultrasonography*, which is less sensitive for detecting disease in the aortic arch. *CT with contrast* is useful when the aortogram is not available or is negative, yet clinical suspicion remains high. Many now proceed directly to CT because it is less invasive and can be done on shorter notice than angiography. *Magnetic resonance imaging* can also detect dissection and provides another noninvasive alternative to contrast angiography.

Other Conditions. Only a few *musculoskeletal* disorders require chest radiography: suspected rib fractures and cervical or thoracic spine disease. If a *gastrointestinal* cause is suspected, a contrast study may be in order. The ECG may show T-wave depression in cholecystitis and pancreatitis and may mistakenly be interpreted as evidence of coronary disease.

The anxious patient with *psychogenic* pain may find a chest radiograph and/or ECG reassuring. In most instances, however, a thorough history and careful physical examination combined with a detailed explanation should suffice. Repeating tests "just to be sure" may begin to undermine the patient's confidence in the physician's explanation and even heighten anxiety, especially if there are repeat studies.

It is important to realize that as many as 10% to 15% of cases remain undiagnosed, even after careful and thorough evaluation. Nevertheless, in such instances it is still possible to rule out the presence of an acutely serious etiology. Most patients with chest pain that initially eludes diagnosis can be followed expectantly for the time being.

SYMPTOMATIC RELIEF

Relief of pain must be based on an etiologic diagnosis. To simply suppress the pain with analgesics or sedatives before a diagnosis is made may hide important clues and endanger the patient. However, musculoskeletal forms of chest pain may benefit from analgesia, especially if the patient is splinting and not ventilating adequately. When the diagnosis of costochondritis is certain, local injection with lidocaine into the point of maximal tenderness can provide dramatic relief. An antacid regimen or H_2-blocker therapy in conjunction with other antireflux and acid-reducing measures are helpful in patients with esophagitis. Nitrates and calcium channel blockers are sometimes of benefit to patients with esophageal spasm (see Chapter 61). Patients with depression or panic disorder require specific therapy directed at the underlying psychopathology; failure to treat etiologically may result in prolonged refractory disability from the chest pain (see Chapter 226 and Chapter 227).

PATIENT EDUCATION AND INDICATIONS FOR REFERRAL

Teaching Recognition of Acute Coronary Syndromes. The availability of effective early interventions for acute coronary syndromes and the risk of delay necessitate that patients are taught to recognize the symptoms and to call for help immediately. Those with multiple cardiac risk factors or known heart disease deserve top priority for such an educational intervention. Knowledge of key symptoms, especially duration in excess of 20 minutes; new rest pain; and epiphenomena of ischemia (e.g., diaphoresis, nausea, jaw or neck pain, lightheadedness) is weak, particularly among socioeconomically disadvantaged groups, minorities, the elderly, and younger patients. Patients should be instructed to call for an ambulance and not delay. Delay has been documented in up to 50% of cases and often compromises outcome. The importance of minimizing delay in presentation makes patient education and telephone triage important tools. Practices should be organized to handle chest pain telephone calls with no delay.

Providing Explanation and Meaningful Reassurance. A detailed review of clinical findings and their meaning is as essential to the effective evaluation of chest pain as is a correct diagnosis. When a harmless etiology is identified, it is not enough to dismiss the chest pain as "nothing to worry about," because the symptom is

associated with too many fears for such words to suffice. Meaningful reassurance requires eliciting patient concerns about their chest pain and addressing these concerns by specifically reviewing the pertinent clinical findings. Failure to do so may lead to unnecessary activity restrictions (e.g., fear to engage in sexual relations, favorite sports, or important work activities) or trigger requests for otherwise unnecessary testing. Patients making repeated visits, asking for referrals, or requesting elaborate testing usually harbor unexplored concerns. The effort taken to provide meaningful explanation is usually well worth the time in terms of patient appreciation, cost containment, and risk management.

Indications for Admission and Referral. As noted earlier, immediate referral to the nearest emergency room is essential to achieving the best possible outcome for the patient with any clinical or laboratory evidence for an acute coronary syndrome, pulmonary embolization, aortic dissection, or large pneumothorax. Key features include a story of unstable angina, sudden onset of severe tearing or searing chest pain with radiation into the back, new pleuritic chest pain in a patient with risk factors for pulmonary embolization or pneumothorax, severe dyspnea, signs of respiratory or hemodynamic compromise, and ischemic ECG changes with pain.

Persons who present with acute ST-segment elevation suggestive of acute myocardial infarction require consideration of immediate referral to a center capable of performing angioplasty, since outcomes are often better than those achieved by thrombolysis, especially when more than 3 hours have elapsed since onset of symptoms or time from referral to balloon can be less than 2 hours. Referral to the nearest emergency room for thrombolysis is reasonable when time from onset of symptoms to administration of tissue plasminogen activator will be less than 3 hours. For the chest pain patient who presents to the office with evidence of postinfarction angina or ECG findings of prior silent infarction, plans should be made for prompt hospital admission and cardiac consultation—such patients are at high risk. Acute chest pain in the context of cocaine use is also an indication for immediate hospitalization, even in a young person with no other cardiac risk factors. Referral for drug counseling should not be overlooked; it too is critical to a successful outcome (see Chapter 235). Patients at risk for a life-threatening chest pain etiology should be taught to recognize key symptoms and instructed to call 911 first if symptoms are acutely severe, even before calling the primary care physician.

Updated: 09/22/03

Outpatient workup is reasonable for the patient with low to intermediate probability of pulmonary embolization, provided there are no signs of respiratory or hemodynamic compromise and the appropriate initial testing (e.g., D-dimer determination, V/Q scan, venous ultrasound) can be completed within 2 to 3 hours. For the patient with pleuritic chest pain due to pneumonia, knowledge of the clinical features predictive of a complication is necessary to determine candidacy for admission (see Chapter 52). The utility of referral for esophageal function testing appears limited, but endoscopy or barium swallow should be considered if there is refractory reflux or dysphagia. The patient with panic disorder or depression severe enough to cause disabling chest pain symptoms will benefit from psychiatric referral (see Chapter 226 and Chapter 227).

RECOMMENDATIONS

- Identify the high-risk chest pain patient who requires immediate hospitalization by performing a triage history focusing on evidence for acute coronary syndrome, significant pulmonary embolization, aortic dissection, and acute cardiopulmonary compromise. Avoid common biases based on patient age, gender, and race.
- If the story is strongly suggestive, admit by ambulance; minimize delay. For suspected acute myocardial infarction with ST-segment elevation on ECG, consider immediate transfer to a center capable of performing angioplasty, especially if more than 3 hours have passed since onset of symptoms or time from referral to angioplasty can be achieved within 2 hours of initial presentation for care. Consider thrombolysis if less than 2 hours have passed since onset of symptoms. **Updated: 09/22/03**
- If the initial history is not strongly indicative of one of these etiologies, evaluate promptly in the office with a more detailed history and careful physical examination, supplemented, where appropriate, by ECG and chest x-ray.
- Formulate the initial differential diagnosis from these data; include a pretest estimate of myocardial ischemia, pulmonary embolization, and aortic dissection, because immediate decision making and the optimal locus and approach to further workup of these conditions heavily depends on such probability estimates.
- Select the appropriate testing strategy based on the pretest probability for the condition in question.

For Suspected Coronary Artery Disease

- Low pretest probability: Explain why the chest pain is unlikely to be of cardiac origin and consider obtaining a resting ECG if it will help reassure the patient.
- Intermediate pretest probability: If the presentation is suggestive of unstable angina, proceed to immediate hospitalization and emergency room triage protocols. If the presentation is one of "stable" (i.e., noncrescendo) chest pain, proceed on a nonemergent basis to stress testing. Obtain either exercise ECG (if the resting ECG is normal) or exercise echocardiography; both are reasonably cost effective; if other noninvasive modalities (e.g., radionuclide stress testing) are available locally at lower cost or with enhanced sensitivity and specificity, then their use may also be cost effective and should be considered.
- High pretest probability: If the presentation is very suggestive of unstable angina, proceed to immediate hospitalization and emergency room triage protocols. For those with ECG changes on arrival in the emergency room, immediate angiography without prior noninvasive testing appears to be the more cost-effective diagnostic approach. For those whose presentation is indicative of stable angina, proceed to nonemergent stress testing for determination of amount of myocardium at risk (see Chapter 36 for test selection).
- To minimize delay in hospitalization, teach the high-risk patient and family the symptoms of acute coronary syndromes and instruct them to call 911 immediately if such symptoms occur.
- Reduce requests for unnecessary testing by eliciting patient concerns about their chest pain, performing a detailed history and physical examination, obtaining an ECG, and addressing their concerns by a careful review of clinical findings.
- Omit routine use of esophageal studies in assessment of chest pain in patients who rule out for coronary disease.

For Suspected Pulmonary Embolization

- Low pretest probability: Screen by ordering a sensitive test noninvasive test, such as D-dimer assay or V/Q scan, with selection dependent on availability and local expertise. A nondiagnostic V/Q scan or a D-dimer level in excess of 0.5 µg/dL necessitates additional testing, with serial venous ultrasound a reasonable choice.
- Intermediate pretest probability: Begin with V/Q scanning. A normal V/Q scan rules out the diagnosis. A nondiagnostic V/Q result does not and should be followed by D-dimer or serial ultrasound, which if negative rules out embolism.
- High pretest probability: Admit to the hospital and begin anticoagulation, pending the results of testing. Start with V/Q scanning, followed by ultrasound if the result is indeterminate. If ultrasound is positive, the diagnosis is confirmed; if negative or equivocal, then angiography is indicated, because noninvasive testing remains insufficiently sensitive at this time to rule out embolization in a patient with a high pretest probability.

CHAPTER 21 EVALUATION OF THE ASYMPTOMATIC SYSTOLIC MURMUR

In the outpatient setting, systolic murmurs are often noted incidentally in otherwise asymptomatic patients. Although many asymptomatic murmurs are due to conditions of no prognostic significance, the absence of symptoms does not rule out the presymptomatic phase of potentially serious pathology, such as tight aortic stenosis. The primary physician should be able to conduct an effective clinical assessment in the office that differentiates the harmless murmur from one that requires additional investigation. Early detection of clinically silent but prognostically important disease is critical to optimizing outcomes and to identifying patients who require close follow-up. Routinely ordering a cardiac ultrasound examination on every patient discovered to have a systolic heart murmur is both expensive and unnecessary, but close follow-up and serial testing are essential in selected cases. This chapter focuses on clinical assessment of the asymptomatic patient (see Chapter 20, Chapter 24, Chapter 25, Chapter 33, and Chapter 40 for detailed discussions of evaluation and management of symptomatic patients with structural heart disease).

PATHOPHYSIOLOGY AND CLINICAL PRESENTATION (SEE ALSO CHAPTER 33)

Systolic murmurs can be divided into two broad categories: ejection and regurgitant. *Ejection murmurs* result from turbulent flow of blood across the ventricular outflow tracts during systole. They are characteristically crescendo-decrescendo, medium to low pitched, and heard best at the base of the heart, beginning after the first heart sound and ending before the second. *Regurgitation murmurs* represent backflow of blood due to incompetence of the mitral or tricuspid valve or the ventricular septum. They are typically higher in pitch, heard best at the apex or midsternal border, holosystolic or mid to late systolic in timing, and, like ejection murmurs, crescendo-decrescendo in pattern (unless rheumatic in origin, where the intensity is constant).

Ejection murmurs are common and often occur in the absence of heart disease. However, absence of symptoms does not mean absence of important underlying pathology. Regurgitant murmurs are associated with some abnormality of the mitral or tricuspid valve apparatus, valve ring, or septum, but the underlying lesion is not always of clinical significance.

Ejection Murmurs

"Physiologic" murmurs occur when there is increased ejection velocity across a normal valve creating turbulence. Causes of increased velocity include fever, anemia, pregnancy, hyperthyroidism, exercise, and conditions associated with a large stroke volume (e.g., aortic regurgitation, bradycardia, atrial septal defect [ASD]). Dilation of the aorta, as in hypertension or aging, may also produce a flow murmur by causing turbulent flow in the dilated segment.

"Innocent" murmurs occur in normal hearts under resting conditions. The origin of such murmurs is a subject of debate, with recent evidence pointing to the aortic root. Because there is no obstruction in the outflow tract, the murmur reflects the normal ejection pattern of blood from the ventricles and is early systolic and crescendo-decrescendo. Because chamber pressures are normal, there is normal splitting of heart sounds. Valves are normal; there are no adventitious sounds or other murmurs.

Early *aortic* and *pulmonic valve disease* may produce murmurs identical to physiologic ones, except that the former are often accompanied by an early systolic *ejection click*. In *pulmonic stenosis*, the murmur increases with inspiration, and the pulmonic component of the second sound is delayed as the disease progresses, widening the splitting of the second heart sound. With increasing stenosis, ejection murmurs usually become louder and more prolonged, with peak intensity occurring later in systole. In hemodynamically significant aortic stenosis, a sustained left ventricular heave develops, the carotid upstroke becomes delayed and lower in amplitude (the *parvus et tardus* pattern), and the second heart sound becomes softer and single as the aortic closing sound decreases.

Calcific aortic stenosis is the most common cause of aortic stenosis in the elderly. Onset is in the fourth decade if the underlying valve is bicuspid and in the sixth to eighth decades if the valve is an otherwise normal tricuspid one. Most patients present with symptoms of advanced disease (angina, heart failure, syncope), because the condition often goes unrecognized in the asymptomatic phase. Early diagnosis is often made difficult by the speed of disease progression and the deceptively subtle and atypical physical findings in elderly persons with hemodynamically significant disease. Valve calcification can progress rapidly, leading to hemodynamically significant outflow tract obstruction in as little as 1 to 2 years. Unlike other forms of aortic stenosis, the murmur at the base may reappear at the apex as a higher pitched sound and simulate mitral regurgitation (*Gallavardin's phenomenon*). In addition, the left ventricular lift associated with hemodynamically significant disease may be less prominent due to myocardial decompensation, and the carotid upstroke may be normal if the carotid artery is stiff due to age.

Hypertrophic cardiomyopathy (*idiopathic hypertrophic subaortic stenosis*) produces an ejection quality murmur by dynamically obstructing the left ventricular outflow tract. Displacement of the mitral valve may also occur dynamically and cause regurgitation. The ejection murmur is affected by the size of the left ventricular cavity and contractility. Maneuvers that decrease cavity size (e.g., Valsalva) increase obstruction and intensify the murmur. When there is marked obstruction, the murmur lasts through most of systole and its peak is delayed beyond mid-systole. Some patients are prone to tachyarrhythmias. The electrocardiogram (ECG) shows high voltage.

ASDs produce physiologic murmurs due to increased right ventricular stroke volume. However, unlike other physiologic murmurs, there is often wide and fixed splitting of the second sound due to left-to-right shunting of blood and a delay in right ventricular ejection.

Patients with physiologic or innocent murmurs are generally asymptomatic from a cardiac standpoint and usually have no previous history of heart disease. Patients with mild varieties of aortic or pulmonic stenosis, hypertrophic cardiomyopathy, or a small ASD may be asymptomatic as well. In patients with aortic stenosis, onset of symptoms (e.g., angina, dyspnea, postural lightheadedness) is usually a late development indicating advanced disease (see Chapter 33).

Regurgitant Murmurs

Regurgitant murmurs of the arterioventricular valves may be *holosystolic* or *late systolic*, depending on the anatomy and function of the compromised valve apparatus. The holosystolic regurgitant mitral murmurs are seen with causes that render the valve incompetent throughout systole, such as *rheumatic mitral valve disease, endocarditis*, severe cases of *dilated cardiomyopathy, papillary muscle rupture*, and *endocardial fibrosis* of the valve surface from *phentermine/fenfluramine* use (see below). Mid-late systolic murmurs are characteristic of regurgitation due to *mitral valve prolapse* (MVP) and *papillary muscle dysfunction*, where valve incompetence develops as systole progresses.

The murmur of *tricuspid regurgitation* is similar in quality and timing to that of mitral regurgitation but heard best along the left sternal border and characteristically increasing with inspiration. Valve injury and right ventricular dilatation are the principal causes. *A ventricular septal defect* (VSD) may also produce a holosystolic murmur at the left sternal border, caused by left-to-right shunting of blood. It is differentiated from tricuspid regurgitation by maneuvers that increase afterload (see below).

The most common cause of an asymptomatic mitral regurgitant murmur in the outpatient setting is *MVP*. In the Framingham study, the prevalence was as high as 17% among young women, 4% among young men. Overall, 5% of the population had echocardiographic evidence of MVP, with 4% manifesting a murmur of grade 2/6 or louder. MVP, with its late systolic murmur, is often preceded by a click as the redundant mitral valve leaflets prolapse into the atrium during late systole. Most patients with MVP have no other signs or symptoms of heart disease, although an important minority experience atypical chest pain, dysrhythmias, or dyspnea. In a few instances, hemodynamically significant mitral regurgitation occurs. Asthenic builds in both men and women have been associated with MVP, as has small breast size in women. Nonspecific T-wave changes, particularly inferior lead T-wave inversion, have been described. Diagnosis is confirmed by finding prominent late systolic prolapse on M-mode echocardiography or definite prolapse on the mitral valve leaflets in the parasternal long-axis view on two-dimensional ultrasound study.

The widespread use of the diet-pill combination *phentermine/fenfluramine* in the mid-late 1990s (see Chapter 234) was associated with reports of new onset of clinically significant incompetence of mitral, tricuspid, and aortic valves. The valves of persons who came to surgery were characterized by striking fibrosis of the

endocardial surface identical to that seen in carcinoid syndrome, leading some to speculate that this might be the consequence of excessive seratonergic effects on valve endocardial metabolism. Patients at greatest risk appeared to be those taking the combination program at maximal doses for prolonged periods, but the true magnitude of the risk has been hard to determine. Because of concern over valve injury, both drugs have been withdrawn from the market.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis can be listed according to the underlying pathophysiology. Thus, systolic ejection murmurs can be classified as innocent, physiologic, aortic, and pulmonic. Regurgitant murmurs may be caused by incompetence of the mitral or tricuspid valves or by a VSD (Table 21.1).

1. Innocent Murmurs
2. Physiologic Murmurs
   a. Exercise or emotion
   b. Fever
   c. Anemia
   d. Hyperthyroidism
   e. Conditions with large stroke volumes: atrial septal defect, aortic regurgitation, bradycardia
   f. Pregnancy
3. Aortic Murmurs
   a. Aortic stenosis
   b. Hypertrophic cardiomyopathy
   c. Sub- and supravalvular fixed stenoses
4. Pulmonic Murmurs
   a. Pulmonic stenosis
5. Mitral Regurgitation Murmurs
   a. Rheumatic mitral insufficiency
   b. Mitral valve prolapse syndrome
   c. Congenital mitral valve disease
   d. Rupture of chordae tendineae
   e. Papillary muscle dysfunction
   f. Left atrial myxoma
   g. Dilated mitral valve ring
6. Tricuspid Regurgitation Murmurs
   a. Rheumatic tricuspid insufficiency
   b. Dilated tricuspid valve ring
7. Ventricular Septal Defect

Table 21.1. Differential Diagnosis of Systolic Ejection Murmur

WORKUP

Differentiating Systolic Regurgitant Murmurs from Ejection Murmurs

Making the distinction early in the evaluation helps focus the workup and narrow the differential diagnosis (Table 21.1). The murmur's *timing, quality*, and *location* are among the most important differentiating features. As noted earlier, ejection quality murmurs are typically harsh, best heard with the bell, usually loudest at the base, and radiate into the neck and down to the apex. In elderly patients with calcific aortic stenosis, the murmur may be higher pitched and maximal at the apex, mimicking mitral regurgitation. The systolic regurgitant murmurs of mitral and tricuspid regurgitation are characteristically high pitched, well localized to the apex or left sternal border (unless veryloud), and pansystolic or late systolic (and sometimes preceded by a click). All ejection murmurs and most regurgitant murmurs (except for those of rheumatic origin) have a crescendo-decresendo pattern, making this feature of little use in differentiation. Similarly, finding of electrocardiographic evidence of hypertrophy does not rule out a regurgitant etiology, because some degree of eccentric hypertrophy often develops in compensated mitral regurgitation.

A few additional murmur characteristics and responses to *maneuvers* can be helpful diagnostically. Ejection murmurs change in intensity with heart *rate* and length of the cardiac cycle, becoming softer with increases in rate and louder as rate decreases. Regurgitant murmurs change little if at all with heart rate. *Handgrip* and other maneuvers that increase systolic pressure (e.g., *transient arterial occlusion* by inflation of blood pressure cuffs applied to both arms) markedly augments the intensity of the regurgitant murmurs of mitral regurgitation and VSD. Right-sided heart murmurs can be differentiated from left sided ones by the augmentation in intensity that occurs with quiet *inspiration*.

Assessment of Ejection Murmurs

Separating Harmless Causes from More Serious Pathology. Attention to *timing, quality, intensity, and location* are helpful. *Innocent and physiologic murmurs* are usually mid-range in frequency, less than 3/6 in intensity, peak in early systole, stop long before S_2, and are heard best at the base, although they can radiate to neck and apex. Valsalva and standing decrease their intensity. The second sound is normally split and of normal intensity; there are no clicks, heaves, S_3S_4, or other murmurs. The *ECG* and *chest radiograph* are normal. Signs of anemia, fever, hyperthyroidism, and anxiety should be sought.

The murmurs resulting from *ASD* and hemodynamically *insignificant aortic and pulmonic stenoses* may resemble physiologic murmurs. However, in most cases of ASD there is widened and fixed splitting of S_2, and in more than 90% of cases there is a conduction defect of the *right bundle branch* type, producing a QRS and lead V_1 with an RSR prime configuration. A normal ECG and normal splitting of S_2 make an ASD unlikely. When one is in doubt, an echocardiogram can be used to look for abnormal septal motion and right ventricular enlargement; a normal study rules out the diagnosis. *Mild aortic stenosis* in the young patient may be impossible to distinguish from a physiologic murmur; the presence of an ejection click is an important clue to the former.

Estimating Severity of Aortic Stenosis. As aortic stenosis progresses and becomes more hemodynamically significant, the murmur typically gets louder and peaks later in systole, the second heart sound decreases in intensity (becoming equal to or less intense than the first sound at the base), a left ventricular lift develops, a thrill may be palpable, and the carotid upstroke becomes delayed. Evidence of left ventricular hypertrophy may appear on ECG (e.g., increased voltage, strain pattern), although the test is not a sensitive indicator.

A high index of suspicion is necessary both for the detection of *calcific aortic stenosis in the elderly* and the estimation of its severity. One needs to remember to listen at the apex and at the base and not to be lulled into a false sense of security by the softness of the murmur, the absence of a vigorous left ventricular heave, or the normality of the carotid upstroke. Its presentation as a medium- to high-pitched muscial murmur, heard best at the apex, may lead to confusion with mitral regurgitation. Helping to differentiate it from mitral regurgitation is the decrease in the murmur's intensity with increase in heart rate; in mitral regurgitation, there is no change in the murmur with heart rate.

Confirmation of suspected valvular and subvalvular obstruction to left ventricular outflow and accurate estimation of its severity can be accomplished noninvasively by *cardiac ultrasound* performed in conjunction with a continuous-wave *Doppler study*. For aortic stenosis, reasonably accurate estimates can often be obtained of valve area and pressure gradient across the valve. Severe stenosis is defined as a mean gradient in excess of 40 mm Hg with a calculated valve area less than 0.75 cm^2. A valve area in the range of 0.76 to 1.1 cm^2 and a gradient in the range of 15 to 39 mm Hg defines moderate disease. Overestimates of severity can occur in the setting of low flow. The degree of valve calcification noted on echocardiography corresponds to the severity of stenosis. The test is also diagnostic of hypertrophic cardiomyopathy and essential to estimation of its severity.

Clinical Recognition of Idiopathic Hypertrophic Subaortic Stenosis. Several maneuvers help differentiate the systolic ejection murmur associated with this type of cardiomyopathy from other ejection murmurs. Most distinctive are the murmur's responses to *squatting*, passive *leg elevation*, and *Valsalva*, maneuvers that affect left ventricular chamber size through their effects on venous return. A lessening of venous return decreases chamber size and increases obstruction to outflow by the hypertrophic heart muscle. This is why Valsalva (bearing down against a closed glottis) results in an increase in the intensity of the murmur. With passive leg elevation and with change from standing to squatting, the murmur of hypertrophic disease characteristically *decreases* as venous return rises. Although sometimes the murmur may not change substantially with increasing venous return, any clearcut increase in the murmur under such circumstances rules out hypertrophic cardiomyopathy. The murmur peaks around mid-systole, which helps distinguish it from those innocent murmurs that peak earlier. Other features of the murmur include maximal intensity along the left sternal border and a brisk *carotid upstroke* that is sometimes *bisferiens* (bifid) in quality.

Clinical Recognition of Pulmonic Stenosis. Hemodynamically significant pulmonic stenosis is suggested by a prolonged and loud murmur (greater than 3/6) that characteristically increases with *inspiration*, wide splitting or absence of the pulmonic component of the second heart sound, an ejection click that decreases with inspiration, a right ventricular lift, evidence of pulmonary artery dilation on chest film, and prominent R wave in V_1 indicative of right ventricular hypertrophy. A normal ECG and an early systolic murmur rule out significant pulmonic stenosis. Mild hemodynamically insignificant pulmonic stenosis may be indistinguishable from an innocent murmur, but usually no therapy is indicated and therefore misdiagnosis is of little consequence.

Summary. The key components of the initial evaluation of the systolic ejection murmur in the asymptomatic patient includeattention to carotid upstroke; left and right ventricular impulses; second heart sound; clicks; the quality, timing, intensity, and location of the murmur; and the effects of provocative maneuvers that affect venous return, heart rate, and systemic resistance. ECG and chest radiograph may be helpful. Cardiac ultrasound examination, in conjunction with Doppler study, are indicated if there is clinical suspicion of hemodynamically significant disease or the diagnosis remains in doubt and there are adverse consequences to not identifying the lesion.

Assessment of Regurgitant Murmurs

The *timing* and *location* of the regurgitant murmur are among the most helpful features diagnostically. The response to a number of simple bedside maneuvers can also provide useful information.

Holosystolic Murmurs. A holosystolic murmur suggests rheumatic or cardiomyopathic *mitral insufficiency, tricuspid insufficiency*, or a *VSD*. The murmur of classic mitral insufficiency is best heard at the apex and radiates laterally into the axilla; it varies little with cycle length or with respiration but increases markedly with *handgrip* and other maneuvers that transiently increase systemic resistance (e.g., bilateral blood pressure cuff inflation). With chronic increase in volume load, there is likely to be palpable enlargement of the left ventricle. Because multivalve involvement is the rule and heart failure may occur, a careful listening for other murmurs and a check for signs of heart failure (e.g., rales, third heart sound) are in order. However, a third heart sound is quite common in mitral regurgitation and not as predictive of systolic dysfunction as it is in other forms of heart disease.

Differentiating Tricuspid from Mitral Insufficiency. One notes the effect of *respiration* on the murmur. The systolic regurgitant murmur of tricuspid insufficiency increases with quiet inspiration and sustained abdominal pressure (applied to the right upper quadrant to compress the liver). Moreover, it is usually loudest at the lower left sternal border, but when the right ventricle is very large, it may be heard at the apex. It does not radiate well to the axilla. Intensity is strongly influenced by respiration, increasing at the beginning of inspiration and fading during early expiration. The presence of *hepatojugular reflux* is very suggestive and should be checked.

Identifying Ventricular Septal Defect. The holosystolic murmur of *VSD* can be heard best at the sternal border and does not radiate to the axilla. Intensity does not vary with respiration, but like mitral regurgitation, it is increased with Valsalva, handgrip, and blood pressure cuff application. The murmur often has some mid-systolic accentuation and may be confused with an ejection murmur. Like mitral regurgitation, intensity of the murmur increases markedly with handgrip and other maneuvers that increase systemic resistance.

Late Systolic Murmurs. *MVP* is characterized by a mid- to late-systolic murmur preceded by a mid-systolic click. Some forms of *papillary muscle dysfunction* will also result in a mitral regurgitant murmur of similar timing, usually in the setting of anteroseptal ischemia. Suspicion of MVP is reinforced by hearing a mid-systolic click, which tends to move toward the first heart sound with standing (a maneuver that reduces left ventricular volume and softens the murmur). The MVP murmur may occur in the absence of a click. The intensity of the suspected MVP murmur should be noted. The louder the murmur, the more hemodynamically significant the regurgitation, and the greater the risks of endocarditis and other cardiovascular complications. Handgrip or Valsalva maneuver may increase the intensity of the murmur. Increasing duration of the murmur is a sign of worsening prolapse. Development of a holosytolic murmur without a systolic click in a person with known MVP is associated with an increased risk of an adverse event.

Testing for Mitral Valve Prolapse. An *echocardiogram* can confirm MVP when uncertainty persists. Minor degrees of valve prolapse are normal. One should insist that ultrasound criteria are met before giving the patient a diagnosis of MVP. The major criterion is *systolic displacement* of one or both valve leaflets into the left atrium beyond the plane of the mitral annulus in the parasternal long-axis view on two-dimensional ultrasound study. *Valve thickening* and *redundancy* are other features, but a *nonclassic form of MVP* has been described in which there is no thickening, little risk for endocarditis, and little hemodynamically significant regurgitation. Ultrasound can differentiate the two and thus may help with cardiac risk stratification, although a very small risk of embolic stroke is similar in both forms.

Indiscriminate use of echocardiography is to be avoided. Searching for "silent" MVP in the patient with vague chest pains and an entirely normal cardiac examination is of no value. Use of ultrasound in suspected MVP can facilitate diagnosis, but the contribution to outcome remains to be demonstrated. In most instances, the change in management engendered involves initiation of endocarditis prophylaxis (see Chapter 16). However, Doppler echocardiographic studies suggest that audible, and especially loud, systolic regurgitant murmurs are very likely to represent hemodynamically significant disease. An ultrasound examination is indicated when such a murmur is encountered.

PATIENT EDUCATION AND INDICATIONS FOR REFERRAL

Patient Education

When the murmur is determined to be innocent or hemodynamically insignificant after careful evaluation, it is essential to provide detailed explanation as part of the delivery of meaningful reassurance. Marked concern and even distrust may be precipitated by a perfunctory explanation that "it's harmless and nothing serious," especially if detailed auscultation continues to be conducted on subsequent visits. Concern about a murmur that is left incompletely explained can lead to unnecessary self-restriction of activity. Reassurance should include a discussion of the cause of the murmur, its significance, and prognosis. Informing the patient of other possible causes considered and ruled out is particularly helpful to the well-educated or medically curious patient and can obviate the demand for unnecessary testing or referral. The patient with a harmless murmur should be specifically told there is no need to restrict activity or undergo further evaluation at the present time.

Aortic Stenosis. Asymptomatic persons found to have aortic stenosis (especially the elderly) should be informed of the importance of regular follow-up examinations and taught to watch for the symptoms of hemodynamically significant disease(i.e., postural lightheadedness, angina, exertional dyspnea), with instructions given to report immediately should they occur. (Also see Chapter 33).

Mitral Valve Prolapse. Counseling is particularly important for the patient with insignificant *MVP*. Patients should be informed that MVP is a heterogeneous condition, with most at no increased risk for cardiac complications. Those with readily audible MVP regurgitant murmurs should be advised about the need for endocarditis prophylaxis (see Chapter 16).

Indications for Referral

The person with hemodynamically significant aortic stenosis (valve area less than 0/9 cm^2) needs close follow-up, annual echocardiography, and consideration of cardiac consultation if stenosis continues to progress, even in the absence of symptoms. Onset of symptoms makes the referral urgent (see Chapter 33). Worsening exertional dyspnea in the patient with rheumatic, ischemic, or cardiomyopathic mitral regurgitation is also an indication for prompt cardiac consultation, because it suggests the left ventricle is decompensating (see Chapter 33). Annual echocardiography has been recommended for asymptomatic persons with hemodynamically significant mitral regurgitation, with referral indicated if there is progressive enlargement of the left ventricle or a fall in ejection fraction below 60%. Referral is also needed for the patient with tricuspid regurgitation and worsening hepatojugular reflux and other signs of right-sided failure.

Those with particularly loud murmurs of MVP suggestive of hemodynamically significant disease should be referred for cardiac consultation after undergoing ultrasound examination for confirmation. Most can be reassured that they are at no increased risk and that progression to more serious disease is very rare. Prompt referral is indicated for the rare MVP patient with complex ventricular irritability, prolonged QT intervals, a family history of sudden death, or a transient ischemic event.

RECOMMENDATIONS

- Begin by determining whether the systolic murmur is regurgitant or ejection in quality by attention to the murmur's location, quality, and timing.
- Differentiate right-sided from left-sided pathology by observing response of the murmur to inspiration.
- If the murmur is ejection in quality, distinguish between innocent/physiologic murmurs and those due to structural heart disease.
- For left-sided ejection murmurs, distinguish between aortic stenosis and hypertrophic cardiomyopathy.

- If aortic stenosis is suspected, estimate clinical severity by physical examination and obtain Doppler cardiac ultrasound in those persons with physical findings suggestive of hemodynamically significant disease.
- Follow patients with calcific aortic stenosis closely and repeat ultrasound examination periodically.
- If there is evidence of hypertrophic cardiomyopathy (idiopathic hypertrophic subaortic stenosis) by physical examination, order Doppler cardiac ultrasound to confirm.
- For holosystolic murmurs, differentiate by physical examination between arteriovenous valve regurgitation and VSD; if arteriovenous valve regurgitation is suspected, determine whether the murmur is mitral or pulmonic. Obtain Doppler ultrasound if there is clinical evidence of hemodynamically significant regurgitation.
- For late systolic murmurs, differentiate between MVP and valve regurgitation due to papillary muscle dysfunction. If hemodynamically significant MVP is suspected, obtain Doppler ultrasound to confirm.
- Refer for cardiac consultation any patient found to have severe aortic stenosis or any other hemodynamically significant lesion with poor prognosis (e.g., hypertrophic cardiomyopathy, mitral regurgitation with falling ejection fraction).
- Provide detailed reassurance to patients with harmless lesions to minimize demand for unneccesary testing, and make clear to patients with hemodynamically significant disease the need for close follow-up.

CHAPTER 22 EVALUATION OF LEG EDEMA

Leg edema can be a bothersome complaint and an initial symptom of serious underlying disease. Acute onset of unilateral swelling raises the question of deep vein thrombophlebitis (DVT), which must be addressed promptly. Bilateral disease is particularly common in the elderly and often a manifestation of chronic venous insufficiency, congestive heart failure, or venodilating medications; however, pulmonary hypertension may account for as much as a fifth of cases and usually goes unrecognized. Noninvasive methods, particularly venous and cardiac ultrasound, have greatly facilitated evaluation, but clinical estimation of pretest probability is essential to optimal test selection and interpretation. Especially important to the pretest assessment of unilateral edema is knowledge of the incidence, risk factors, symptoms, and signs of DVT. In bilateral edema, awareness of the potential contributions from often overlooked etiologies (such as pulmonary hypertension and use of nonsteroidal antiinflammatory drugs [NSAIDs]) can inform the clinical assessment and guide workup.

PATHOPHYSIOLOGY AND CLINICAL PRESENTATION

Edema is defined as an increase in extracellular volume. It develops if hydrostatic pressure exceeds colloid oncotic pressure, capillary permeability increases, or lymphatic drainage becomes impaired. Hydrostatic pressure is a function of intravascular volume, blood pressure, and venous outflow. Colloid oncotic pressure depends on the serum albumin concentration.

Decreased oncotic pressure is usually due to *hypoalbuminemia*, which can occur secondary to malnutrition, hepatocellular failure, or excess renal or gastrointestinal loss of albumin. The resultant fall in intravascular volume from excessive transudation of fluid stimulates salt retention. This compensatory effort to maintain adequate intravascular volume leads to further edema formation because the underlying oncotic deficit remains. Edema sets in when the serum albumin concentration falls below 2.5 g/100 mL. Leg swelling due to hypoalbuminemia is typically bilateral, pitting, and sometimes accompanied by edema of the face and eyelids (especially on awakening).

Increased hydrostatic pressure may result from excessive *fluid retention* (such as is seen with congestive heart failure or drugs [NSAIDs, corticosteroids]), *impairment of venous outflow* from DVT, or *pulmonary hypertension* (which may be a consequence of sleep apnea, left heart failure, or chronic obstructive lung disease). Venodilating drugs (such as *nifedipine*) may lead to an increase in hydrostatic pressure as blood pools in the lower extremities. A localized increase in hydrostatic pressure develops in the legs during prolonged standing, especially if the valves in the leg veins are incompetent. Increased hydrostatic pressure due to fluid retention produces bilaterally symmetric edema, whereas swelling due to venous insufficiency may be asymmetric and accompanied by varicosities and other signs of venous disease, such as stasis dermatitis, ulcers, and brawny induration.

DVT may have a very subtle presentation, with acute onset of *unilateral or asymmetric leg edema* as the only manifestation. Such textbook findings as calf tenderness, palpable cord, and positive Homan's sign are often absent. The findings most predictive of significant DVT are swelling of the entire leg, asymmetric leg edema (more than 3 cm difference in calf circumferences), pitting edema of the involved leg, tenderness along deep veins, and prominent collateral superficial veins. Most clots due to thrombophlebitis form in the small veins of the calf; 20% to 30% propagate proximally into the popliteal and femoral veins of the knee and thigh. Clot below the knee poses little risk of pulmonary embolization, but extension above the knee markedly increases its chances. Unilateral lower leg edema can also result from venous compression by a *popliteal (Baker's) cyst*. A stroke that causes paresis in one leg may result in unilateral edema due to reductions in vascular tone and venous and lymphatic drainage; thrombophlebitis may ensue. In addition to paralysis, the independent predictors of DVT include active cancer, recent plaster cast/prolonged immobilization, and recent major surgery (especially of the hip or knee). Hypercoagulability increases risk and occurs with estrogen use and with resistance to activated protein C. The latter is seen in patients with *factor V Leiden mutation*, affecting 2% to 3% of white populations, producing a relative risk for DVT of 3.3, and accounting for about 5% of cases.

Increased capillary permeability is another mechanism of leg edema associated with immunologic injury, infection, inflammation, or trauma. A permeability defect is also believed to be responsible for *idiopathic edema*, a poorly understood but common problem seen almost exclusively in women. Although some patients report a periodicity to the problem that seems to parallel the menstrual cycle, careful studies have failed to find sufficient evidence to warrant the label *"cyclic edema.'* The condition is especially aggravated by hot weather and standing, more so than occurs with venous insufficiency. Transient abdominal distention is common, and weight may fluctuate several pounds over the course of the day. The disorder is not progressive, but it can cause considerable discomfort. It is often accompanied by headache, fatigue, anxiety, and other functional symptoms. Some patients are bothered by nocturia.

Lymphatic obstruction hinders reabsorption of interstitial fluid. The swelling usually starts in the feet and progresses upward; often the problem is unilateral. The edema of lymphatic obstruction tends to have a brawny quality and evidences little pitting, except in its early stages. Recumbency provides only minor relief compared with edema from other causes.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of edema can be organized according to clinical presentations and pathophysiologic mechanisms (Table 22.1). The list of etiologies for bilateral edema is particularly extensive. In primary care practice, the leading causes of bilateral disease include venous insufficiency, heart failure, pulmonary hypertension, and hypoalbuminemia; pulmonary hypertension is the most commonly missed diagnosis. Certain infiltrative conditions may be mistaken for edema, such as pretibial myxedema and lipedema (a familial bilateral deposition of excess fat).

Table 22.1. Important Causes of Leg Edema

WORKUP

Diagnosis of leg edema can be challenging. The initial clinical impression often undergoes revision upon laboratory testing, underscoring the difficulty in making an accurate diagnosis on the basis of history and physical examination alone. In a study from primary care practice, venous insufficiency was overdiagnosed clinically and heart failure and pulmonary hypertension markedly underdiagnosed. Nonetheless, attention to clinical features is critical to making the best possible pretest probability assessment, which is essential to test selection and interpretation.

History. The distribution of the swelling should be ascertained, because it helps to focus the differential diagnosis. If edema is reported to be predominantly *unilateral*

or asymmetric, the patient ought to be questioned about the major risk factors for DVT, including active malignancy, recent paralysis or plaster casting, prolonged immobilization, major surgery (especially of the hip or knee), estrogen use, and family history of DVT (suggestive of an inherited hypercoagulable state). Any report of tenderness along deep veins, swelling of the entire leg, and marked asymmetry of the swelling should be noted and confirmed by physical examination (see below). If the edema is reportedly *bilateral and symmetric*, then it is important to check for a history of venous insufficiency, but also for dyspnea on exertion; orthopnea; paroxysmal nocturnal dyspnea; severe snoring; daytime sleepiness; interrupted sleep; chronic productive cough; a history of cardiac, pulmonary, renal, or hepatic failure; malnutrition; and use of such drugs as nifedipine, other vasodilators, NSAIDs, and corticosteroids. A report of acute facial swelling suggests an allergic reaction or hypoalbuminemia if the swelling is more chronic.

Physical Examination. The first priority is to confirm the distribution of the problem. Careful measurements of calf and thigh diameters is also very helpful.

In *unilateral edema*, if the swelling is predominantly limited to one leg, the limb ought to be examined for tenderness, redness, increased warmth, varicosities, and a palpable thrombosed vein. Unfortunately, the often-cited classic signs of DVT (i.e., calf tenderness, palpable cord, positive Homan's sign) are neither very sensitive nor specific; unilateral edema may be the only clue aside from a history of risk factors. Nonetheless, a difference in calf circumferences of more than 3 cm is an independent predictor of DVT, as is tenderness along deep veins, swelling of the entire leg, pitting edema, and prominence of collateral superficial veins. Encountering three or more of these findings in a patient with risk factors for DVT is associated with a pretest probability for DVT of about 75%. If edema is prominent but pitting is only minimal, it suggests that lymphatic obstruction might be the cause.

The patient with *bilateral leg edema* should have the blood pressure measured for hypertension, which might be a sign of renal failure. The skin is checked for evidence of chronic cardiopulmonary disease (cyanosis, clubbing) and for signs of hepatocellular failure (jaundice, spider angiomata, ecchymoses); the jugular veins for distention; the chest for rales, wheezes, and effusion; the heart for signs of pulmonary hypertension (a right ventricular heave or right ventricular S_3, increased prominence of P_2, widened splitting of S_2) and signs of heart failure (S_3, abnormal splitting of S_2); and the abdomen for hepatojugular reflux and ascites. Any lymphadenopathy should be noted.

Laboratory Studies. The patient with new onset of unilateral or asymmetric leg edema needs diagnostic testing to address the question of DVT, because of the high false-positive and false-negative rates based on clinical findings alone. Only 20% to 40% of patients thought to have DVT on clinical grounds prove to have clot on further testing. Testing is also critical in bilateral leg edema, because underlying cardiopulmonary disease is often inapparent from the history and physical examination alone.

Unilateral or Asymmetric Leg Edema. Risk stratification can help guide the approach to test ordering and interpretation. Although the diagnosis of DVT cannot be made clinically, reasonable estimates of pretest probability for DVT can be made by attention to clinical features found to be independent predictors of DVT (Table 22.2). Using this probability estimate in conjunction with the results from noninvasive testing helps to determine who requires anticoagulation, further testing, or no anticoagulation. For example, a person at high or intermediate risk with a positive study should be immediately anticoagulated. A person at low risk with a normal ultrasound has the diagnosis ruled out. A person at intermediate risk with an initially normal study needs serial testing; if repeatedly negative at 2 weeks, then the diagnosis is ruled out; if positive, the diagnosis is ruled in.

CLINICAL FEATURE	SCORE
History	
Active cancer	1
Paralysis, recent plaster cast	1
Recent immobilization or major surgery	1
Physical Examination	
Tenderness along deep veins	1
Swelling of entire leg	1
>3 cm difference in calf circumference	1
Pitting edema	1
Collateral superficial veins	1
Clinical Assessment	
Alternative diagnosis likely	−2

Pretest probability of deep vein thrombosis: high if score of 3 points or greater; intermediate if score of 1–2 points, and low if score of 0 or less.

Table 22.2. Model for Clinical Prediction of Deep Vein Thrombophlebitis [a]

Particularly important is detection of DVT above the knee, because clot here is associated with a high risk of pulmonary embolization. Below the knee, the risk of embolization is only about 3%. Ruling out clot above the knee is the major objective of testing in the patient with unexplained leg edema. High test sensitivity and specificity are required in this setting, not only to rule out DVT but also to provide sufficient positive predictive value to justify initiation of anticoagulant therapy. A number of noninvasive approaches have replaced venography as the initial test of choice.

Venous ultrasound study involving the combination of B-mode or two-dimensional *ultrasonography* and color-flow *Doppler* ultrasound (so-called triplex scanning) has proven practical and highly sensitive and specific. Failure of the vein to compress during ultrasound scanning is highly correlated with DVT. At times, direct visualization of clot is possible. Doppler measures blood flow, helping to identify the vein and any reduction in flow due to clot. Doppler alone is highly technician dependent. Computerized color enhancement of Doppler data facilitates test performance and interpretation. For detection of thrombophlebitis above the knee, sensitivity and specificity of triplex scanning range from 97% to 99%. For thrombophlebitis below the knee, sensitivity and specificity fall to 80%, because as many as 40% of calf vein studies are technically unsuccessful due to poor sound penetration. Successful below-the-knee studies have the same sensitivity and specificity as those above the knee. Duplex ultrasound (triplex minus the color enhancement) is becoming the minimum standard for noninvasive testing for DVT.

A technically satisfactory study that is negative for clot above the knee virtually rules out the diagnosis of worrisome DVT in a person with a low pretest risk. If pretest probability is intermediate and initial testing is negative, then serial testing every 2 to 3 days over 1 to 2 weeks is indicated while anticoagulation is held. A positive study has a very high predictive value, sufficient to warrant initiating anticoagulation. Persistently negative test results rule out the diagnosis. If clinical suspicion is high for DVT and the initial study is negative, serial study or immediate venography is indicated.

Impedance plethysmography remains a widely used noninvasive approach to the diagnosis of DVT. It detects changes in leg volume that follow respiration and inflation and deflation of a thigh blood pressure cuff. In DVT, the normal pattern is altered and detectable by plethysmography. Most reports of test sensitivity range from 83% to 93% and specificity from 83% to 97%, but some figures are in the 65% to 70% range for tests performed in outpatients. The test is somewhat technician dependent, accounting for some of the variation in test performance figures reported. Calf-vein and nonobstructing thrombi are not well detected. Sensitivity can be enhanced by serial studies, which are obtained if there is suspicion of propagation. The test is useful for detection of recurrent thrombophlebitis, because an abnormal test usually reverts to normal 3 months after initiation of anticoagulant therapy. When specificity in a particular laboratory is less than 90%, then the predictive value of a positive test for DVT in a patient with unilateral leg edema will be in the range of 75% to 80%, not high enough to justify anticoagulation without further confirmatory testing. A negative test in a patient suspected on clinical grounds to have DVT should be followed either by a venogram or by serial plethysmography studies 2 and 4 days after the initial study.

D-dimer is a degradation product of cross-linked fibrin. Its formation occurs in the context of ongoing fibrinolysis, making its measurement a potentially sensitive indicator of active thrombosis. D-dimer testing provides a promising approach to quickly screening for DVT without the need to repeat noninvasive testing if the initial noninvasive study is negative but clinical suspicion persists. A quick ruling out of DVT is especially important in the context of suspected pulmonary embolism, the setting in which D-dimer testing for DVT is mostfrequently applied. Reports of sensitivity range from 85% to 100%, depending on the assay used and the cutoff level for a positive test. Specificity is poor (40% to 68%), because D-dimer acts as an acute phase reactant and its level rises in response to any event that induces fibrinolysis, such as inflammation, cancer, or trauma. The combination of high sensitivity and low specificity make the test most useful as a means of ruling out DVT. The test can be used alone in low probability patients to rule out DVT and in conjunction with ultrasound or plethysmography in patients with a higher pretest probability. If both D-dimer and one of the noninvasive studies are normal, then the probability of DVT is extremely low and serial testing can usually be omitted. Because D-dimer testing lacks specificity, confirmatory testing with ultrasound or plethysmography is necessary when a "positive" (i.e., more than 0.5 µg/dL) test result is obtained.

Venography remains the definitive test for the detection of acute deep vein occlusion. When performed and interpreted by an experienced radiologist, it is nearly 100% sensitive and specific. However, it is invasive, expensive, often painful, requires considerable expertise to perform and interpret, and includes a small (2% to 3%) risk of inducing thrombosis or a hypersensitivity reaction to the contrast medium. Moreover, as many as 25% of patients who are candidates for venography have unsuccessful studies. Hospitalization is usually required. These disadvantages plus the advent of sensitive noninvasive methods have relegated venography to a backup role in the evaluation for DVT, mostly for cases where noninvasive study is technically difficult (e.g., after knee or hip replacement). In the case of suspected lymphedema, venography is the test of first choice for detecting a cause of lymphatic obstruction and should be obtained before lymphangiography is attempted. Severe lymphatic obstruction may interfere with attaining a satisfactory lymphangiogram.

Testing for underlying etiology and hypercoagulable state of DVT is essential to determining the risk of recurrence and the proper duration of anticoagulation (see Chapter 35).

Bilateral Leg Edema. The patient with more generalized edema involving both legs should have a *chest film* in search of heart failure and pleural fluid, a *urinalysis* for detection of albuminuria, a check of the serum *albumin*, and determinations of the serum *creatinine and blood urea nitrogen* for evidence of renal insufficiency. If the serum albumin is low, then measurements of the prothrombin time and liver function testing are indicated for further documentation of hepatocellular failure (see Chapter 71). If the serum albumin is low and protein is detected in the urine, a *24-hour urine* collection for albumin and creatinine is indicated (see Chapter 130).

When the diagnosis of bilateral leg edema remains inapparent, consideration of underlying cardiopulmonary disease is indicated and a *cardiac ultrasound with Doppler* should be considered, especially in persons over the age of 45. The test provides an excellent noninvasive approach to detection of heart failure, be it due to systolic or diastolic dysfunction and to identification of pulmonary hypertension that might not be otherwise apparent. If pulmonary hypertension is suggested by cardiac ultrasound, then consideration of sleep apnea is indicated, because of its high prevalence among adults and the subtlety of its presentation (see Chapter 46).

PATIENT EDUCATION AND SYMPTOMATIC THERAPY

When edema is due to increased hydrostatic pressure or decreased oncotic pressure, a number of simple measures can provide the patient some symptomatic relief. The patient should be advised to *restrict salt* intake, avoid prolonged standing or prolonged sitting with the legs dependent, elevate the legs whenever possible, and avoid wearing garments that might restrict venous return (e.g., garters and girdles). Proper *support stockings* might provide some added benefit. If possible, use of salt-retaining drugs should be discontinued or minimized. Severe edema may require *diuretic* therapy (see Chapter 35 for details on therapy of venous insufficiency). Lymphatic obstruction and increased capillary permeability do not respond well to these measures.

Patients with idiopathic edema are sometimes helped by salt restriction, support hose, elevation, and diuretic use in the early evening. In addition to diuretics, other drugs have been reported to be useful, including propranolol and captopril. It is important to reassure the patient with this condition that the edema poses no threat to health. Furthermore, idiopathic edema often runs a self-limited course, subsiding spontaneously over a few months to several years.

Patients with chronic leg edema should be instructed to call the physician at the first sign of unilateral increase in swelling or pain, because they are at increased risk of thrombophlebitis.

RECOMMENDATIONS

For Unilateral or Markedly Asymmetric Leg Edema

- Review history for risk factors for DVT (e.g., active malignancy, recent paralysis or plaster casting, prolonged immobilization, recent major surgery [especially of the hip or knee], current estrogen use, family history of DVT).
- Check physical examination for key signs of DVT (e.g., difference in calf circumferences of more than 3 cm, tenderness along deep veins, palpable cord, pitting edema of the entire leg, prominence of collateral superficial veins).
- Estimate pretest probability of DVT based on history and physical examination.
- Obtain compression Doppler venous ultrasound or plethysmography of the involved limb in all patients. If a negative result is obtained but clinical suspicion persists, then repeat within 3 to 5 days.
- Use combination of pretest probability and tests result to determine need for further testing. When pretest probability is intermediate and initial noninvasive study is negative, either repeat the noninvasive study every 3 days for up to 2 weeks or obtain a D-dimer determination; if these are not available, then proceed directly to venography.

For Bilateral Leg Edema

- Review history for symptoms of venous insufficiency, heart failure, and chronic pulmonary disease, especially sleep apnea. Also check for a history of renal or hepatic disease, malnutrition, and use of such drugs as nifedipine, NSAIDs, and corticosteroids.
- Check serum albumin; if normal and no other etiology evident, obtain cardiac ultrasound for detection of subclinical heart failure and pulmonary hypertension.

CHAPTER 23 EVALUATION OF ARTERIAL INSUFFICIENCY OF THE LOWER EXTREMITIES

DAVID C. BREWSTER

Peripheral arterial disease of the lower extremities is usually a manifestation of systemic atherosclerosis. It is more common in men and increases in prevalence with age. The condition affects a large segment of the elderly population, many of whom are asymptomatic during the early stages of their illness. With progression, intermittent claudication ensues, experienced by about 5% of the U.S. population more than 55 years of age and by over 20% of those more than 75 years of age. Atherosclerotic occlusive disease is by far the most common cause of arterial insufficiency, although lower extremity ischemia may also be caused by embolism, arterial dissection, trauma, thrombosis of an aneurysm, or Buerger's disease.

Proper clinical management requires the physician first to recognize the manifestations of ischemic disease and carefully evaluate its severity. Many patients with mild to moderate vascular insufficiency can be managed conservatively, whereas others with acute ischemia or more severe chronic ischemia that threatens to cause tissue necrosis require more intensive investigation and often surgery (see Chapter 34).

The primary physician must be able to differentiate between patients with arterial insufficiency and those with exertional limb pain due to other causes (e.g., radiculopathy, spinal stenosis). Moreover, one needs to know the indications for and limitations of the newer noninvasive techniques for evaluating blood flow and the indications for arteriography and referral for consideration of revascularization.

PATHOPHYSIOLOGY AND CLINICAL PRESENTATION

Risk Factors and Associated Conditions. The major risk factors for peripheral arterial disease are those for atherosclerosis, with cigarette smoking and diabetes mellitus making the greatest contributions. Adding to risk are low high-density lipoprotein cholesterol, high triglycerides, and high homocysteine levels. Such risk factors are the same as those for *coronary artery disease* and *cerebrovascular disease*, which have increased prevalences in persons with peripheral artery disease. The probability of encountering symptomatic cardiovascular disease in patients with peripheral artery insufficiency is about 30%; more than 60% prove to have underlying cardiovascular disease when subjected to diagnostic testing. Peripheral artery disease is an independent risk factor for development of atherosclerotic disease elsewhere.

Reduction in Flow. Occlusive disease generally becomes symptomatic by gradual reduction of blood flow to the involved extremity or organ. Symptoms finally occur when a critical arterial stenosis is reached. Pressure and blood flow are not significantly diminished until at least 75% of the cross-sectional area of the vessel lumen is obliterated by the disease process. This is approximately equivalent to a 50% reduction in lumen diameter. More severe stenoses or even total occlusions may remain essentially asymptomatic as long as collateral circulation maintains sufficient blood flow around a lesion to satisfy the metabolic demands of the distal limb at rest and during exercise. Development of ischemic symptoms in the leg implies either inadequate collateral circulation or additional occlusive disease distal to the particular collateral bed. Thus, lesions in the aortoiliac segment may cause little difficulty unless, as is commonly the case, there is associated disease in the femoropopliteal arterial territory.

Distribution of Disease. Arteriosclerotic plaques producing stenosis or occlusion of the arterial lumen are often segmentally distributed, with a predilection for arterial bifurcations. The infrarenal abdominal aorta and aortic bifurcation are common sites of disease, as are the iliac and femoral artery bifurcations. Diabetic patients seem prone to onset of arteriosclerosis at an earlier age and often have a more distal distribution of occlusive arterial lesions involving the more distal infrapopliteal, tibial, and small runoff vessels.

Early Manifestations. The first sign of impaired arterial circulation is usually *intermittent claudication* (from the Latin *claudicare*, to limp), a manifestation of reduced arterial blood flow that remains adequate at rest but inadequate during exercise. During exercise, the metabolic demands of skeletal muscle in the legs require a 5- to 10-fold increase in blood flow and oxygen delivery. In patients with occlusive disease of major conduit vessels, the requisite increase in blood flow cannot be achieved and a supply-and-demand mismatch occurs, resulting in muscle ischemia and pain. With cessation of activity, metabolic demand quickly returns to baseline and symptoms abate.

Patients report pain or discomfort in the lower extremity brought on by walking and relieved by stopping. Discomfort is usually described as a cramping or aching that steadily increases in severity as distance or speed of walking increases and is frequently worse when walking up an incline. Most characteristically, it involves the calf muscles as a result of disease in the superficial femoral artery, the most common location of lower extremity obliterative disease. However, claudication may also be noted in more proximal muscle groups of the hip, thigh, and buttock area when there is aortoiliac involvement.

Later Manifestations. As the severity of the occlusive process worsens, blood flow becomes inadequate for tissue needs even at rest, resulting in the manifestations of more severe arterial insufficiency: *ischemic rest pain* and tissue *necrosis* (ischemic ulceration or gangrene). Rest pain typically occurs at night from leg elevation associated with lying in bed. Patients classically describe ischemic rest pain as an "ache," "pain," "numbness," or "squeezing," most often in the toes and arch of the foot. It may awaken them from sleep and ease when the leg is placed in a dependent position (e.g., dangling the leg over the bedside or standing and walking about). Simple gravitational effects improve arteriolar flow and lessen ischemia.

Ischemic ulcers are painful and appear as punched out lesions on the dorsum or lateral aspect of the foot. A hallmark of ischemic ulceration is intense pain associated with the lesion.

Clinical Variants. Peripheral arterial insufficiency has three basic anatomic variations, though any number may be present in a given patient. Aortoiliac disease is most common in patients who smoke or have hypercholesterolemia. Claudication in the buttock or thigh is characteristic. The femoral pulses are absent or diminished, but pedal pulses may be intact. *Femoropopliteal disease* accounts for two thirds of cases and presents as calf pain with exertion. Femoral pulses may be preserved, but popliteal and pedal pulses are absent or diminished. *Tibioperoneal occlusion* is a disease of diabetics and older patients. Skin ulcers and atrophic skin changes are common.

Clinical Course and Prognosis. The natural history and associated clinical course of peripheral arterial disease is quite variable and often favorable. In the Framingham study population, only one third of those developing claudication went on to have persistent symptoms; the remainder experienced remission or transient symptoms. However, 15% of those presenting with severe disease required amputation over the ensuing 2 years. Persistent smokers and diabetics have the worst prognoses.

Any consideration of prognosis for this atherosclerotic disease has to include the substantial risks of *cardiovascular morbidity* and *mortality*, which are increased fivefold compared with persons without peripheral arterial disease.

DIFFERENTIAL DIAGNOSIS

Lower extremity ischemia may also be caused by arterial embolism, dissection, trauma, thrombosis of an aneurysm, or thromboangiitis obliterans (Buerger's disease). Other nonvascular conditions may mimic the symptoms of claudication or ischemic rest pain. Pain in the hip, thigh, or knee region with walking is frequently a result of *degenerative disc disease, osteoarthritis* of the hip or knee, or *Paget's disease.* Sciatic or other radicular pain may cause confusion. Various other neurologic or musculoskeletal disorders may be at fault. *Cauda equina compression* by disc, tumor, or spinal canal stenosis produces a well-known *"pseudoclaudication'* syndrome. Such nonvascular causes of pain may be suspected when pain is not clearly related to a predictable amount of exercise and is not promptly relieved by cessation of activity. *Nocturnal leg cramps* are commonly mistaken for ischemic pain, being localized to the calf but differing in that they are exclusively a nighttime phenomenon.

Diabetic neuropathy can be difficult to differentiate from ischemic rest pain, particularly in a patient with diminished or absent pulses. In both conditions, a burning constant ache is often present in the forefoot and toes. The presence of paresthesias in addition to pain suggests a neurologic source. True ischemic rest pain is usually worse with elevation and frequently is relieved somewhat by dependency of the limb. Such features may be used in differentiation. In all such instances, noninvasive studies during exercise may be of substantial help in the differential diagnosis.

WORKUP

The diagnosis of peripheral vascular disease and an accurate assessment of its level and severity may be made by a careful history and physical examination to an extent not usually possible in many other disease states. The availability of effective treatment for peripheral vascular disease makes it mandatory that early and accurate diagnosis be established before end-stage problems develop and threaten limb loss.

History. *Intermittent claudication* is the hallmark of vascular insufficiency and, by multivariate analysis, an independent predictor of the disease. A reliable story for its presence can be pathognomonic in a person with atherosclerotic risk factors (Table 23.1). The patient who describes a cramp or ache in the calf or thigh muscles that is reproducibly brought on by *walking a predictable distance* should be suspected, especially if the discomfort is relieved within minutes by simply stopping. The location of the pain may help to localize the occlusive process. In some instances of proximal disease, the pain may be located principally in the hip or buttock region, causing confusion with other neuroorthopedic conditions such as spinal stenosis and lumbar radiculopathy. If the walking distance required to produce the pain varies considerably from day to day or if the patient must sit or lie down for more than several minutes to obtain relief, the physician should suspect a nonvascular cause, such as spinal stenosis. Weightbearing and other activities that extend the lumbar spine will aggravate the pain of spinal stenosis. Similarly, the pain should involve the same areas consistently and not different portions of the leg from day to day. Crampy pain occurring in the calf at rest, particularly at night, rarely signifies a vascular problem. The triad of discomfort brought on by exercise, relief achieved within 2 to 5 minutes by stopping, and ability to walk the same distance again once the discomfort ceases is strongly suggestive of vascular insufficiency.

CLINICAL FEATURE	CLAUDICATION	PSEUDOCLAUDICATION
Character of discomfort	Cramping, tightness, tiredness, aching	Same, tingling, weak, clumsy
Location	Buttock, hip, thigh, calf, foot	Same
Exercise-induced	Yes	Yes
Distance to pain	Same each time	Variable
Occurs with standing	No	Yes
Relief	With cessation of walking	With sitting or position change

Adapted from Krajewski LP, Olin JW. In: Young JR, Olin JW, Bartholomew JR, eds. Peripheral vascular disease, 2nd ed. St. Louis: Yearbook, 1996:204, with permission.

Table 23.1. Differentiating True Claudication from Pseudoclaudication

Complaints of *pain at rest* and with exercise suggest more advanced ischemia. A history of prior claudication is almost always obtained in such patients unless the distribution of the occlusive process is quite distal or in small vessels only. Ischemic rest pain typically involves the toes or forefoot, not the calf or thigh. It is usually improved with dependency of the limb and therefore is worse at night. Pain that is not confined to the distal foot, that is better with elevation, or that occurs in a patient without intermittent claudication should alert the physician to look for other possible causes, such as diabetic neuropathy or a neuroorthopedic problem.

Symptoms of tissue necrosis will usually be quite apparent. Peripheral *gangrene* without prior symptoms should raise the possibility of embolic disease or small vessel occlusions due to conditions other than chronic arteriosclerosis. In patients with leg ulceration, historical clues suggesting a traumatic, dermatologic, or venous origin should also be sought; many leg and foot ulcers are not ischemic in origin.

A complete history should include questioning for sexual difficulties. Erectile *impotence*, long associated with severe aortoiliac occlusive disease, has been termed the *Leriche syndrome* after the French surgeon who first reported its significance in 1923. Finally, it is of utmost importance to note the existence of known risk factors for arteriosclerosis (e.g., family history, smoking, diabetes mellitus, hypertension, lipid disorders) and related problems in the coronary and cerebrovascular systems indicative of the systemic nature of the atherosclerosis.

Physical Examination. Exam can help confirm, localize, and establish the severity of the arterial lesion. Findings that independently predict disease include abnormal pedal pulses and femoral artery bruits.

Palpation of peripheral pulses is the keystone of the examination. Palpation of the abdomen for the aortic pulsation and of both extremities for femoral, popliteal, posterior tibial, and dorsalis pedis pulses should be routine in all patients. Reduced or absent pulses in the symptomatic region are characteristic of arterial insufficiency. In one study, the absence of the posterior tibial pulse was the best predictor of peripheral arterial disease. Local factors such as edema or marked obesity may hinder palpation. Abnormally prominent pulsations suggest aneurysmal disease. *Auscultation* of the aortic and groin regions should also be performed, with the finding of *bruits* further supporting the possible existence of arterial occlusive disease. Simple exercise of the patient at the bedside may greatly intensify femoral bruits, and this is occasionally a useful maneuver. The absence of a bruit, however, has little meaning, because marked reduction of flow in a severely stenotic or occluded vessel will not produce a bruit.

Other useful findings are abnormal pallor on elevation of the legs, *rubor on dependency*, and *prolonged capillary filling time* (especially when one leg is compared with the other). Temperature differences and atrophic skin and nail changes are less reliable indicators of chronic arterial insufficiency. Careful spine, hip, knee, and neurologic examinations are important to rule out nonvascular causes of exertional lower extremity pain.

Laboratory Studies. History and physical examination are usually sufficient to establish the diagnosis and provide a rough estimate of severity. In patients with mild-to-moderate disease free of limb-threatening ischemia or unacceptable activity limitations, no further investigation is necessary other than evaluation for potential *risk factors* such as hypertension, hyperlipidemia, smoking, and diabetes (see Chapter 14, Chapter 15, Chapter 54, and Chapter 93, respectively). Blood sugar determination may detect a previously undiagnosed diabetic, but there is still no firm evidence that tight control of the serum glucose level prevents or ameliorates macrovascular disease (see Chapter 102).

In patients with premature atherosclerotic disease but no evident precipitants, the possibility of *hyperhomocysteinemia* deserves consideration. The relation between this inborn error of metabolism and vascular disease has now been established. Diagnosis is suggested by elevated serum homocysteine levels after overnight methionine loading.

Noninvasive vascular laboratory studies are indicated if the diagnosis or degree of impairment is uncertain or if the disease appears clinically severe enough to warrant consideration of surgical correction. A host of noninvasive testing methods is available, ranging from segmental blood pressure measurements to Doppler and two-dimensional ultrasound techniques. These methods are becoming widely available and are relatively simple to use, inexpensive compared with angiography, and without risk or discomfort to the patient. Such tests may be extremely helpful in establishing a vascular etiology for complaints of pain in the leg and in quantifying clinical impressions, which are often somewhat imprecise. Because they can be used repeatedly, such tests are also particularly helpful in evaluating improvement or deterioration of the patient's condition over time and in assessing the benefit of various forms of treatment or operation.

It should be emphasized that these methods are not meant to replace or lessen the value of a good history and physical examination but rather to supplement them and provide such additional information as site and severity of stenosis.

Segmental blood pressure measurements are taken at the arm, upper thigh, above and below the knee, and above the ankle with the patient supine. A *Doppler* device measures systolic pressure in each location. Normally there is an increase in pressure as the pressure wave moves distally. A reduction in pressure suggests arterial

occlusion. Sensitivity and specificity are maximized by determining the *ankle/brachial ratio or index* (a ratio of the systolic pressure found in the posterior tibial–dorsalis pedis arteries divided by the pressure in the brachial artery). An index of less than 0.9 has a 95% sensitivity in patients with angiographically proven disease and a 100% specificity in normals. Segmental pressures can be used as a screening test for further evaluation and in gauging severity. A ratio of less than 0.8 correlates with moderate disease, 0.6 with severe or multilevel disease, and less than 0.4 with severe disease and a high risk of complications. The test is not reliable in patients with calcified vessels (e.g., diabetics).

Pulse-volume recordings are particularly useful for assessment of distal vascular disease, especially in patients with stiff vessels. Doppler and plethysmographic methods are used. The patient with stiff vessels and distal disease may have a normal ankle pressure, but the normally sharp pulse-volume wave form becomes blunted with obstruction. Sensitivity is improved when treadmill exercise is added to the examination. Diabetics, who tend to have stiff vessels and distal disease, are good candidates for pulse-volume recording.

Duplex ultrasonic scanning combines two-dimensional (B-mode) real-time ultrasound with pulsed Doppler to provide more precise anatomic and flow data than are available from other methods. The ultrasound probe is placed over specific vessels to measure velocity of flow. B-mode ultrasound identifies the site and nature of the stenosis. Adding *color-flow enhancement* (triplex scanning) improves test performance. Triplex scanning has a sensitivity of 88% and a specificity of 95%; the figures for duplex scanning are 82% and 92%, respectively. Although such examinations are somewhat time consuming and require an experienced examiner, they are likely to play an increasing role in noninvasively assessing peripheral vascular disease.

Preoperative Studies. When surgery is being contemplated, one needs to determine the precise anatomy of the occlusive disease. Although *contrast arteriography* has little place in the initial diagnostic evaluation of arterial insufficiency, its contribution is essential in the assessment of the patient who is being considered for surgical intervention (see Chapter 34). The procedure is generally regarded as indispensable for precise localization of the disease process and proper selection of the most appropriate invasive procedure. A major disadvantage and risk associated with arteriography is acute *dye-induced renal failure*. Patients with peripheral vascular disease commonly have concurrent renal vascular disease or renal dysfunction, making them especially vulnerable to acute renal failure upon exposure to a large iodinated contrast load. Arteriography should also be used with caution in persons with other forms of underlying renal disease and in persons with a history of allergy to iodine or iodinated radiologic contrast agents.

Magnetic resonance angiography (MRA) provides a noninvasive alternative to contrast arteriography for imaging the peripheral arterial circulation without risk of dye-induced acute renal failure or allergic reaction. It is particularly helpful in patients with a history of severe allergic reactions to iodinated contrast, renal insufficiency, or other contraindications to conventional catheter arteriography. Further advances in MRA using noniodinated contrast hold promise for providing an even more effective diagnostic alternative to conventional contrast arteriography in patients being considered for surgery.

INDICATIONS FOR REFERRAL AND ADMISSION

Although most patients with mild to moderate lower extremity occlusive disease can be well managed conservatively (see Chapter 34), those with pain that markedly limits daily activities and significantly impairs life-style may benefit from referral for consultation with an experienced vascular surgeon to review available treatment options, including revascularization. Those with evidence of more advanced disease (ischemic rest pain, nonhealing ischemic ulcerations) need prompt referral for revascularization due to the high likelihood of amputation and limb loss without revascularization. The noninvasive vascular laboratory may be very helpful in providing objective data to help define patients with critical ischemia and the need for prompt revascularization (Table 23.2). Patients with gangrenous lesions of the lower extremities or an infected ischemic ulcer require prompt hospital admission, particularly if they are diabetic.

- Severe (disabling) intermittent claudication; ankle systolic pressure < 50 mm Hg after exercise; cannot complete standard 5-min treadmill exercise study
- Persistent ischemic rest pain; resting ankle systolic pressure < 50 mm Hg
- Ischemic ulceration or gangrene of foot/toes

CHAPTER 24 EVALUATION OF SYNCOPE

Syncope and near-syncope are among the most difficult of conditions to evaluate, especially when recurrent and not accompanied by readily identifiable precipitants. Often contributing to the diagnostic difficulty are vague descriptions of the event, an unrevealing physical examination, and initial laboratory studies that are unremarkable. When confronted with a report of loss of consciousness, the primary physician first needs to check for an underlying cardiovascular or seizure disorder, for these may require prompt attention. In about 50% of cases, the cause of syncope will not be evident on initial evaluation, necessitating consideration of a more extensive workup. A detailed knowledge of important clinical clues and a thorough understanding of the indications for and limitations of available testing modalities are essential for a cost-effective evaluation of this difficult problem.

PATHOPHYSIOLOGY AND CLINICAL PRESENTATIONS

Basic Mechanisms. Syncope may ensue from inadequate cerebral perfusion, seizure activity, severe metabolic derangement, or psychological disturbance. The pathophysiologic common denominator of many cases is inadequate cerebral perfusion. Contributing mechanisms include sudden decrease in peripheral vascular resistance, inadequate cardiac output, failure of vasoconstrictive reflexes, and functional or anatomic cerebral vascular occlusion. Any number may be operative in a given case. Metabolic disturbances, such as hypoglycemia, hypocarbia, and hypoxia, usually do not result in syncope unless profound, although they may alter consciousness. Generalized seizure activity that spreads to the brainstem will rapidly lead to loss of consciousness. Most psychogenic precipitants of syncope operate by the neurocardiovascular mechanisms noted above, with the exception of hysteria, in which there may not be a true loss of consciousness.

Neurocardiogenic syncope, also referred to as *"vasodepressor"* or *"vasovagal"* syncope, accounts for a large number of cases, especially those occurring in otherwise healthy young persons. Although the precise mechanistic details are still being elucidated, its hallmarks are inappropriate bradycardia and vasodilation. The normal compensatory responses to standing up are vasoconstriction, tachycardia, withdrawal of vagal tone, and release of vasoconstricting and volume-retaining hormones (renin and vasopressin). In persons with neurocardiogenic syncope, there is interruption of these sympathetic reflex responses and an increase in vagal activity. The result is *bradycardia, vasodilation*, and marked falls in systemic blood pressure and cerebral perfusion. Among the explanations advanced to account for the phenomenon are excessive vagal tone, excessiveinitial sympathetic stimulation producing very vigorous contractions that overstimulate intracardiac parasympathetic mechanoreceptors, and hypersensitivity of these receptors. Beta-blockers and disopyramide have been found helpful. The myocardium and conduction system are normal—an important reason why prognosis is excellent.

Clinical presentations range from the common "simple faint" associated with emotional distress to the near-syncopal episode of a trained athlete in the midst of competition. Distention of a viscus (as occurs in performing an esophagoscopy, pleural tap, or bladder puncture) may also trigger an episode.

The patient experiences *premonitory symptoms* of sweating, epigastric queasiness, lightheadedness, and pallor. Dilation of the pupils, blurring of vision, yawning and sighing, or hyperventilation may occur. The patient feels restless and unable to concentrate. At the outset, the heart rate may be rapid, but it slows markedly as the process unfolds. The onset of premonitory symptoms usually helps prevent a drop attack and resultant injury. After several minutes, full consciousness is regained, though weakness, sweatiness, and nausea may persist. Control of bladder and bowels is never lost.

The presence of *pallor* and *diaphoresis* is paradoxical, but both may be prominent and reflect the high circulating levels of epinephrine found in this state of otherwise marked sympathetic inhibition. Such features make for a very distressing clinical presentation, mimicking serious cardiovascular disease.

Sometimes the hypotension and hypoperfusion that occur are so profound that cerebral hypoxia and seizure activity (*convulsive syncope*) ensue. This convulsive syncope is distinct from loss of consciousness that accompanies a generalized seizure disorder and does not respond to antiseizure medication.

Tilt-table study can reproduce the symptoms in susceptible persons. Many patients report a prodrome of blurred vision, vertigo, tinnitus, and nausea when tested on a tilt table (see below).

Autonomic insufficiency is another cause of reduced cerebral perfusion pressure, and it is particularly important in the setting of a fall in intravascular volume from dehydration or acute blood loss. On standing, the patient experiences *orthostatic hypotension*, because reflex vasoconstriction and increase in heart rate fail to occur. Hypotension progresses over seconds to a few minutes, until perfusion is inadequate for maintenance of consciousness. During the presyncopal period, there is no increase in heart rate or other signs of autonomic response, such as pallor, nausea, or sweating. The period of syncope is brief, and consciousness returns promptly. Near-syncope is common among these patients, as are impotence and bladder and bowel disturbances.

Postprandial hypotension is a form of postural hypotension analogous to autonomic insufficiency. It is defined as a 20-mm Hg decrease in systolic pressure within 2 hours of beginning a meal. Prevalence is greatest among elderly hypertensive patients. Postulated mechanisms range from inadequacies in sympathetic response and baroreceptor function to excessive insulin-induced and vasopeptide-induced vasodilatation and splancnic pooling. Consequences may be serious and include falls, syncope, angina, and stroke.

Carotid sinus hypersensitivity can cause marked *reflex bradycardia* and a fall in arterial resistance. Most patients with this condition are elderly and have underlying atherosclerotic heart disease manifested by ischemic changes on electrocardiogram (ECG). Massage of the carotid sinus often results in long asystolic pauses. Digitalis administration seems to aggravate the condition. Carotid sinus syncope may also cause a vasodepressor form of syncope in which heart rate remains unchanged. Minor events can trigger symptoms; wearing a tight collar, turning the head, or shaving may cause lightheadedness, sweating, pallor, and nausea, followed by fainting. When the predominant mechanism is asystole, the loss of consciousness can be precipitous.

Posttussive syncope is characterized by loss of consciousness that follows a prolonged bout of forceful coughing. Men with chronic bronchitis are most often affected. The mechanism is believed to involve decreased cardiac output due to decreased venous return, increased cerebral vascular resistance secondary to hypocapnia, and compression of cerebral vessels by an increase in cerebrospinal fluid pressure. Prolonged Valsalva maneuvers have a similar effect; the increase in intrathoracic pressure impedes venous return and decreases cardiac output.

Postmicturition syncope takes place in the context of emptying a distended bladder. The typical setting involves a male who has gotten up at night to urinate after consuming considerable amounts of alcohol. Consciousness is lost without much warning. Drainage of ascitic fluid or a distended bladder may produce a similar effect. The mechanism is unknown. Valsalva maneuver and reflex vasodilation have been implicated. Valsalva plays an important role in *postdefecation syncope*, in which straining decreases venous return and consequently cardiac output.

Cerebrovascular disease leads to syncope if there is vertebrobasilar insufficiency of the midbrain affecting the reticular activating system or in the rare instance of total or near-total occlusion of the major vessels supplying the brain. Lesser degrees of obstruction may contribute to minor lightheadedness on standing and can be aggravated by use of antihypertensive agents and volume depletion. Patients with substantial cerebrovascular disease often have evidence of previous strokes manifested by focal neurologic deficits. A *transient ischemic attack* involving the vertebrobasilar circulation may lead to syncope by temporarily depriving the brainstem's reticular activating system of adequate perfusion. Brainstem neurologic deficits typically accompany or precede the loss of consciousness.

Subclavian steal syndrome results from occlusion of the proximal subclavian artery, leading to reversal of flow in the adjacent vertebral artery. When vascular resistance in the arm falls, for example, during exercise, flow is redirected away from the brain and ischemic symptoms may ensue.

Effort syncope occurs in the setting of underlying *valvular heart disease*. Exercise induces peripheral vasodilation, but cardiac output cannot be increased adequately and syncope results. *Severe aortic stenosis* and marked *hypertrophic cardiomyopathy* obstruct the ventricular outflow tract to a degree sufficient to limit

cardiac response to exercise (see Chapter 33). Total blockade of the mitral orifice from an *atrial myxoma* and *pulmonary hypertension* can have similar consequences. Loss of consciousness comes with little warning.

Cardiac dysrhythmias may precipitate sudden loss of consciousness with none of the premonitory manifestations of neurocardiogenic syncope. Important dysrhythmias associated with syncope include *complete heart block* (Stokes-Adams attacks) and *ventricular tachycardia* (see Chapter 29). Occasionally, a supraventricular tachycardia with a very rapid ventricular response rate will sufficiently compromise cardiac output to result in near-syncope (see Chapter 28). Once effective systoles have ceased, fewer than 5 seconds of consciousness remain. Palpitations are sometimes reported, and loss of consciousness can occur while the patient is supine. Common precipitants of these dysrhythmias include acute ischemia, sick sinus syndrome, digitalis toxicity, and the preexcitation syndromes. Patients with chronic bifascicular and trifascicular block are more likely to have syncopal attacks, but those with syncope have not been found to have an increased risk of sudden death.

Seizures differ from other causes of syncope in that aura, postictal symptoms, incontinence, and tonic-clonic movements often dominate the clinical picture. However, akinetic petit mal attacks have few of these features, although normal blood pressure and pulse help distinguish them from seizures having cardiovascular causes (see Chapter 170). As noted above, convulsions may occur in the setting of vagally mediated cerebral hypoperfusion in the absence of an underlying seizure disorder.

Psychiatric Disease. Psychiatric causes are becoming increasingly appreciated as etiologic factors in syncope of unknown origin. *Generalized anxiety disorder, panic disorder,* and *depression* are frequently found in populations of such patients who have no evidence of heart disease. Their fainting spells often resolve with treatment of the underlying psychopathology. Prevalence is greatest in younger persons with frequent syncopal episodes, in those who never sustain injury from their loss of consciousness, and in patients who present with multiple somatic and psychiatric symptoms, such as fear, anxiousness, nausea, lightheadedness, and numbness. Reproduction of symptoms by 2 to 3 minutes of open-mouth hyperventilation is characteristic. *Hysteria* may result in apparent loss of consciousness; the spell is a *conversion reaction* characterized by graceful fainting to the floor or couch; frequent presence of an audience; normal pulse, skin color, and blood pressure; and an emotionally detached description of the episode.

Metabolic factors (e.g., hypoxia, hypocarbia, hypoglycemia) are more likely to alter consciousness than to cause actual syncope. Restlessness, confusion, and anxiety are prominent and precede loss of consciousness. When hyperventilation is responsible, the patient first complains of a smothering or suffocating feeling in conjunction with paresthesias in the limbs and circumorally (see Chapter 226). Syncope may take place while the patient is sitting or lying down. Hypoglycemia rarely causes loss of consciousness (see Chapter 97).

DIFFERENTIAL DIAGNOSIS

Important causes of syncope are listed in Table 24.1. In a series of 176 ambulatory patients evaluated for syncope, 9% had a cardiac etiology, 45% had some form of vasomotor instability, 1% had seizures, 6% had other causes, and 39% were unexplained. With the addition of tilt-table testing and psychiatric assessment, at least half of the unexplained cases demonstrate evidence of a neurocardiogenic (vasovagal) mechanism and many of the remainder have a psychiatric etiology (generalized anxiety, panic disorder, depression). In the elderly, the prevalence of cardiac disease among patients presenting with syncope increases to about 33%.

1. Cardiac
   a. Arrhythmias (sick sinus syndrome, ventricular tachycardia, very rapid supraventricular tachycardia)
   b. Heart block (Stokes-Adams attacks)
   c. Aortic stenosis, severe
   d. Asymmetric septal hypertrophy, severe
   e. Primary pulmonary hypertension
   f. Atrial myxoma
   g. Prolapsed mitral valve
2. Vascular-Reflex
   a. Neurocardiogenic (vasovagal, vasodepressor)
   b. Orthostatic hypotension (ganglionic blocking agents, diabetes, old age, prolonged bedrest)
   c. Carotid sinus hypersensitivity
   d. Cerebral vascular disease, severe
   e. Subclavian steal syndrome
   f. Posttussive syncope
   g. Valsalva syncope
   h. Postmicturition syncope (emptying distended bladder)
   i. Postprandial syncope
3. Psychologic-Neurologic
   a. Seizures
   b. Hysteria
   c. Generalized anxiety disorder
   d. Depression
   e. Panic disorder
4. Metabolic
   a. Hyperventilation
   b. Hypoxia
   c. Hypoglycemia (rarely)

Table 24.1. Important Causes of Syncope

The prognosis for syncope due to underlying cardiac disease is much worse (1-year mortality rates of 18% to 33%) than that for noncardiac or unexplained syncope (1-year mortality rates of 6% to 12%). In the elderly with unexplained syncope, the mortality rate nearly doubles. However, recurrence rates are similar for both categories (about 33%), and recurrence is not a risk factor for adverse outcome.

WORKUP

Evaluation Strategy

Initial Workup. The principal task initially is to differentiate between cardiac and noncardiac etiologies, because prognosis is poorest for those with underlying heart disease. A *detailed history, focused physical examination*, and the resting 12-lead *ECG* are the most valuable elements of the initial evaluation. These elements alone provide a diagnosis in at about 50% of cases and suggest the diagnosis in many others. The physician and patient should appreciate that routinely ordering a battery of "syncope tests" is not only wasteful and ineffective but also more likely to produce false-positive results than true-positive ones when ordered in the context of a low pretest probability for the condition in question.

Subsequent Testing. For the 50% of patients who remain undiagnosed after the initial history, physical, and ECG, the evaluation proceeds according to the clinical presentation and probability of underlying heart disease. In persons with known or strongly suspected heart disease, the key task is detection of a serious dysrhythmia or conduction disturbance, for which *Holter monitoring and electrophysiologic study* (EPS) are the tests of choice. *Continuous-loop electrocardiographic recording* is useful in those who have no evidence of structural heart disease but report palpitations and have frequent syncopal episodes. Persons free of organic heart disease who have infrequent syncopal episodes and suspected neurocardiogenic (vasovagal) syncope are the best candidates for *tilt-table testing. Psychiatric evaluation* is indicated for patients with frequent events, no heart disease, and no injury from their spells.

This approach results in a diagnosis in most patients. Fortunately, the prognosis for patients with a single unexplained episode of syncope is excellent. Nonetheless, a detailed search for underlying heart disease is essential and a major priority in the evaluation.

History

The differentiation of cardiac and neurologic disease from less worrisome etiologies begins with a *thorough description* of the syncopal event and its surrounding circumstances. The absence of premonitory symptoms in the presyncopal period is consistent with a sudden fall in cardiac output or the abrupt onset of generalized seizure activity. Nausea, diaphoresis, pallor, and lightheadedness are more typical of reflex and vascular causes. If recall of premonitory details is sketchy, one should be careful about interrogating the patient too vigorously with leading questions, for the absence of associated or prodromal symptoms may have important diagnostic meaning. Although a seizure disorder may present with sudden loss of consciousness and no warning, more typically there are some vague premonitory symptoms and the characteristic tonic-clonic movements and sphincter incontinence.

Identification of precipitants requires asking about emotional upsets, crowded hot surroundings, sudden standing (especially in elderly hypertensive patients after a meal), prolonged and forceful coughing, Valsalva maneuvers, micturition, vigorous exercise, hyperventilation, and symptoms of acute blood loss. Effort syncope raises the question of hemodynamically significant ventricular outflow tract obstruction. Exertional chest pain is another important clue of underlying organic heart disease. Position just before syncope is worth noting, because loss of consciousness while recumbent argues against a reflex or vascular mechanism. A check of medications

is always in order and especially productive in the assessment of the elderly person presenting with syncope.

The *past medical history* should be searched for prior infarction, heart murmur, and use of cardioactive medications. A history of diabetes, stroke, use of antihypertensive agents, prolonged bedrest, impotence, and bladder and bowel incontinence should be checked for when the patient reports lightheadedness or syncope on standing.

Reports from witnesses should be sought whenever possible. Activity, position, complaints, and appearance before syncope and duration of the episode, associated motor activity, and behavior on regaining consciousness deserve attention. Some observers will even report pulse and respirations. A seizure disorder is usually not difficult to distinguish from cardiac syncope because of the preceding aura, motor activity, incontinence, and postictal symptoms of confusion, drowsiness, and paresis. However, when there are no motor manifestations, as in akinetic petit mal seizures, the differentiation may be impossible to make by history alone.

It is important not to mistake other conditions for true loss of consciousness. Vertigo (see Chapter 166), neuroglycopenic symptoms (see Chapter 97), and the lightheadedness associated with an anxiety and other psychiatric conditions (see Chapter 226 and Chapter 227) are sometimes confused with syncope or near-syncope. On the other hand, reports of the combination of psychiatric and somatic symptoms (e.g., lightheadedness, anxiousness, numbness, nausea) in a patient with otherwise unexplained loss of consciousness should suggest an underlying psychiatric etiology.

Physical Examination

The emphasis is again on the cardiovascular system. *Postural signs* provide essential information. *Blood pressure* and *pulse* are first measured in both arms with the patient lying supine for about 5 minutes and again on standing up. Most patients who demonstrate a postural fall in blood pressure will do so within 30 to 60 seconds of assuming the standing position. However, it may be necessary to wait as long as 5 minutes. Recent studies have found that 95% of cases with postural hypotension will be detected within 2 minutes of standing and most within 30 to 60 seconds. The skin is checked for pallor and ecchymoses (the latter, a sign of trauma from a seizure). Torso and head, including the tongue, require scrutiny for signs of trauma sustained during a motor seizure.

Carotid pulses are auscultated for bruits and gently palpated for volume and carotid upstroke (see Chapter 33). If there is no evidence of carotid artery disease, one can *massage* the carotid and observe for reflex bradycardia (asystole of more than 3 seconds) and hypotension. The maneuver is indicated when a hypersensitive carotid sinus reflex is suspected, as in elderly patients with unexplained falls. However, because it may also cut off blood supply and cause syncope when there is severe cerebral occlusive disease, it should not be attempted in such patients.

The neck veins are noted for distention and the chest for rales and rhonchi. The *heart* is palpated for heaves and thrills and is auscultated for clicks and murmurs with the patient in the supine, decubitus, and sitting positions. Systolic murmurs should be evaluated for evidence of aortic stenosis, asymmetric septal hypertrophy, and mitral valve prolapse (see Chapter 21). A variable diastolic murmur raises the question of atrial myxoma. Neurologic assessment includes a search for focal deficits indicative of prior stroke.

Provocative maneuvers are particularly helpful in identifying conditions that alter consciousness but do not cause syncope. Asking the patient to voluntarily hyperventilate or spin around may reproduce symptoms and confirm a clinical suspicion. Exercising the arm is worthwhile if subclavian steal syndrome is suspected.

Laboratory Studies

As noted earlier, routinely ordering a battery of "syncope tests" is wasteful and ineffective. Although one does not want to miss an underlying cardiac etiology, test selection should still reflect consideration of the pretest probability of heart disease. Test yield in patients with a very low pretest probability of heart disease is extremely low, and risk of false-positives is high (see Chapter 2).

Electrocardiogram. Most patients should have an ECG performed at the time of initial evaluation, because detection of underlying heart disease remains a major priority of the diagnostic workup. One needs to check not only for ischemic changes, heart block, and tachyarrhythmias but also for subtle clues suchas a short PR interval, delta waves, or new onset of bundle branch block. However, neither an ECG nor other laboratory studies is necessary when the history strongly suggests a harmless faint brought on by emotional factors, the physical examination is normal, and the patient has no risk factors for organic heart disease.

Holter Monitoring. If the ECG is unrevealing but an arrhythmia transient heart block or other form of underlying heart disease is still suspected on clinical grounds (e.g., sudden loss of consciousness without warning, effort syncope, chest pain), then a *24-hour ambulatory ECG recording* (*Holter monitor*) deserves consideration. Holter monitoring has become an almost routine part of the syncope workup, especially in patients who remain undiagnosed after initial history, physical examination, and resting ECG. Yet the correlation between findings on Holter monitoring and symptoms is poor, with arrhythmia-related symptoms occurring in only 2% of patients studied and syncope or presyncope occurring without an associated arrhythmia in 15%.

Although the correlation between symptoms and Holter findings is not strong, Holter findings do provide an independent assessment of risk for underlying heart disease and sudden death. Syncopal patients with frequent premature ventricular contractions (more than 10 an hour), repetitive premature ventricular contractions (32 in a row), or sinus pauses (more than 2 seconds) on Holter monitoring have an increased risk of sudden death and overall mortality that is independent of other factors. Patients with these findings constitute a high-risk subgroup that deserved further cardiac evaluation. There may be an increase in yield of arrhythmias detected if Holter monitoring is extended to 48 hours, but many arrhythmias are asymptomatic and of unclear significance.

Continuous-loop (event) recording for detection of symptomatic arrhythmias is made feasible with *patient-activated intermittent recorders*. By virtue to their *continuous loop* technology, these recorders can capture the previous several minutes of cardiac rhythm and detect a symptom-producing dysrhythmia shortly after it has occurred, provided the patient is capable of activating the unit. Continuous-loop recording is useful in persons with relatively frequent syncopal episodes who have little likelihood of serious underlying heart disease (and thus are at low risk for a life-threatening dysrhythmia). Yield is highest in those who report palpitations (range, 27% - 45%).

Exercise stress testing may bring out arrhythmias not found during Holter monitoring, but even more useful is the test's sensitivity for the diagnosis of ischemic heart disease (see Chapter 36). Patients who report chest pain before syncope, effort syncope, or have an abnormal resting ECG suggestive of ischemic disease are prime candidates for stress testing. However, those with effort syncope should not be subjected to stress testing until tight aortic stenosis and other forms of critical ventricular outflow tract obstruction have been excluded by echocardiography, because there is the risk of sudden death with stress testing in such patients. Routine use of stress testing to rule out "silent" heart disease in the absence of clinical or electrocardiographic evidence yields little and increases cost.

Echocardiography can provide key diagnostic information in patients suspected of valvular or structural heart disease because of effort syncope, chest pain, palpitations, systolic ejection murmur, systolic click, abnormal carotid upstroke with transmitted bruit, or an abnormal ECG. It is also the noninvasive test of choice if a left atrial myxoma is suspected. In the absence of evidence for heart disease, routine echocardiography contributes little to the assessment. Syncope patients who are going to have a stress test should be subjected to echocardiogram before stress testing if there is any suggestion clinically of obstruction to the left ventricular outflow tract (e.g., systolic ejection murmur).

EPS has been advocated to detect arrhythmogenic causes of syncope, particularly *ventricular tachycardia*, because of the limited specificity of Holter monitoring results described above. The value of EPS in the assessment of patients with structural heart disease and fixed conduction defects is well documented, but its sensitivity and specificity for identifying transient rhythm disturbances, especially *bradyarrhythmias*, in patients with unexplained syncope has been disappointing.

The detection of ventricular tachycardia and hemodynamically significant bradycardia are the principal reasons for performing EPS. Consequently, prime candidates are those with an increased risk of such an arrhythmia (e.g., persons with previous myocardial infarction, ischemic heart disease, or congestive heart failure). To improve EPS performance, criteria for better patient selection have been sought. In the largest study to date, patients with evidence of underlying organic heart disease and frequent premature ventricular contractions on resting ECG were at increased risk for sustained ventricular tachycardia during EPS. Those with first-degree arterioventricular block, bundle branch block, or sinus bradycardia on resting ECG were at increased risk of a hemodynamically significant bradyarrhythmia during EPS. Overall, 87% of those with at least one of these clinical risk factors had an important outcome on EPS, whereas the EPS was normal in 95% of those with none of these risk factors. Holter findings may also prove predictive, but data are limited.

Although invasive and very expensive (requiring cardiac catheterization), EPS may be preferred to outpatient Holter monitoring in elderly persons with syncope and

conduction disease on ECG, because another episode might result in serious injury. Another reason for consideration of EPS is presence of preexcitation (short PR interval, less than 0.12 seconds) on ECG. Such patients are at increased risk of sustained rapid supraventricular tachycardia with hypotension. Patients with unexplained syncope but no evidence of structural heart disease and a normal ECG are not likely to benefit from EPS. The test should not be considered a routine part of a syncope-of-unknown origin workup.

Upright Tilt-Testing. The growing appreciation of neurocardiogenic mechanisms of syncope has stimulated interest in provocative maneuvers such as upright tilt testing. The best candidates are those in whom heart disease has been ruled out and a vasovagal mechanism is suspected on the basis of the clinical history (e.g., premonitory nausea and flushing). The test is predicated on the hypothesis that in susceptible persons the decrease in venous return from placement on a tilt table brought up to 60 degrees elevation will trigger the potent reflex responses that lead to neurocardiogenic syncope (see above). *Isoproterenol* infusion is added to enhance sensitivity and speed the test if tilting without isoproterenol produces no response after 15 minutes.Criteria for a positive test vary and include hypotension and bradycardia, but reproduction of the patient's syncope and associated symptoms is the *sine qua non* of a diagnostic study.

Sensitivity ranges from about 65% to 80%, enhanced by isoproterenol infusion. *Specificity* is 90% without isoproterenol and decreases to 75% when it is infused, because of false-positive responses, particularly in young healthy persons. Most authorities recommend first performing the tilt test without isoproterenol infusion, reserving it for patients with a negative initial study who have premonitory symptoms suggestive of a vasovagal mechanism. In older patients, tilt testing with isoproterenol can be conducted safely, but prior stress testing is recommended to rule out underlying ischemia, which might be exacerbated by isoproterenol infusion.

Tilt-table testing is sometimes helpful in uncovering underlying psychopathology, such as a conversion reaction, in which the apparent loss of consciousness occurs during testing but without hypotension or bradycardia.

Other Studies. The *electroencephalogram* has repeatedly been shown to be of little use in evaluating syncope in the absence of either a history suggestive of seizure or neurologic deficits. Even when a seizure disorder is present, the routine electroencephalogram has a sensitivity of only 50%. Sleep studies and photic stimulation may improve sensitivity to 80% (see Chapter 170). Similarly, neuroimaging studies (computed tomography, magnetic resonance imaging) should generally be reserved for patients with focal seizures or defects on neurologic examination (in one study, 7 of 20 patients with and none of 17 patients without such findings had abnormalities detected on computed tomography).

Random *blood sugar* determinations are of little use in documenting hypoglycemia; a blood sugar at the time of symptoms is better (see Chapter 97). Arterial *blood gases* can detect hypocarbia when hyperventilation is suspected and hypoxia when ventilation/perfusion mismatching is of concern. However, such testing is usually unnecessary because the etiologies responsible for such blood gas abnormalities are usually self-evident.

Patients with Unexplained Syncope

When the above evaluation ends without an answer other than the absence of evidence for serious underlying cardiac or neurologic pathology, then a period of watchful waiting can be considered. Patients with a fully negative evaluation are at low risk for an occult life-threatening etiology and sudden death. Those with a rare event can be reassured and followed expectantly.

Patient with Frequent Recurrences. Frequent syncopal attacks of unknown etiology are difficult to manage with a watchful-waiting approach. Recurrent episodes beg an explanation. Patients with unexplained disease despite a full assessment benefit from close follow-up and careful reassessment for new clues by careful history and physical examination at the time of recurrences. *Hospitalization* for observation in persons with very frequent syncopal attacks may help guide further evaluation by providing the opportunity to directly observe an episode.

Assessment for a psychiatric etiology (e.g., generalized anxiety disorder, panic disorder, depression) should be considered in younger persons with frequent episodes, in those who never sustain injury from their loss of consciousness, and in those with multiple bodily complaints and symptoms of anxiousness (e.g., numbness, nausea, constant lightheadedness, fearfulness). Screening instruments for anxiety and depression (see Chapter 226 and Chapter 227) are useful for initial assessment, as is the *hyperventilation maneuver*, in which the patient breathes rapidly and deeply with mouth open for 2 to 3 minutes. The development of syncope or near-syncope in response to hyperventilation has a positive predictive value of over 50% for a psychiatric etiology. *Tilt-table testing* for persons with suspected hysteria (in which syncope represents a conversions reaction) may reveal the characteristic apparent loss of consciousness in the absence of changes in vital signs.

Elderly Patient with Unexplained Syncope. In many instances the etiology is not one single factor but a combination (e.g., blunted autonomic responsiveness, medications, dehydration, underlying heart disease). A review of current medications is always in order as are the circumstances of each syncopal event (e.g., standing after a meal, urination, or a bowel movement). Because the prevalence of cardiovascular disease is high in this age group, reconsideration of the common etiologies (e.g., coronary disease, heart failure, conduction system disease, other dysrhythmias) and less common etiologies (e.g., calcific aortic stenosis, carotid sinus hypersensitivity) is in order (see above). If not already performed, carotid sinus massage should be carried out, provided there is no evidence of ongoing cardiovascular or cerebrovascular disease, such as recent myocardial infarction, carotid bruit, recent stroke, or ventricular arrhythmias. The rationale for performing carotid massage is that persons with a positive test (asystole greater than 3 seconds in response to massage) appear to benefit from implantation of a demand pacemaker.

SYMPTOMATIC THERAPY AND PATIENT EDUCATION

The most effective therapies are those that are etiologic, particularly treatments that address serious underlying cardiac pathology (e.g., see Chapter 28, Chapter 29, Chapter 30, Chapter 32, and Chapter 33). A number of symptomatic measures help patients with less-threatening conditions, which are still important to treat because of their impact on the quality of daily life.

Orthostatic Hypotension. The first priority is to review all medications and reduce or eliminate those that are likely to exacerbate the problem (e.g., diuretics, vasodilators, beta-blockers, hypnotics). A number of simple measures deserve emphasis. One teaches the patient to avoid abrupt postural changes by sitting on the edge of the bed in the morning before getting up and to elevate the head of the bed at night to counter the reflex hypertension that occurs when supine. Girdles, garters, and other constricting garments should not be worn if they decrease venous return, but elastic stockings may be helpful. One can advise the patient to avoid prolonged standing and to contract the calf muscles when standing to increase venous blood flow. Liberalization of salt intake is useful; *fludrocortisone* (0.1 to 1.0 mg daily) may be necessary. Patients with severe orthostatic hypotension due to multiple system failure or pure autonomic dysfunction may require additional treatment. Agents to be considered include *phenylpropanolamine* in low doses, *midodrine, indomethacin, and yohimbine*. Careful testing is required, because responses are very idiosyncratic.

Postprandial Hypotension. Simple measures include smaller more frequent meals, liberalized salt intake, adequatefluid intake, reduction in carbohydrate content of meals, patient education regarding the risk of falling up to 90 minutes after eating, avoidance of prolonged sitting, avoidance of standing still after a meal, encouraging a walk after eating, and avoidance of alcohol before or with meals. In addition, the above measures for management of orthostatic hypotension can be implemented. a-Agonists (e.g., phenylephrine every 6 to 12 hours) are sometimes used but of questionable safety in elderly persons. Caffeine is of little benefit. The somatostatin analogue octreotide (50 μg SC a half hour before meals) can be considered, but only for the most seriously affected persons because a painful injection is required to administer the substance.

Neurocardiogenic Syncope. Patients with confirmed neurocardiogenic disease may be candidates for a trial of a *beta-blocker* (e.g., metoprolol) or *disopyramide*. The role of *demand pacing* in such cases is unresolved; some nonrandomized studies suggest a benefit in up to one fourth of patients, but there are no randomized trials. Loosening the collar is sometimes helpful for the person with a *hypersensitive carotid sinus* reflex; demand pacing can be considered if simpler measures fail. A demand pacemaker is indicated only when heart block or severe bradycardia has been proven responsible for syncope. Empiric pacing in patients with undiagnosed recurrent episodes is to be discouraged.

Underlying Psychiatric Illness. The treatment of any underlying anxiety disorder, depression, or panic disorder results in a significant reduction in syncopal episodes and is strongly recommended (see Chapter 226 and Chapter 227).

Patient Education. The patient without evidence of underlying cardiac or neurologic disease can be reassured, even if syncopal episodes continue. Mortality does not increase with recurrent episodes, as long as there continues to be no evidence of underlying cardiac or neurologic disease. The value of a thoughtful workup in conjunction with thorough explanation should not be underestimated in helping patients with unexplained syncope to remain active. If serious heart and neurologic

diseases have been ruled out, further evaluation can safely proceed on an outpatient basis even though the cause may remain undetermined. Family members and close friends should be instructed to take careful note of all events surrounding the syncopal period, including appearance, position, activity, complaints, and behavior. They might even be taught to palpate the radial or femoral pulse to provide data on heart rate and rhythm during an episode.

INDICATIONS FOR ADMISSION

It is safest to hospitalize patients with syncope who have any clinical evidence suggesting underlying heart disease, including those with a history of effort syncope, chest pain, known coronary or valvular disease, systolic ejection murmur, abnormal resting ECG, or severe postural drop in blood pressure. Similarly, persons with evidence indicating the possibility of cerebrovascular disease or a seizure disorder (e.g., carotid bruit, prior stroke, witnessed seizure activity, or suggestive symptoms) are best served by hospitalization. Although many elderly patients benefit from an inpatient evaluation because of the increased probability of underlying cardiovascular disease, not all do, especially when the circumstances are clearly situational (e.g., postprandial, postmicturition). Admission to the hospital for observation of the obscure case is a difficult decision, but, as noted above, is most useful if episodes are frequent enough to provide opportunity for observing one.

RECOMMENDATIONS*

- Begin the evaluation with a comprehensive history and focused physical examination that emphasizes detection of underlying heart disease; obtain a resting ECG.
- Base further test selection on the pretest likelihood of underlying heart disease.

For Intermediate to High Pretest Probability of Serious Underlying Heart Disease

- Conduct the initial evaluation in the hospital and include Holter monitoring or EPS (if high suspicion of ventricular tachycardia), supplemented by stress testing and/or echocardiography.

For Low Pretest Probability of Serious Underlying Heart Disease

- Conduct the assessment in the outpatient setting and include continuous-loop event monitoring (especially for persons with structurally normal hearts, a history of palpitations, and frequent episodes), psychiatric testing (especially for younger persons with frequent episodes in the absence of evidence for heart disease, for those with multiple somatic and psychiatric symptoms, and for those with no injury from syncopal episodes), tilt-table testing (especially for persons with infrequent episodes who have no evidence of underlying heart disease and a story suggestive of neurocardiogenic [vasovagal] syncope or conversion reaction).
- Also consider conducting the initial evaluation on an inpatient basis for persons suspected of having a seizure disorder or stroke and for the frail elderly person who sustains a serious injury from a first syncopal episode.

CHAPTER 25 EVALUATION OF PALPITATIONS

Palpitations are disconcerting and often incite fear, although most cases seen in the office occur among persons with no serious underlying heart disease. The patient with palpitations reports a disquieting awareness of one's heartbeat, which may be described as a pounding, racing, skipping, flopping, or fluttering sensation. The primary physician must be able to differentiate the high-risk person in need of an intensive evaluation from the low-risk individual who can be reassured after a screening assessment. Ambulatory monitoring techniques and electrophysiologic study have improved detection of arrhythmias; their indications and limitations need to be understood.

PATHOPHYSIOLOGY AND CLINICAL PRESENTATION

Most healthy individuals are unaware of their resting heartbeat. Sudden change in rate or rhythm, increase in stroke volume or contractility, and unusual cardiac movement within the thorax may cause awareness of the heartbeat. Acute changes in heart rate or rhythm may be noted, but chronic dysrhythmias often go unnoticed. Patients with depression and other somatization disorders have excessive health concerns and a heightened awareness of normal bodily sensations that can make even the normally imperceptible heartbeat of daily life an unpleasant experience that they report as palpitations. For most other patients, palpitations represent an acute disturbance of the heartbeat.

Premature Atrial or Ventricular Contractions. Awareness of a premature beat derives from the pause and vigorous beat that follows the premature contraction. The delay allows for prolonged ventricular filling, which triggers an increase in contractility and stroke volume. The excessive motion of the heart may be felt as a "turning over" or "flopping." The sensations are isolated and tend to be most noticeable when the heart rate is slow and the patient is lying in bed supine or in the left lateral decubitus position. If there is atrioventricular dissociation and atrial contraction against a closed arterioventricular valve (as may occur in ventricular premature contractions), then a "pounding in the neck" or a sudden bulging of the neck veins (jugular *cannon venous A waves*) may be the presentation. Some patients with frequent jugular cannon A waves may report inability to catch one's breath, although they deny frank dyspnea.

In the absence of underlying heart disease, ventricular premature beats (even when frequent or complex) have no adverse effect on prognosis. Only in the context of heart disease does the presence of PVCs connote an unfavorable prognosis (see below). Similarly, atrial premature beats are harmless in the absence of heart disease, but may be a harbinger of more compromising atrial dysrhythmias when they occur in the setting of cardiac pathology.

Sinus Tachycardia. Excess adrenergic stimulation results in increased contractility and sinus tachycardia, which may present as palpitations with a fast regular rhythm. Onset can be abrupt; resolution is usually more gradual. A constant rapid pounding at rest is felt by patients with *hyperkinetic states* (e.g., fever, severe anemia, hyperthyroidism, anxiety, agitated depression) due to the catecholamine-induced increase in contractility and stroke volume. Patients with anxiety-induced palpitations often have an underlying *panic disorder* (see Chapter 226); typically, they have difficulty telling whether the palpitations or the anxiety came first. Unappreciated is the high frequency of other supraventricular dysrhythmias in this group of patients (see below). An uncommon variant of sinus tachycardia, *inappropriate sinus tachycardia*, is believed to represent a hypersensitivity to catecholamine stimulation. *Hyperthyroidism* may have a palpitation presentation similar to that of anxiety (see Chapter 103); it may also cause atrial fibrillation (see below). In rare instances, the source of adrenergic outpouring is a *pheochromocytoma*. Its incidence is less than 0.1%, with about half of cases presenting as paroxysms of palpitations, hypertension, perspiration, tremor, nervousness, and other signs of adrenergic stimulation. Episodes are often spontaneous in origin but may be triggered by emotion and thus mimic an anxiety attack. An *insulin reaction* can produce a similar clinical picture (see Chapter 102), driven by an outpouring of catecholamines. A regular rhythm without tachycardia is noted in cases of valvular disease accompanied by large stroke volumes, as in *aortic regurgitation*.

Supraventricular Tachycardias. Attacks of palpitations that are regular in rhythm and rapid in rate may also be due to paroxysmal *supraventricular tachycardia* (SVT), sometimes referred to as *paroxysmal atrial tachycardia*. There are two basic mechanisms. *In atrioventricular nodal tachycardia*, the most common SVT, there are two functionally distinct conduction pathways in the nodal area that enable a reentrant circuit to develop, producing ventricular response rates as high as 160 to 180 beats/min. If the atria in this rhythm disturbance are unaffected by the nodal rhythm disturbance, there can be arterioventricular nodal dissociation manifested as rapid regular pounding in the neck. The condition is considerably more common in women than men and occurs in a wide variety of patients, including those with normal hearts, sick-sinus syndrome, mitral valve prolapse and other forms of valvular disease, coronary artery disease, and cardiomyopathy. Onset may occur in the setting of emotional stress (e.g., panic attack). Some patients note that standing up after bending over may bring on an episode that can be terminated by lying down.

In the second form of SVT with a regular rhythm, *atrioventricular reciprocating tachycardia*, there is a large macrorentrant circuit that involves the atrium, the arterioventricular node, an accessory pathway (e.g., Bundle of Kent or James), and the ventricle. The *preexcitation syndromes* (so-called because of their short electrocardiographic PR intervals), *Wolff-Parkinson-White* (WPW) and *Lown-Ganong-Lown*, operate by the reciprocating mechanism. An electrocardiographic hallmark of WPW is the delta wave at the beginning of the QRS, indicative of aberrant conduction through the accessory bundle; the QRS may be widened considerably during a run of SVT and mimic a ventricular dysrhythmia, especially when WPW is complicated by a very rapid ventricular response rate, as in atrial flutter or atrial fibrillation (see below). Any SVT with a very rapid ventricular response rate may seriously compromise cardiac output in a patient with underlying heart disease and cause chest pain, dyspnea, profound weakness, or even loss of consciousness.

Onset of SVT is characteristically sudden and may be precipitated by excess *alcohol, emotional upset*, or strenuous *exertion*. Caffeinated beverages are less of a risk factor. SVTs may be initiated by the occurrence of premature beats that alter conduction in the normal pathway. Paroxysms cease when the conducting properties of the reentrant circuit are disturbed by changes in vagal tone, hence the report by patients of ability to terminate attacks by Valsalva. Resolution is typically abrupt. Syncope is uncommon, but may occur at the outset if the rate is very rapid and/or there is acute vasodilation.

Some of the conditions associated with SVT are responsible for other dysrhythmias as well. For example, almost half of patients with *sick sinus syndrome* experience *heart block* or marked *bradycardia* in addition to bouts of SVT.

Paroxysmal Atrial Fibrillation. Sudden onset of palpitations with an irregularly irregular rhythm and rapid rate typifies *paroxysmal atrial fibrillation*, which occurs in a host of settings including *acute alcohol excess* ("holiday heart"), *infection, hyperthyroidism, sick-sinus syndrome, WPW syndrome, cardiomyopathy*, and acute worsening of *ischemia or congestive heart failure*; the condition is also found among otherwise healthy young people ("lone" *atrial fibrillation*). High levels of circulating catecholamines may trigger atrial fibrillation, especially in someone with underlying organic heart disease. A common precipitant is exercise or the termination of exercise with its surge of vagal tone. Chronic atrial fibrillation usually does not produce palpitations. An irregularly irregular tachycardia may also be seen if there are runs of *multifocal atrial tachycardia* (MAT), which takes place in the context of severe pulmonary disease, particularly when there is an acute fall in P O_2 or pH. Frequent atrial or ventricular premature contractions can lead to a similarly irregular rhythm and rapid rate.

Ventricular Tachycardia. Ventricular tachycardia is among the most worrisome of dysrhythmias related to palpitations, being associated in some instances with risk of sudden death. Nonetheless, not all ventricular tachycardia represents life-threatening disease. *Nonsustained ventricular tachycardia* (NSVT) may occur in otherwise normal persons (*idiopathic ventricular tachycardia*) and in those with underlying heart disease. In idiopathic disease, the ventricular arrhythmia most often arises from the right ventricular outflow tract; the heart appears structurally normal. Onset is typically in the second or third decades of life and may present as palpitations, near-syncope, or even true loss of consciousness. In normal subjects, NSVT is not associated with an increased risk of sudden death; however, any NSVT that compromises cardiac output may lead to dizziness, near syncope, or loss of consciousness.

More worrisome are runs of nonsustained or sustained ventricular tachycardia occurring in the context of underlying heart disease. Patients with such a presentation have an increased risk of sudden death, especially those with *ischemia*, prior myocardial infarction with *scar* formation, *dilated cardiomyopathy, hypertensive heart disease* with left ventricular remodeling, or hemodynamically significant *valvular disease*. The clinical picture may be dominated by manifestations of the underlying

heart disease, but more subtle forms of heart disease (e.g., *hypertrophic cardiomyopathy and prolonged QT syndrome*) also may trigger ventricular tachycardia and result in sudden death.

Hypertrophic cardiomyopathy is a hereditary condition featuring asymmetric hypertrophy, right ventricular involvement, outflow tract obstruction, prominent septal Q waves in the anteroapical leads of the electrocardiogram (ECG), and a wall thickness on ultrasound of more than 13 mm. A characteristic finding on physical examination is a systolic ejection murmur along the left sternal border that increases with Valsalva and decreases with passive leg elevation (see Chapter 21).

Prolonged QT syndrome is a disorder of repolarization that increases susceptibility to potentially lethal polymorphic ventricular tachycardias (*"torsades de pointes"*). Hereditary and acquired forms have been described. In the hereditary form, there is a strong family history of sudden death below the age of 30 and congenital deafness. Ten-year mortality rates after onset of syncope approach 50%. Precipitants include severe emotional stress and very vigorous exercise. On ECG, prolongation of the QT interval, bradycardia, T-wave alternans, and notched T waves are characteristic. In the much more common acquired form, QT prolongation occurs as a result of medications or clinical conditions. Medications with this potential include the commonly used antihistamines such as *terfenadine and astemizole,* usually when taken in excess or concurrently with a drug that inhibits its metabolism (e.g., cimetidine) or causes QT prolongation itself (e.g., the *macrolide antibiotics, ketoconazole, itraconazole*). Other pharmacologic precipitants include the *class IA antiarrhythmics* (e.g., quinidine, procainamide, disopyramide), *class III antiarrhythmics* (e.g., sotalol), *tricyclic* antidepressants, and *phenothiazines.* Clinical conditions that prolong the QT interval include *hypokalemia, hypomagnesemia, hypocalcemia, hypothyroidism, starvation* and *liquid protein* diets.

Patients with underlying heart disease have a lowered threshold for ventricular tachycardia. In addition to the factors associated with prolonged QT interval, *digitalis toxicity* is an important precipitant of ventricular tachycardia. Digitalis toxicity is associated with ventricular tachycardia, atrial fibrillation, ventricular bigeminy, and junctional tachycardias. Concurrent hypokalemia and hypomagnesemia lower the threshold for development of "dig-toxic" rhythm disturbances (see Chapter 28, Chapter 29). The *methylxanthines* (e.g., theophylline) have a narrow therapeutic range, which when exceeded increases the risk of serious rhythm disturbances, including ventricular tachycardia, especially in persons with underlying heart disease.

DIFFERENTIAL DIAGNOSIS

The causes of palpitations can be listed in terms of their clinical presentation (Table 25.1).

Table 25.1. Important Causes of Palpitations

WORKUP

Although determining the nature of the heartbeat disturbance helps to identify etiology and prognosis, the key determinant of prognosis is the presence, type, and severity of underlying heart disease. Consequently, a search for cardiac pathology is a high priority.

History. Eliciting a complete *description* of the patient's palpitations is essential, including its mode of onset, frequency, rate, rhythm, duration, termination, associated symptoms, and precipitants and alleviating factors. Unfortunately, many patients are unable to give an accurate or detailed account of their symptoms. The relation of the onset of symptoms to exertion can aid in separating the anxious individual, whose symptoms may occur at rest and are usually not worsened by exertion, from the patient with heart disease and impaired exercise tolerance. Identification of precipitants such as emotional upset, stimulant intake, fever, pregnancy, volume depletion, and severe anemia is essential, because their recognition can contribute to design of proper therapy. Inquiry into symptoms of an insulin reaction (see Chapter 102) and hyperthyroidism (see Chapter 103) may also prove productive.

The more hypochondriacal or somatizing the patient, the poorer the correlation between symptoms and Holter monitoring results; however, reports of fluttering, stopping, or beating irregularly are predictive of finding an arrhythmia. Any isolated thumping or flip-flopping in the chest suggests an atrial or ventricular premature beat. Associated pounding in the neck is indicative of arterioventricular dissociation, as seen with ventricular premature beats or arterioventricular nodal tachycardia. Sudden onset and sudden cessation of rapid regular heartbeats are characteristic of nodal and reentrant SVT and NSVT, whereas more gradual onset and cessation characterize sinus tachycardia. Palpitations brought on by exercise or emotional stress point to idiopathic ventricular tachycardia, atrial fibrillation, other SVTs, prolonged QT interval, and inappropriate sinus tachycardia. Onset in conjunction with a panic attack is indicative not only of sinus tachycardia but also of nodal reentrant tachycardia, as is onset with standing up after bending over and cessation with lying down.

Inquiries into concurrent dyspnea, chest pain, lightheadedness, near-syncope, and syncope are essential both for etiology and assessment of hemodynamic severity. Syncope suggests ventricular tachycardia or a very fast SVT with vasodilatation. Chest pain and dyspnea may also be signs of marked hemodynamic compromise. Additionally useful are questions about risk factors for coronary disease (smoking, diabetes, hypertension, hyperlipidemia, positive family history of early onset syncope or sudden death before age 30) and prior cardiac history (heart murmur, rheumatic fever, myocardial infarction, other forms of cardiac illness, family history of heart disease). Although one should not mistake symptoms of anxiety, such as chest tightness and air hunger at rest, for evidence of organic heart disease, the presence of anxiety symptoms does not rule out an arterioventricular nodal tachycardia. Nonetheless, assessment is not complete without specific inquiry into symptoms of panic and somatization disorders (see Chapter 226 and Chapter 230).

Use of all cardiotonic drugs should be detailed, including antiarrhythmics, digitalis preparations, theophylline compounds, sympathomimetics, and anticholinergics. Also to review are drugs associated with QT prolongation: antiarrhythmics, terfenadine, astemizole, macrolide antibiotics, ketoconazole, itraconazole, phenothiazines, and tricyclic antidepressants. Many over-the-counter decongestants and diet pills contain catecholamines or theophylline derivatives; their abuse may be responsible for symptoms. The history should include inquiry into alcohol abuse (see Chapter 228), a common precipitant of paroxysmal SVT. Family history of early-onset syncope can be a clue to hereditary prolonged QT syndrome or hypertrophic cardiomyopathy.

Physical Examination. Important observations include determination of the blood pressure for elevation, marked postural change, and widened pulse pressure. The apical pulse is noted for rate and rhythm disturbances; relying on the peripheral pulse may be misleading when there is a pulse deficit, as occurs in atrial fibrillation or premature beats. The temperature should be recorded. The skin is examined for pallor and signs of hyperthyroidism and anemia; the eyes for exophthalmos; the neck for goiter; the carotid pulse for upstroke; the jugular venous pulse for distention and cannon A waves; the chest for rales, rhonchi, wheezes, and dullness; the heart for heaves, thrills, clicks, murmurs, rubs, and third heart sound; and extremities for edema and calf tenderness. The finding of a systolic ejection murmur along the left sternal border should be followed by examining its response to Valsalva maneuver; an increase in intensity suggests hypertrophic cardiomyopathy. Response to modest exercise should also be noted, because a number of dysrhythmias may be triggered by it. Finally, the mental status examinationshould include checking for manifestations of anxiety, depression, panic disorder, and substance abuse (see Chapter 226, Chapter 227, Chapter 228, Chapter 230, and Chapter 235). In addition to possibly providing important diagnostic information, the careful unhurried physical examination can be of considerable use in reassuring the worried patient.

Laboratory Studies. A few basic hematologic and chemistry studies contribute to the assessment of etiology and risk. Patients with signs of a hyperkinetic state require a *hemoglobin* determination to rule out a significant anemia and a *thyrotropin* test to rule out hyperthyroidism. Patients with underlying heart disease should have a check of the serum *potassium, calcium*, and magnesium, especially if taking a digitalis preparation; a serum cardiac glycoside level (e.g., for *digoxin*) is equally

important to rule out toxic accumulation of the drug. A finger-stick *blood glucose* can be diagnostic in the setting of a suspected insulin reaction triggering hypoglycemia (see Chapter 102). When there is sufficient clinical evidence to warrant consideration of pheochromocytoma, a 24-hour *urine for VMA* can be helpful (see Chapter 26). Most of the remainder of the laboratory workup is directed toward identifying the rhythm disturbance and detecting underlying heart disease.

Resting Electrocardiogram. Most if not all patients with palpitations should have a resting 12-lead ECG. Even if physical examination is completely normal and no disturbances of rate or rhythm are noted on the ECG, one might detect a manifestation of underlying heart disease. Specifically, the ECG needs to be studied for axis shift, short PR interval (less than 0.12 seconds), abnormal P-wave morphology including signs of atrial enlargement, QRS widening, increase in QRS voltage, prominent septal Q waves, prolonged QT interval, delta waves, and ST- and T-wave changes. If a dysrhythmia is noted, it is worth obtaining a 2-minute rhythm strip to better characterize the rhythm disturbance. The anxiety-laden person often insists on having an ECG and finds comfort in a normal result; unfortunately, in many cases the reassurance is only transient.

Ambulatory Electrocardiographic Monitoring. Patients whose palpitations are accompanied by evidence of *underlying heart disease* are the best candidates for ambulatory monitoring, because they are at increased risk of having a clinically significant arrhythmia. So long as they are not experiencing syncope, near-syncope, heart failure, or angina in association with their palpitations, they can undergo an outpatient evaluation that includes ambulatory monitoring. The utility of ambulatory monitoring in otherwise healthy patients who complain solely of palpitations remains less clear, although the reassurance value can be considerable if typical episodes occur in the presence of a normal ECG recording.

The most cost-effective approach to ambulatory monitoring is use of an *event recorder* rather than *Holter monitoring*, because most episodes of palpitations are relatively infrequent. A 2-week monitoring period using a continuous-loop event recorder yields more diagnoses at lower cost than does 48-hour Holter monitoring or 4 weeks of event recording. The only drawback to the continuous-loop event recorder is that it requires patient activation, which can be a problem if the dysrhythmia incapacitates the patient. Although monitoring may be continuous, preservation of the ECG record is usually limited to a few minutes about the time of activation. Most units use continuous-loop recording technology, although more advanced storage technologies are under development. Some permit telephone transmission of the rhythm disturbance. Intermittent ECG recorders allow prolonged monitoring at reasonable cost in patients with relatively infrequent episodes of palpitations. Ambulatory monitoring has been disappointing as a method for detecting ischemia.

The yield from Holter monitoring is greatest in patients with daily symptoms. Patients are asked to keep a diary to ascertain the relationship between symptoms and rhythm disturbances. Because atrial and ventricular premature beats and short runs of SVT are common in normal asymptomatic patients, a positive test requires a clear-cut correlation between symptoms reported in the patient log and ECG findings. Most studies of Holter monitoring show a very high incidence of recorded "abnormalities" but a very poor correlation between ECG findings and reported symptoms. The patient who experiences typical symptoms but no concurrent rhythm disturbances during the Holter monitoring can be reassured. The patient who fails to have a symptomatic episode during Holter monitoring—a common occurrence—may be scheduled for a repeat study; however, yield is low in patients whose initial Holter study is normal and frequency of episodes is low. The cost of repeat Holter monitoring can be high.

One of the more disconcerting findings on event monitoring is a *wide QRS tachycardia*. Although not usually encountered in the outpatient setting, it may be found on an event monitoring and needs to be addressed to determine whether it represents a rather harmless *SVT with aberrancy* or a more ominous *ventricular tachycardia*. Findings associated with a ventricular origin include a history of heart disease, evidence of an old myocardial infarction on a resting ECG, arterioventricular dissociation (which is often absent but can be diagnostic if present), a QRS duration of more than 160 ms if there is a right bundle branch pattern or more than 140 ms if the pattern is left bundle, a combination of left bundle branch block and right axis deviation, extreme left axis deviation (less than -90 to +180 degrees), and a different QRS pattern during tachycardia than on resting ECG in patients with preexisting bundle branch block. The combination of these findings provides reasonable sensitivity and specificity; most single findings are relatively weak discriminants.

Exercise Stress Testing. Although Holter monitoring is more likely to detect ventricular irritability than is stress testing, stress testing will sometimes uncover ventricular tachycardias that do not appear on Holter or event monitoring, suggesting to some that the studies might be complementary. The best candidates for exercise stress testing are those who report palpitations occurring during or immediately after exercise. SVTs, atrial fibrillation, and idiopathic ventricular tachycardia are commonly triggered by exercise or its termination and may be detected by the test. Alternatively, one can ask the patient to exercise during ambulatory monitoring. Stress testing is also indicated if palpitations occur in the context of angina-like chest pain, suggesting either an ischemic mechanism or sufficient hemodynamic compromise to result in ischemia (see Chapter 20 and Chapter 36). To ensure patient safety, one needs to rule out hemodynamically significant aortic stenosis, hypertrophic cardiomyopathy, and QT prolongation before proceeding with exercise testing, because they are associated with an increased risk of an adverse event with stress testing.

Echocardiography. Patients suspected of having valvular or cardiomyopathic disease on the basis of history, physical examination, or ECG should undergo echocardiography for confirmation and determination of severity of disease (see Chapter 21 and Chapter 33). Routine ordering of cardiac ultrasound in the absence of clinical suspicion is of little utility and only increases the cost of evaluation.

Electrophysiologic Study. Palpitations leading to syncope or near-syncope raise the question of a major rhythm disturbance (e.g., very rapid SVT, ventricular tachycardia, complete heart block). When occurring in the context of underlying organic heart disease, such arrhythmias have an especially poor prognosis (see Chapter 28 and Chapter 29). Electrophysiologic study (EPS) can help uncover such arrhythmias and their pathologic mechanisms. The search for a focus of malignant arrhythmogenicity also helps guide treatment. The value of EPS in syncopal patients who have significant organic heart disease is well documented, but sensitivity and specificity for identifying important arrhythmias or conduction system disturbances in syncopal patients without signs of underlying heart disease have been disappointing. EPS remains an important diagnostic modality in the evaluation of patients with suspected ventricular tachycardia or documented heart block. Careful patient selection is essential (see Chapter 24 and Chapter 29). EPS is very expensive and not without risk, because it includes induction of potentially dangerous dysrhythmias. The study requires cardiac catheterization, sophisticated equipment, and a highly trained and experienced staff.

PATIENT EDUCATION AND SYMPTOMATIC RELIEF

Providing Reassurance. When palpitations prove to be no more than a manifestation of excessive bodily concern or a harmless dysrhythmia with no adverse consequences, efforts should be made to provide meaningful reassurance. Failure to do so is likely to lead to unnecessary limitation of activity and demands for additional testing or referrals to specialists. Hasty or perfunctory words of comfort are worthless. A careful history and physical examination, combined with eliciting and responding directly to patient concerns, views, and requests (within reason), must take place before the patient can be told the palpitations are harmless. Such reassurance may be all that is needed, especially when combined with advice to increase physical activity and cut down on alcohol, smoking, and stress. Ambulatory monitoring or exercise stress testing may have a role in helping to reassure the overly anxious patient. Directly addressing any underlying psychopathology may be required (see Chapter 226, Chapter 227, and Chapter 230).

Symptomatic Management. Proper management of dysrhythmias in patients with underlying heart disease is treatment of the underlying pathology. For patients with no underlying heart disease who find their symptoms intolerable, a few simple measures are worth considering.

Atrial and Ventricular Premature Beats. If the palpitations persist and are bothersome, a trial of beta-blocker therapy may be beneficial symptomatically. Often as little as 25 to 50 mg/day of atenolol or the equivalent decreases the frequency of atrial or ventricular premature beats to the point where they are tolerable. Patients with idiopathic chronic ventricular bigeminy causing fatigue or exertional near-syncope because of a slow effective heart rate might benefit from consideration of radioablation if they do not respond to beta-blockade. All nonessential drugs capable of causing palpitations should be stopped.

The role of *caffeine* in precipitating cardiac arrhythmias and the usefulness of restricting its intake in symptomatic patients has been debated for decades. Available data show benefit only for restricting excessive intake (more than five cups a day), unless the patient reports caffeine-induced symptoms.

Supraventricular Tachycardia and Sinus Tachycardia. Detailed discussion of treatment for SVT is presented in Chapter 28, but a few simple measures are worth noting. *Vagal maneuvers* are often effective in halting SVT. *Valsalva* and *carotid sinus massage* (in the absence of carotid disease) can be taught to the patient and suggested as the first line of therapy after the onset of an attack. Prophylaxis of SVT attacks can be accomplished by avoiding known precipitants, such as alcohol and stimulants. If a panic attack disorder is the cause of episodes of palpitations, one can consider beta-blockade, a minor tranquilizer, or an antidepressant (see Chapter 226).

Symptomatic treatment of sinus tachycardia necessitates correcting the underlying precipitant (e.g., anemia [see Chapter 82], volume depletion, hyperthyroidism [see

Chapter 103], fever [see Chapter 11]), and congestive failure [see Chapter 32]). Patients with hypoglycemic episodes need an adjustment in their insulin regimen and/or dietary program (see Chapter 102). Treatment of MAT requires correction of the underlying pulmonary problem rather than use of antiarrhythmic drugs. Improvement in oxygenation and pH status is essential.

Ventricular Tachycardia. Episodes that cause syncope require attention even when there is no threat of sudden death associated with them (see Chapter 29).

INDICATIONS FOR ADMISSION AND REFERRAL

Admission. Patients with palpitations associated with syncope, near-syncope, angina-like chest pain, or true dyspnea are candidates for prompt inpatient evaluation, especially if they have evidence of underlying organic heart disease. Hospitalization is also indicated if a patient with known heart disease demonstrates runs of ventricular tachycardia, even if these are not sustained or hemodynamically compromising; mortality risk is high. Patients with SVT who manifest hemodynamic compromise (e.g., fall in blood pressure, dyspnea, angina, near-syncope) also need prompt hospital admission.

Referral. Patients with underlying heart disease and palpitations leading to syncope, near-syncope, chest pain, or dyspnea require cardiac consultation for consideration of electrophysiologic study, as do those with underlying heart disease and episodes of ventricular tachycardia (sustained or nonsustained), whether hemodynamically compromising or not. All such patients are at high risk and likely to benefit from EPS both diagnostically and often therapeutically (see Chapter 28 and Chapter 29).

CHAPTER 26 MANAGEMENT OF HYPERTENSION

KATHARINE K. TREADWAY

INTRODUCTION

Hypertension is one of the few conditions in medicine that can be readily detected and effectively treated in the asymptomatic period before irreparable harm is done. It ranks as a leading risk factor for cardiovascular disease and as a major reason for office visits and prescription of medication. Cardiovascular disease is the leading cause of death in the United States. Of these deaths, 83% are caused by myocardial infarction and 17% are from stroke. There has been a steady decline in cardiovascular death over the last three decades, at least some of which is attributable to the lowering of blood pressure in the general population. The frequency and importance of hypertension demand that the primary physician be expert in its management and capable of designing a regimen that is safe, effective, and well tolerated.

PRINCIPLES OF MANAGEMENT

The first tasks are to confirm the diagnosis and estimate overall cardiovascular risk. This guides program design, which includes nonpharmacologic and pharmacologic interventions.

Confirming the Diagnosis and Estimating Overall Cardiovascular Risk

Confirming the Diagnosis. Because treatment of hypertension is likely to be lifelong, it is essential that the diagnosis be well established before committing the patient to therapy. Initiation of antihypertensive treatment should be preceded by a careful evaluation that not only confirms the diagnosis but also rules out secondary causes, identifies any additional cardiovascular risk factors, and assesses presence and degree of target-organ damage (see Chapter 14 and Chapter 19).

Classification. In 1997, the Sixth Joint National Committee (JNC VI) recommendations eliminated the designations of "mild," "moderate," "severe," and "very severe" hypertension to avoid the misleading notion that so-called mild hypertension was not a significant health risk. In addition, a "high-normal" category was designated for adults with systolic blood pressure (SBP) 135-139 mm Hg or diastolic blood pressure (DBP) 85-89 mm Hg to highlight the increased risk of developing sustained hypertension in this group. In 2003, JNC VII went a step further, introducing the term "prehypertension" for adults with systolic blood pressure 120-139 mm Hg or diastolic blood pressure 80-89 mm Hg. The current classification includes: **Updated: 5/21/03**

BP Classification	Systolic BP, mm Hg	Diastolic BP, mm Hg	Updated: 5/21/03
Normal	< 120	< 80	
Prehypertension	120-139	80-89	
Stage 1 Hypertension	140-159	90-99	
Stage 2 Hypertension	> 160	> 100	

Such classification systems are necessarily arbitrary. The relationship between blood pressure and cardiovascular risk is continuous. For people aged 40 to 70 years, each increment of 20 mm Hg in SBP or 10 mm Hg in DBP doubles the risk of cardiovascular disease. This effect exists across the range of blood pressure from 115/75 to 185/115 mm Hg. Most excess cardiovascular mortality from hypertension in the United States derives from patients with stage 1 disease, accounting for almost 80% of the hypertensive population and almost 60% of the excess cardiovascular mortality attributable to hypertension. Blood pressures in this range are not benign. **Updated: 5/21/03**

Estimating Total Cardiovascular Risk. Because the goal of antihypertensive therapy is to reduce cardiovascular morbidity and mortality, the treatment program must address the patient's *total cardiovascular risk,* not just the elevation in blood pressure. This requires determining not only the *degree* of *blood pressure elevation* but also identifying any other *cardiovascular risk factors* (e.g., smoking, diabetes, hypercholesterolemia, concurrent cardiovascular or peripheral vascular disease, age, gender) and any manifestations of *target-organ disease* (e.g., left ventricular hypertrophy [LVH], retinopathy, nephrosclerosis; see Chapter 19). **Updated: 5/21/03**

For any stage of hypertension, the presence of other risk factors increases the importance of effective control. For example, the risk of a 40-year-old man developing coronary disease in the next 10 years with stage 1 to 2 hypertension is about 15%. If that same 40-year-old also has elevated cholesterol, a low high-density lipoprotein (HDL), diabetes, LVH on electrocardiogram, and smokes, risk increases to about 60% (see Appendix). **Updated: 5/21/03**

Nonpharmacologic Measures

The principal nonpharmacologic measures for treatment of hypertension include *salt restriction, reduction of excess weight* (see Chapter 223), *exercise* (see Chapter 18), and use of a *diet* low in saturated fat and rich in fruits and vegetables. The Dietary Approaches to Stop Hypertension (DASH) diet, which recommends high intake of fruits, vegetables, low-fat dairy products, and grains, achieves an average BP decrease of 6 mm Hg systolic and 3 mm Hg diastolic when combined with other lifestyle changes in randomized controlled trials of persons with prehypertension and greater reductions in persons with stage 1 hypertension (see below). Additional benefit (1-2 mm Hg) is seen by combining the DASH diet with sodium restriction. These proven lifestyle measures should be the foundation of every treatment program. Because these measures are an excellent means of primary prevention, they should be encouraged in all adults and strongly advised for those with prehypertension. Additional measures include elimination of excess alcohol intake and ensuring adequate dietary potassium, magnesium, and calcium. Behavioral therapies may make a modest contribution to reduction in pressure but do not appear sufficient as the sole means of therapy in most patients. All nonpharmacologic measures should continue even if drug therapy needs to be instituted, because they enhance its effectiveness and allow for use of fewer medications at lower doses. **Updated: 6/30/03**

Salt Restriction. *Salt restriction* still ranks as one of the mainstays of nonpharmacologic therapy for all hypertensive patients, regardless of underlying pathophysiology, although the degree of benefit is rather modest when examined by meta-analysis of randomized trials (i.e., 3 to 5 mm Hg for SBP, 2 to 3 mm Hg for DBP). Although it is clear that individuals vary in their degree of salt sensitivity, *African-Americans* and the *elderly,* who tend to have low-renin volume-expanded hypertension, appear to respond particularly well to sodium restriction. Because we currently do not have effective ways to identify those most likely to respond to sodium restriction, all patients should be instructed in either a *no-added-salt diet* (4 g sodium/d) or a *low-sodium diet* (2 g/d), depending on their volume status. Not only may salt restriction alone provide adequate control in some mild cases, but it can profoundly affect the efficacy of pharmacologic therapy. Patients receiving diuretics who had an unrestricted salt intake showed a blood pressure reduction of 4% compared with a 15% reduction for those restricting their sodium intake.

Weight Reduction. *Weight reduction* achieves significant decreases in blood pressure, even if ideal weight is not reached. The effect is independent of salt intake. All patients who are more than 15% above their ideal body weight should be urged to lose weight. In the TAIM study, patients receiving placebo who lost 4.5 kg or more of weight had the same reduction in pressure as those who maintained their usual diet and were treated with chlorthalidone or atenolol. The relation between obesity and blood pressure is particularly strong among young to middle-aged adults. In addition, weight loss is important in patients with central adiposity (hip to waist ratio

more than 0.85 in women and more than 0.95 in men). Such patients have a higher incidence of hypertension, diabetes, and hyperlipidemia and a higher risk of cardiovascular disease. Weight loss in this group will therefore reduce multiple risk factors simultaneously.

Reduction in Excess Alchol Consumption. Epidemiologic data indicate a relationship between excess alcohol consumption and risk of hypertension. More than 2 oz of alcohol per day significantly increases the risk of becoming hypertensive. Small scale studies suggest that a daily alcohol intake of less than 1 oz may result in a modest decrease in blood pressure. Excessive alcohol intake is a frequent cause of "refractory" hypertension.

Exercise. *Exercise* of the aerobic variety helps to reduce weight, improves cardiovascular conditioning and lipid profile, and may help in patients with prehypertension and stage 1 hypertension (see Chapter 18). Such patients given an exercise program of aerobic and circuit weight training three times per week for 10 weeks showed pressure reductions comparable with those achieved with beta-blocker or calcium channel blocker therapy and obviated the need for chronic drug treatment. Candidates for a vigorous exercise program should undergo cardiac stress testing first (see Chapter 18). | **Updated: 5/21/03**

Other Dietary Measures. In addition to salt restriction, *other dietary measures* include a *low-saturated-fat* diet rich in *fruits, vegetables,* and *low-fat dairy products,* which can reduce blood pressure significantly in persons with mild hypertension taking no medications. Such diets provide full daily requirements of calcium, potassium, and magnesium, factors believed to contribute to blood pressure control. The landmark Dietary Approaches to Stop Hypertension study demonstrated reductions of 11.4 mm Hg in SBP and 5.5 mm Hg in DBP in stage 1 hypertensive patients put on such a diet. These benefits were achieved in the context of modest sodium restriction (3 g/d), limitation of alcohol intake, and no weight reduction, indicating that a restricted-fat diet rich in fruits, vegetables, and low-fat dairy products makes an independent contribution to treatment and to prevention. This dietary approach appears to be more effective than prescribing supplementation of individual elements. Meta-analysis of randomized clinical trials of dietary *calcium* supplementation shows a statistically significant but not clinically significant decrease (1 to 2 mm Hg) in SBP only. | **Updated: 5/21/03**

Behavioral Therapies. Behavioral therapies such as *relaxation* techniques and *biofeedback* programs have gained popularity in recent years. Small-scale studies suggested a modest benefit, especially in those with mild pressure elevations, but a rigorous meta-analysis of available studies found little specific benefit. Although behavioral techniques were superior to no therapy, they provided no more benefit than self-monitoring or sham techniques.

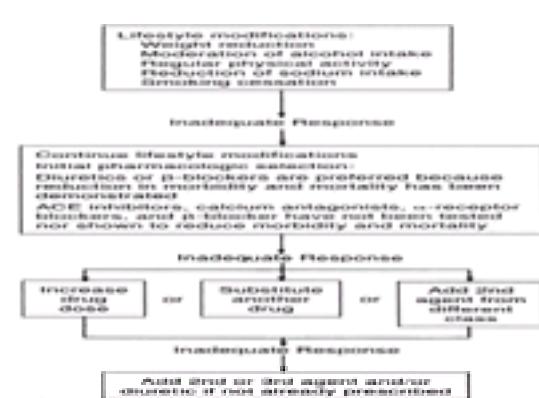
Pharmacologic Therapy—Basics Issues (Fig. 26-1) | **Updated: 7/10/03**


Figure 26-1. Treatment algorithm for pharmacologic therapy of high blood pressure. (From the Joint National Committee. The fifth report of the Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure. Arch Intern Med 1995;155:5, with permission.) | **Updated: 7/10/03**

When to Initiate Medication. As note above, treatment is guided by estimate of overall cardiovascular risk. Persons with stage 2 hypertension, target-organ damage, or multiple cardiovascular risk factors (especially diabetes) should begin pharmacologic therapy at the outset. For many of these patients consideration should be given to initiating therapy with two agents, one of which should be a thiazide-type diuretic. For most patients with stage 1 hypertension initiation of therapy with a thiazide-type diuretic is appropriate, though for lower levels within stage 1, pharmacologic treatment can be deferred for weeks to months while the lifestyle modifications enumerated above are instituted. If blood pressure does not normalize, pharmacologic therapy should be initiated promptly. Patients with prehypertension should be strongly advised and supported in adoption of nonpharmacologic measures. | **Updated: 5/21/03**

Elderly patients with *isolated systolic hypertension* have a significant risk of cardiovascular disease and should be treated. The Systolic Hypertension in the Elderly Program study found a significant reduction in fatal and nonfatal strokes and a lesser reduction in fatal and nonfatal myocardial infarction when the SBP was lowered to *less than 160 mm Hg.*

Goals, Efficacy, and Duration of Treatment. As noted earlier, the reduction in overall cardiovascular risk to prevent heart attack and stroke requires not only reducing blood pressure but also attending to the other cardiovascular risk factors amenable to treatment (e.g., smoking, lipids, hyperglycemia, LVH; see Chapter 54, Chapter 27, and Chapter 102). Blood pressure should be lowered to least 140/90 mm Hg, or to 130/80 mm Hg for patients with diabetes or chronic kidney disease. The Hypertension Optimal Treatment study found the optimal DBP for reducing cardiovascular risk in middle-aged hypertensive men to be 83 mm Hg and lower for those with diabetes and increased risk of hypertensive stroke. When following patients with home monitoring devices, home blood pressures should generally be less than 135/85 mm Hg, which takes into account any underestimates of true pressure by home readings. | **Updated: 5/21/03**

Because there is no cure for essential hypertension, drug treatment has often been viewed as lifelong. Some patients with very mild elevations may be able to stop medication, provided they continue nonpharmacologic measures and successfully control other risk factors. Even patients with substantial hypertension who require multidrug regimens may be candidates for a reduction in drug therapy. Patients with stage 1 disease whose blood pressure is well controlled with pressures in the 120/80 range for some months may be gradually weaned off medication with the caveat that they should continue to be monitored biyearly for some time as pressures can slowly rise months after stopping therapy. | **Updated: 5/21/03**

Selection of Drugs. Regardless of medical regimen selected, all nonpharmacologic measures should be continued, because they enhance the effectiveness of drug therapy and allow for use of fewer medications at lower doses. JNC VII recommends *thiazide-type diuretics* as the preferred first-line agents in most instances for pharmacologic treatment of uncomplicated hypertension. These agents have demonstrated significant reductions in cardiovascular morbidity and mortality in large-scale, prospective, randomized, controlled trials and are low in cost. | **Updated: 1/15/03**

This represents a shift in emphasis in that JNC VI had also recommended other drugs as first line agents (i.e., beta–blockers, angiotensin-converting enzyme inhibitors [ACEIs], calcium-channel blockers [CCBs], and alpha-blockers). The shift reflects new evidence from large--scale, long-term randomized controlled trials providing head-to-head comparisons of alternative antihypertensive drugs. The most statistically powerful of these studies, the Antihypertensive and Lipid-Lowering Treatment to Prevent Heart Attack Trial (ALLHAT), was conducted in more than 33,000 high-risk patients (age over 55 years and one or more additional cardiovascular risk factors) who were followed for a mean of nearly 5 years. It revealed that diuretic therapy with chlorthalidone was just as effective as ACEI therapy with lisinopril and CCB treatment with amlodipine in reducing rates of fatal coronary heart disease, nonfatal myocardial infarction, and all-cause mortality. In addition, diuretic therapy was superior to amlodipine in terms of lowering risk of heart failure and better than lisinopril at reducing risks of heart failure, stroke, and combined forms of cardiovascular disease. ALLHAT also uncovered an increased risk of heart failure with first-line use of the alpha-blocker doxazocin in this high-risk patient population. A single exception to the consistency of the unsurpassed effectiveness of thiazide diuretics can be found in the Second Australian National Blood Pressure trial. Here, among white men, a regimen that began with an ACE inhibitor had slightly better outcomes than a regimen that began with a diuretic. | **Updated: 5/25/03**

Combination Therapy and Compelling Indications. On the basis of the ALLHAT and other data, JNC VII recommends that thiazide diuretics should be used as initial therapy alone or in combination with one of the other classes of drugs (beta blockers, ACE inhibitors, ARBs, CCBs). The JNC VII report also notes that most patients with hypertension will require two or more medications to achieve the goal of <140/90 mm Hg (or <130/80 mm Hg for patients with diabetes or chronic kidney disease). | **Updated: 5/25/03**

Furthermore, JNC VII emphasizes that therapy should be guided by "compelling indications," existing conditions for which antihypertensive agents may provide benefit independent of their effect on blood pressure. These compelling indications for agents from other classes include ischemic heart disease, congestive heart failure, diabetes, chronic kidney disease, and cerebrovascular disease. | **Updated: 5/25/03**

Cost Containment. Primary care physicians must consider affordability in the design of the modern antihypertensive regimen. Without attention to cost, the financial burden of a long-term pharmacologic program can easily become so great that patients fill only part of a prescription or cut frequency or dose, compromising compliance and threatening blood pressure control. Thiazides and generic beta-blockers (e.g., propranolol, metoprolol, atenolol) provide the most cost-effective approach to pharmacologic therapy (Table 26-1). The reaffirmation of the primacy of thiazide-diuretics by ALLHAT should help to reduce the cost of treatment as reliance on the newer, more expensive antihypertensive agents diminishes over time. Especially helpful should be the cost savings from use of thiazide diuretic therapy as a preferred first-line therapy, a practice that had been on the decline over the past decade out of concern for possible adverse metabolic effects (see below). Also helping to reduce cost is the increasing availability of generic formulations of ACEIs and CCBs.

Table 26-1. Antihypertensive Drugs

Additional approaches to minimizing cost include substituting a *sustained-release preparation* if it is less expensive than a multidose regimen, staying with a less expensive older antihypertensive agents if reasonably effective and well tolerated, and using the lowest dose possible. If a second first-line agent must be added, one should always consider prescribing a *thiazide* diuretic, which is capable of markedly enhancing program efficacy at very little additional cost.

Pharmacologic Therapy—First-Line Agents

The first-line agents are the drugs of choice because of efficacy and minimal side effects. They may be used singly or in combination. Several, but not all, have been shown to reduce cardiovascular morbidity and mortality. Cost ranges from modest to very expensive.

Thiazide Diuretics. These agents are experiencing a renaissance of use as first-choice for pharmacologic therapy, spurred on by the findings from ALLHAT (see above), which documented long-term outcomes equal to or better than those achieved with ACEIs or CCBs. Compared with ACEIs, CCBs, and alpha-blockers, thiazides produce comparable reductions in blood pressure and LVH, and similar or superior reductions in risks of cardiovascular morbidity and mortality. Their proven efficacy, safety, and extremely low cost make them a compelling first choice for pharmacologic management of hypertension.

Diuretic use had been declining until recently over concerns raised by a 1990 meta-analysis showing less survival benefit than expected from the blood pressure reductions achieved. To explain this discrepancy in predicted and actual outcomes, several authorities invoked the known potentially adverse thiazide side effects of hypokalemia, elevation in low-density lipoprotein (LDL) cholesterol, and glucose intolerance. Of note, these side effects occur principally with high-dose therapy (e.g., 50 to 100 mg/d hydrochlorothiazide) and can be avoided by restricting use to modest doses (e.g., hydrochlorothiazide, 12.5 to 25.0 mg/d). Because there is little sacrifice in control by restricting doses to these levels, such doses have now become the standard for thiazide use. When used at low doses, thiazides are a safe, well-tolerated, very inexpensive, and effective means of treatment (Table 26-1).

Mechanism of Action. Thiazides enhance sodium excretion, resulting in a reduced intravascular volume and reduced peripheral resistance (presumably by lowering intracellular sodium in vascular smooth muscle cells). Potassium excretion is increased, and uric acid and calcium excretions are decreased.

Adverse Effects. Potassium wasting is a consequence of the drug's effect on the distal tubule and is exacerbated by high salt intake. Clinically significant *hypercalcemia* is exceedingly rare, although a decrease in calcium excretion does occur and can be beneficial in patients with osteoporosis or calcium-containing renal stones (see Chapter 135). *Hyperglycemia* is usually mild and infrequent at the low doses currently recommended. Mild *hyperuricemia* may occur but usually not to the degree that necessitates discontinuation of therapy. A transient increase in *LDL cholesterol* has been noted. Thiazides may cause rash, especially a photo-sensitizing type, and rarely may precipitate pancreatitis. Most adverse metabolic effects can be minimized or eliminated by restricting dose to the equivalent of 25 mg/d or less of hydrochlorothiazide.

Monitoring. Checking the serum *potassium* regularly and correction of even mild hypokalemia are essential in a person with underlying cardiac disease, particularly one bothered by dysrhythmias or taking digoxin (see Chapter 29 and Chapter 32). Hypokalemia can be prevented by concomitant salt restriction, increased dietary potassium, and, when necessary, the addition of potassium-sparing agents or supplements (see Chapter 32). Potassium levels should be maintained in the normal range. Severe degrees of hypokalemia may cause muscle weakness. The serum *glucose* requires close monitoring when thiazides are used in a diabetic, and the *uric acid* should be watched if the patient has clinical gout. There is no need to monitor LDL cholesterol or serum calcium.

Beta-Blockers. These are highly effective in reducing cardiovascular morbidity and mortality, generally well tolerated, and relatively low in cost. In addition, they are the only class of antihypertensive medication that provides secondary prevention following a myocardial infarction. Known ischemic heart disease is, in the absence of contraindications (see below) a compelling indication for use of beta–blockers in treatment of hypertension.

Mechanism of Action. Exactly how these agents lower blood pressure remains unclear. They decrease cardiac output, renin release, central sympathetic activity, catecholamine release, and peripheral resistance. Any or all of these may be involved in the means by which they lower blood pressure.

Adverse Effects. Adverse effects include *bradycardia, fatigue, impotence, depression, decreased exercise tolerance, nightmares, and increased airway resistance.* As such, these agents should be used with great care if at all in patients with asthma, severe chronic obstructive pulmonary disease (COPD), or serious depression. Their cautious use in heart failure may actually be beneficial (see Chapter 32). They may modestly increase insulin resistance and slightly reduce HDL cholesterol, side effects that do not seem to cancel their beneficial effects on hypertension and its associated risks.

The degree of *lipid solubility* has been linked theoretically to the degree of central nervous system (CNS) penetration and the likelihood of neuropsychiatric side effects, such as depression, lethargy, sexual dysfunction, and nightmares. The elderly are particularly susceptible to such side effects. Atenolol and nadolol are the most lipid insoluble, whereas propranolol and metoprolol are among the most lipid soluble. Studies testing these theoretic concerns have shown little difference clinically for lipophilic and lipophobic preparations. However, sexual dysfunction and depression appear to be more common with lipophilic agents than lipophobic ones, although still occurring on occasion with use of the latter.

Preparations. All appear to be equally effective for treatment of hypertension, though differences in their cardioselectivity, lipid solubility, and intrinsic sympathomimetic activity can be used to advantage. *Cardioselectivity* is characterized by greater effect on b_1 adrenergic receptors of the heart than on the b_2 receptors of blood vessels and bronchi. A cardioselective preparation is preferred in patients with COPD or asthma because it reduces the chances of inducing bronchospasm. However, cardioselectivity is a relative quality that declines as dose increases. Furthermore, even cardioselective beta-blockers are not well tolerated in asthmatics and COPD patients with active bronchospasm. *Atenolol* and *metoprolol* are examples of the commonly used cardioselective beta-blockers.

Some beta-blockers have *intrinsic sympathomimetic activity.* Those with such action tend to cause less bradycardia and less disruption of lipid and carbohydrate metabolism. They help maintain cardiac output with exercise, allowing cardiac conditioning. They are comparable with other beta-blockers in ability to lower blood

pressure. Examples include *pindolol, acebutolol,* and *carvedilol.*

The beta-blocker *labetalol* is unique in that it has both *a*- and *b*-blocking actions, with about one fourth the potency of propranolol and one sixth the potency of phentolamine. Its rapid onset of action has made it useful for use in hypertensive emergencies—especially when given parenterally—but its chronic oral use has been limited by tendencies to cause orthostatic hypotension, sexual dysfunction, and hepatocellular injury.

Angiotensin-Converting Enzyme Inhibitors. ACEIs are the class of choice in patients with type 1 or type 2 diabetes, because of their demonstrated protective effect on the kidney. In addition, they have been shown to reduce cardiovascular mortality in patients with heart failure and in those with myocardial infarction complicated by systolic dysfunction. These can be considered compelling indications for inclusion of ACEIs in an antihypertensive regimen. **Updated: 5/25/03**

Mechanism of Action. These drugs block the conversion of renin-activated angiotensin I to angiotensin II, a potent vasoconstrictor that also stimulates the production of aldosterone. In addition, they inhibit the breakdown of bradykinin, itself a vasodilator, which also stimulates the production of vasodilatory prostaglandins. At least some of the effects of these drugs are related to their effect on local angiotensin systems in key organs (e.g., heart and kidney).

Adverse Effects. The most troublesome side effect is an annoying *dry cough* that occurs in about 10% of patients. It is mostly nocturnal, described as an irritation in the throat, and believed to be linked to the effect of the drug on bradykinins. About half of patients who experience the cough find it severe enough to warrant discontinuation of the medication. Switching to another ACEI rarely solves the problem.

Because the ACEIs block the production of aldosterone, they can lead to *hyperkalemia* when used in conjunction with a potassium-sparing diuretic, potassium supplementation, or nonsteroidal antiinflammatory drugs. Potentially fatal hyperkalemia has been reported in diabetic patients with hyporeninemic/hypoaldosteronemic hypertension. Close monitoring of the serum potassium is indicated in such situations.

Although ACEIs preserve renal function in hypertensive diabetics, they can cause *renal failure* in the setting of significant bilateral renal artery stenosis. The originally reported *glomerular injury* and *agranulocytosis* are very rare, except at the extremely high doses used in early clinical trials. However, patients with renal failure are still at risk for glomerular injury when large doses are used, necessitating careful monitoring of renal function. Uncommon side effects include rash, taste disturbances, and *angioedema.*

The blockade of the local renin-angiotensin system in the placenta is thought to be responsible for the adverse effects these drugs have on the developing fetus, presumably by impairing *placental blood flow.*

Preparations. There are a large number of ACEIs on the market, differing predominantly in cost and duration of action. Generic formulations of captopril and lisinopril are the least expensive (Table 26-1). **Updated: 1/25/03**

Angiotensin II Receptor Blockers (ARBs) This class of drugs blocks the angiotensin II receptor, thus inhibiting the vasoconstrictive effects of angiotensin II and the associated stimulation of aldosterone production. These agents have no effect on bradykinin metabolism, which probably accounts for their being free of the cough that may accompany ACEI therapy. Aside from the lack of cough, their side effects resemble those of ACEIs. Emerging data on the ability of these medications to reduce cardiovascular morbidity and mortality suggest they are comparable to ACEIs. Because of their higher cost, they should be reserved for patients intolerant to ACEIs because of cough or angioedema. **Updated: 1/25/03**

Calcium-Channel Blockers (CCBs) Although commonly listed among first-line agents in the past, there remain questions regarding the safety and efficacy of calcium-channel blockers. They are popular because they are generally well tolerated and effective in lowering blood pressure. ALLHAT demonstrated efficacy for amlodipine in reducing cardiovascular morbidity and mortality, but results were not as good as those achieved by use of a diuretic, especially in regard to heart failure . In addition, this class of antihypertensives has been the subject of significant controversy since publication of retrospective data suggesting an increased incidence of myocardial infarction and sudden death associated with their use. These data derive from studies of short-acting preparations (especially nifedipine and its congeners), with speculation that their rapid onset and offset of action may result in wide swings in blood pressure, increasing sympathetic tone and ultimately myocardial oxygen demand. Currently, the short-acting versions of these drugs are not recommended. Whether these adverse effects extend to the long-acting preparations has yet to be settled, and studies are currently ongoing to try to answer this question. Until then, the short-acting preparations should be avoided and long-acting preparations should be used with caution and probably not as a preferred choice for first-line use, a position they once occupied. Among the long-acting calcium-channel blockers, agents with minimum cardiovascular side effects are preferred (e.g., *amlodipine*). In ALLHAT, amlodipine was comparable to diuretic therapy in reducing risk of fatal and nonfatal ischemic heart disease but slightly less effective in reducing risk of heart failure. **Updated: 1/26/03**

Mechanism of Action. These drugs impede the entry of calcium in heart and vascular smooth muscle cells, resulting in a decreased cellular calcium concentration that reduces vascular smooth muscle contraction and lowers peripheral resistance. These agents also have a mild natriuretic effect, making them potentially useful in patients with sodium retention (e.g., the elderly and African-Americans). None adversely affects lipids or insulin sensitivity, and all reduce LVH.

Preparations and Adverse Effects. There is considerable variation in action and side effects among the calcium-channel blockers (Table 26-1). **Updated: 1/26/03**

Amlodipine. *Amlodipine* is currently among the most widely prescribed of the CCBs, superceding many of the earlier agents in this class because it produces less reflex tachycardia, negative inotropy, or peripheral edema. As noted above, in the ALLHAT study it proved as effective as thiazide diuretic therapy in achieving most major endpoints, except for a slightly higher rate of heart failure associated with its use. **Updated: 1/26/03**

Nifedipine. *Nifedipine* and its dihydropyridine congeners (e.g., *nicardipine, isradipine, felodipine*) are potent vasodilators, but they cause little net reduction in inotropy. Their main drawbacks are *reflex tachycardia and peripheral edema* secondary to venodilating effects. As noted above, the reports of increased risk of *myocardial infarction and cardiac sudden death* are associated with use of their short-acting formulations, which trigger reflex sympathetic activation. Occasionally, headache and flushing may be troublesome. In a small number of patients, *esophageal reflux* can become a problem secondary to relaxation of the lower esophageal sphincter.

Verapamil. *Verapamil's* main disadvantages are *negative inotropy* and *conduction system disturbances,* leading to arterioventicular nodal block and bradycardia; the drug should not be used in patients with heart failure or suspected conduction system disease. Leg edema is usually not a problem unless heart failure worsens, but *constipation, headache,* and *dizziness* can be problematic.

Diltiazem. *Diltiazem* falls between nifedipine and verapamil, having mildly negative effects on inotropy and conduction but less likely than nifedipine to cause leg edema. Efficacy is enhanced by addition of a small dose of thiazide diuretic.

Alpha-Blockers. Alpha-blockers are no longer considered first-line agents. The principal concern with their use as first–line agents was an increased risk of heart failure discovered in the ALLHAT study. Among high-risk patients (age over >55 years with at least one other cardiovascular risk factor), there was a significant increase in risk of heart failure in those treated with doxazosin alone, a risk that was not lessened with concurrent use of an additional first-line agent to ensure achievement of target blood pressure. **Updated: 1/14/03**

These drugs act peripherally at vascular postsynaptic a adrenergic receptors, causing arteriolar and venous dilation. Because they affect both the arterial and venous systems, they cause less reflex tachycardia than pure arterial vasodilators (see below).

The principle adverse effect of alpha-blocker therapy is postural hypotension. With some of the older alpha-blockers (e.g., *prazosin, terazosin),* profound *postural hypotension* leading to syncope can occur 1 to 3 hours after the initial dose, especially in elderly patients and those taking diuretics. This can be avoided by starting with a low dose at bedtime and instructing the patient to stay supine for at least 3 hours. The newer preparations such as *doxazosin* are longer acting and appear less likely to cause first-dose syncope. However, even with doxazosin, postural lightheadedness is still a problem, affecting about one-fifth of patients and more likely as dose is increased above 1 mg/d. These drugs have no adverse effects on lipids; in fact, they mildly raise HDL cholesterol and slightly reduce LDL (both on the order of 3% to 5%). In addition, they reverse LVH. Although useful, these agents may increase the rise of heart failure and should not be considered prime first line agents in elderly hypertensive men with symptomatic prostatism (see Chapter 138).

Pharmacologic Therapy—Second-Line Agents

The second-line agents are worth considering when the list of first-line agents has been exhausted; however, most have features that make them less desirable. Consequently, they should not take precedence over a first-line drug. Second-line agents are generally reserved for patients who are refractory to combinations of first-line agents or who have special underlying conditions such as renal failure. They include the loop diuretics, distal tubular diuretics, centrally acting sympatholytics, and the older peripheral vasodilators.

Loop and Potassium-Sparing Diuretics. Loop diuretics (*furosemide, ethacrynic acid, and bumetanide* are reserved for patients with evidence of renal insufficiency (creatinine clearance less than 30% of normal) or with allergy to thiazides. They are typically used in conjunction with *minoxidil* (see below).

Distal tubular diuretics (e.g., *spironolactone, triamterene, amiloride)* are weak antihypertensive agents used predominantly in combination with thiazides to spare potassium loss. The combination preparations are widely promoted, but it is best to avoid starting with such a fixed combination until the necessary thiazide dose has been established. Hypertensive patients who must avoid hypokalemia (e.g., those taking digitalis, experiencing ventricular irritability, or suffering from organic heart disease) are the best candidates. Other indications are mineralocorticoid hypertension, thiazide hypersensitivity, and severe gout. These drugs must be used with extreme *caution* in patients with renal insufficiency, ACEI use, or insulin-dependent diabetes with renin deficiency, where risk of serious *hyperkalemia* is substantial. The tendency of spironolactone to cause gynecomastia limits its use in hypertension to patients with primary hyperaldosteronism.

Centrally Acting Sympatholytics. *a Methyldopa, clonidine, and guanabenz* are centrally acting sympatholytics that reduce blood pressure by stimulating central a adrenergic receptors, which in turn reduce sympathetic outflow to the heart and vasculature. Because they cause secondary *sodium retention* and generally require the use of a diuretic, they should be considered as second-line agents. Although all these agents frequently cause drowsiness, fatigue, and impotence, lower doses are often quite well tolerated, even in the elderly. a Methyldopa occasionally causes fever, acute or chronic hepatitis, and a Coombs'-positive hemolytic anemia. *Clonidine* (and sometimes methyldopa) are more likely to cause sedation, dry mouth, and *rebound hypertension* with abrupt cessation of therapy. A slow-release transdermal clonidine patch is available and convenient but very expensive and commonly irritating to the skin. Low-dose clonidine (0.1 mg) given as a once-daily dose before bed is well tolerated in the elderly. Guanabenz and guanfacine are similar to clonidine in action and side effects.

Reserpine is one of the oldest antihypertensive agents, acting as a postganglionic adrenergic antagonist. Its advantages are low cost, good efficacy, and once-daily dose. Significant side effects include *severe depression,* nightmares, drowsiness, nasal congestion, gastrointestinal disturbances, and bradycardia.

Older Arterial Vasodilators. These drugs are rarely used because of the availability of better tolerated and more effective agents. The older arterial vasodilators (e.g., *hydralazine, minoxidil,* act directly to relax arterial smooth muscle. Disadvantages include reflex tachycardia, sodium and water retention and short duration of action necessitating frequent dosing. *Hydralazine* is typically used as a third-line agent in combination with a beta-blocker and a diuretic agent. It can cause headache, dizziness, and a lupuslike syndrome, especially in doses exceeding 200 mg/d. Reflex tachycardia may exacerbate angina. *Minoxidil* is an extremely potent vasodilator that should be used only in patients with moderately severe hypertension uncontrolled by other medications (see below). Both a beta-blocker and a loop diuretic must be used with it. Salt and water retention may be marked, requiring high doses of furosemide. Hypertrichosis is common and has led to the drug's topical use for hair loss. Rare adverse effects include pericardial effusion and even cardiac tamponade.

Special Situations

Refractory Hypertension. Patients are considered "refractory" if they fail to achieve target blood pressure reductions despite full doses of a three-drug regimen.

Etiologies. The most common causes are *poor compliance, alcohol excess, and obesity.* Worrisome etiologies include *renal failure, renovascular disease,* and other secondary causes of hypertension (see Chapter 19). Use of over-the-counter decongestants containing sympathomimetics, nonsteroidal antiinflammatory agents, and exogenous estrogens are among the pharmacologic causes. At times, the cause is a treatment regimen that contains an irrational combination, such as two agents within the same class, or an *inadequate amount of diuretic* for the degree of salt intake and sodium retention present. Occasionally, the cause is *pseudo-refractoriness,* due to the anxiety of the office visit (so-called "white-coat" hypertension) or to a marked vasoconstrictor response to blood pressure determination performed with an arm cuff. In the former, the act of taking the blood pressure produces a rise predominantly in the systolic blood pressure; in the latter, the rise is predominantly in the diastolic pressure (see Chapter 19).

Assessment. Medication compliance, weight gain, salt and alcohol excess, and use of other drugs should be observed. Pill counts are the best compliance check. A history of nocturia or ankle edema is suggestive of volume overload, from excessive salt intake or deterioration of cardiac or renal function. Physical examination is performed to check for signs of secondary etiologies (see Chapter 19), target organ damage, and volume overload. If white-coat hypertension is suspected, blood pressures should be taken by the patient at home and at work, after checking patient's technique in the office. *Continuous ambulatory monitoring* may also be of use in this situation (see Chapter 19). However, even if a pseudo-refractory etiology is suspected, it should not be grounds for truncating a workup for end-organ damage. Recent data suggest that even white-coat hypertension is associated with an increased risk of LVH and diastolic dysfunction.

If there is no clinical evidence of a secondary cause, then a check of the serum sodium, potassium, blood urea nitrogen, creatinine, and urinalysis should suffice for evidence of renal injury. The *echocardiogram,* a sensitive measure of cardiac target-organ effects, can also help differentiate between true refractoriness leading to target organ damage and pseudo-refractoriness.

Empiric Therapy. If workup fails to reveal a definite cause, the patient should be placed on a 2-g/d sodium/reduced-calorie diet, restricted to 1 oz of alcohol per day, and prescribed an exercise program. A maximal three-drug regimen should be continued (including an adequate diuretic dose). The patient is instructed to monitor pressure at home and should be followed closely. If these measures fail, then before escalating the medication program, one should consider consultation with a hypertension specialist for further consideration of possible causes (e.g., renal artery stenosis; see Chapter 19). Patients who are truly refractory yet free of a serious underlying etiology may respond to the combination of *minoxidil, a loop diuretic,* and a *beta-blocker.* Patients with refractory hypertension believed due to white-coat response should be followed closely. Those who manifest target organ changes should be treated like any other hypertensives. Those who do not show any target organ changes should be watched for the development of such changes and, in the meantime, be prescribed a program of diet and exercise.

Hypertension Associated with Estrogen Use. Elevation of SBP and DBP occurs in most patients receiving estrogen therapy over prolonged periods. Five percent of patients become outright hypertensive, and approximately one half of these remain hypertensive after hormonal therapy has been discontinued. Factors that predispose to the development of hypertension include family history or past history of high blood pressure, chronic renal disease, and hypertension with a previous pregnancy. A patient should be started on oral contraceptive or estrogen replacement therapy only after a careful history has excluded these predisposing factors. Once therapy has begun, continued blood pressure monitoring is required for the duration of treatment. The development of hypertension should prompt cessation of therapy.

Hypertension in Pregnancy. Hypertension that develops during pregnancy may represent either *preexisting hypertension* or *preeclampsia.*

Preexisting Hypertension. Pressure elevations that appear before 20 weeks are almost always due to preexisting disease. Some preexisting hypertension improves during pregnancy because of the hemodynamic changes that occur. Such patients may terminate therapy for the duration of their pregnancy, but pressures should be followed closely as should the urinalysis for early development of proteinuria (a powerful predictor of adverse outcomes). Others require continuation of treatment. The goal of lowering blood pressure in those with preexisting disease is the safety of the mother. There is no fetal benefit to blood pressure reduction;

antihypertensive drugs do not cure or reverse preeclampsia.

The usual threshold for initiating antihypertensive medication is a DBP exceeding 100 mm Hg. For DBPs between 90 and 100 mg Hg, *modest sodium restriction* and increased *rest* often suffice. If they do not and blood pressure continues to rise, then beginning *methyldopa or hydralazine* is safe and effective in pregnancy. *Beta-blockers* should be avoided in the first trimester due to risk of growth retardation, but they may be used in low doses later. *ACEIs are contraindicated* due to the dependence of placental blood flow on intrauterine renin angiotensin. *Diuretics* taken before pregnancy may be continued, as may *alpha-blockers and calcium channel blockers,* although recommendations regarding their use remain to be fully formulated.

Preeclampsia. Blood pressure of 140/90 mm Hg or higher, *edema,* and *proteinuria* all appear in the *third trimester.* The typical patient is a very young primagravida, but multiple births, diabetes, and hydatidiform mole contribute to risk. At 17 to 20 weeks of gestation, a resting blood pressure more than 110/75 mm Hg (sitting) or more than 100/65 mm Hg (left lateral decubitus position) suggests an increased risk of developing preeclampsia, because normally the pressure is lower at this time of pregnancy. If DBP rises above 90 mm Hg, *bedrest* is initiated and hospitalization considered.

Most antihypertensive medications safe for use in pregnancy are appropriate for treatment of preeclampsia. Low-dose aspirin does not prevent preeclampsia. *Nitroprusside* is given in severe cases that require hospitalization. The use of volume expansion remains controversial. *Diuretics and salt restriction are to be avoided,* because these patients usually are intravascularly volume constricted. Such treatment might aggravate the condition by further stimulating the renin-angiotensin-aldosterone axis. *Magnesium sulfate* is still the treatment of choice for prevention of seizures associated with eclampsia.

Hypertension in the Elderly. *Isolated systolic hypertension* (SBP more than 160 mm Hg) is a common finding in the elderly. For some time we have known that it significantly increases the risk of cardiovascular morbidity and mortality in persons over the age of 65 years. In fact, we now know that SBP is among the most powerful of predictors of risk, and that treatment lowers risk among people over age 50 years. | **Updated: 5/25/03**

Nonpharmacologic Therapy. The elderly tend to have low-renin volume-overload hypertension and exhibit considerable sensitivity to salt intake. For those with very modest pressure elevations, one can begin with *salt restriction,* a gentle exercise program, and *weight reduction* if overweight. Many elderly patients respond well to a 2-g/d low-sodium diet. Reduction of excess *alcohol* intake to no more than 1 oz/d is also important and occasionally overlooked. Nonpharmacologic measures can lower pressure by as much as 10 mm Hg.

Pharmacologic Therapy. When drug treatment is necessary, a *thiazide* diuretic is the drug of choice for initial therapy. It is best to start with a low dose (e.g., hydrochlorothiazide 12.5 to 25.0 mg/d) and increase dose gradually. Increments should be small to avoid rapid lowering of pressure and postural hypotension, which can lead to lightheadedness and falls. In general, the elderly do not tolerate aggressive diuretic therapy or *beta-blockers* as well as younger patients. A review of 10 beta-blocker trials in the elderly found their use often failed to achieve adequate control or reductions in cardiovascular risk. Other drugs likely to cause marked postural hypotension (e.g., alpha-blockers) or daytime sedation (centrally acting sympatholytic agents, e.g., methyldopa, clonidine) are also less desirable. JNC VII recommendations for the elderly, including those with isolated systolic hypertension, follow the same principles outlined above for the general care of hypertension. | **Updated: 5/25/03**

The African-American Patient. Hypertension is more prevalent in African-Americans (38.2%), more commonly of the low-renin salt-sensitive variety, and more likely to be accompanied by target-organ damage than in whites. The high prevalence of obesity, smoking, and salt excess contribute, as does decreased access to medical care. African-Americans show twice the risk of developing renal insufficiency, even when treated. They respond particularly well to *thiazides, sodium restriction, weight loss,* and *smoking cessation. Calcium channel blockers* have shown very promising results, though their use greatly increases cost of treatment, which, in turn, might compromise long-term compliance. *ACEIs* and *beta-blockers* are somewhat less effective, perhaps because of the low-renin physiology prevalent in this population. However, drug combinations that include an adequate dose of thiazide diuretic largely eliminate these differential responses to different classes of drugs. Angioedema is induced by ACIs 2-4 times more frequently among black patients than among white patients. | **Updated: 5/26/03**

The Diabetic Patient. Control of hypertension is particularly important in diabetics, because their risks of stroke, cardiovascular disease, and renal failure are particularly high. *ACEIs* are the class of choice because they decrease proteinuria and slow the progression of diabetic nephropathy. *Calcium channel blockers* also may be protective of the kidney. Although *thiazide* diuretics may slightly worsen glucose intolerance and hyperlipidemia, these adverse effects can be minimized or avoided by using small doses (e.g., 12.5 to 25 mg/d of hydrochlorothiazide). *Beta-blockers* are not contraindicated in patients taking insulin, but a relatively cardioselective preparation (e.g., atenolol or metoprolol) is preferred, because it is less likely to mask catecholamine-induced hypoglycemic symptoms. | **Updated: 5/25/03**

The Patient with Renal Failure. Hypertension can lead to renal injury and exacerbate it. Blood pressure control is essential in the setting of renal parenchymal disease. A *reduced protein* diet (40 to 45 g/d) and *salt restriction* (2 g/d) helps preserve renal function and control of blood pressure in patients with azotemia. When the serum creatinine rises above 2.5 mg/dL, sodium retention occurs, which can lead to exacerbation of blood pressure. *Furosemide, metolazone,* and other potent diuretics can help counter this sodium retention and reduce pressure. ACEIs reduce proteinuria and can be helpful in the setting of renal failure, unless the cause is renal artery stenosis, in which case they may aggravate renal dysfunction. ACEIs and ARBs have favorable effects on progression of diabetic and nondiabetic renal disease. *Beta-blockers, vasodilators,* and *calcium channel blockers* are also effective. *Minoxidil,* in combination with a loop diuretic and a beta-blocker, may be necessary in refractory cases. | **Updated: 5/25/03**

The Stroke Patient. Control of hypertension reduces the risk of recurrent stroke. The main pitfalls of treatment are reductions in pressure that are too rapid or too vigorous, leading to cerebral hypoperfusion. Gradual gentle pressure reductions that preserve CNS perfusion and avoid postural hypotension are the objective. Recurrent stroke risk is reduced by the combination of a thiazide-type diuretic and an ACEI. | **Updated: 5/25/03**

PATIENT EDUCATION

Patient education is essential to ensuring *compliance.* Being a silent condition, hypertension does not always command the full attention of patients. High cost of medication, high frequency of doses, and drug side effects further compromise compliance. Nonetheless, some educational and behavioral efforts can enhance patient cooperation. Educationally, one needs to review the cardiovascular consequences of untreated hypertension and the ability of treatment to greatly reduce risk. Knowledge of the importance of nonpharmacologic measures is also critical and reassuring to many. That weight reduction, smoking cessation, and decrease in sodium intake may allow reduction or even elimination of antihypertensive medication can serve as a powerful motivating force.

One of the best approaches to improving compliance is to have the patient monitor blood pressure at home. Teaching the patient to perform *home blood pressure determinations* can foster considerable interest in blood pressure control and greatly stimulate adherence to a treatment program. Effective home monitoring may even decrease the need for some office visits.

Medication side effects need to be addressed. Sexual dysfunction, fatigue, and depression have long bothered hypertensive patients who require drug therapy and lead many to stop their medication, often without notifying the physician. It is essential to specifically inquire about potential side effects, including symptoms of sexual dysfunction (see Chapter 229) and depression (see Chapter 227), before and after initiation of a medical regimen and to incorporate the findings into design of the patient's program. Patients may be reluctant to raise these issues themselves. Use of a medication that does not interfere with sexual capacity or mental function (e.g., an ACEI such as captopril) may be indicated (see above).

INDICATIONS FOR REFERRAL AND ADMISSION

Immediate hospitalization is indicated for patients with evidence of *malignant hypertension* (DBP more than 130 mm Hg, retinal hemorrhages, papilledema, mental status changes, heart failure). Referral may be useful for patients with refractory hypertension of unknown etiology (see above), a suspected secondary cause, or worsening renal failure in the setting of adequate control.

THERAPEUTIC RECOMMENDATIONS

For Patients with Prehypertension (SBP 120-139 mm Hg, DBP 80-89 mm Hg) | Updated: 5/25/03

- Patients with compelling indications (ischemic heart disease, congestive heart failure, diabetes, chronic kidney disease, and cerebrovascular disease) should be treated for those conditions with the appropriate agents for those conditions. **Updated: 5/26/03**
- Prescribe the DASH diet, a no-added-salt diet (3 to 4 g/d) that is low in saturated fat and rich in fruits, vegetables, and low-fat dairy products; consider greater sodium restriction in persons likely to have volume-overload hypertension (e.g., African-Americans, the elderly). **Updated: 6/30/03**
- Advise weight reduction (especially if more than 15% above ideal weight).
- Limit alcohol intake to 1 oz/d.
- Insist on complete smoking cessation (see Chapter 54).
- Prescribe an exercise program (see Chapter 18).

For Patients with Stage 1 Hypertension (DBP 90 to 99 mm Hg, SBP 140 to 159 mm Hg), with No Compelling Indications **Updated: 5/26/03**

- Institute full nonpharmacologic measures (as described above for prehypertension), including a 2 gm/d salt-restricted diet. **Updated: 6/30/03**
- Repeat blood pressure determinations regularly over the next 3 months. **Updated: 7/10/03**
- If improvement noted (DBP less than 90, SBP less than 140), then continue nonpharmacologic measures and monitor blood pressure every 3 months.
- If after 3 months, nonpharmacologic therapy has failed to lower the blood pressure (DBP less than 90, SBP less than 140), then begin pharmacologic therapy with a thiazide–type diuretic (e.g., hydrochlorothiazide [HCTZ], 25 mg/day). May consider a beta–blocker (atenolol, 25 mg/day) as an alternative initial therapy. If, with continued monitoring, blood pressure does not reach goal, two agents should be used, one of which should be a thiazide-type diuretic. **Updated: 5/26/03**

For Patients with Stage 1 Hypertension (DBP 90 to 99 mm Hg, SBP 140 to 159 mm Hg), with Compelling Indications (Ischemic Heart Disease, Congestive Heart Failure, Diabetes, Chronic Kidney Disease and Cerebrovascular Disease) **Updated: 5/26/03**

- Institute nonpharmacologic program (as described above for prehypertension). **Updated: 5/26/03**
- Treat compelling condition(s) with appropriate drugs. **Updated: 5/26/03**
- If after 3 months, nonpharmacologic therapy and drugs for compelling indications have failed to lower the blood pressure (DBP less than 90, SBP less than 140), then begin pharmacologic therapy with a thiazide–type diuretic (e.g., hydrochlorothiazide [HCTZ], 25 mg/day). If with continued monitoring, blood pressure does not reach goal, additional agents should be added. **Updated: 5/26/03**

For Patients with Stage 2 Hypertension (DBP ³100 mm Hg, SBP ³160 mm Hg), without Compelling Indications **Updated: 5/26/03**

- Institute a full nonpharmacologic program. **Updated: 6/27/03**
- Institute drug therapy with a thiazide-type diuretic and, for most, a second agent (e.g., a beta-blocker, ACEI, ARB or CCB). **Updated: 5/26/03**
- Monitor blood pressure closely to assure that goal is attained (DBP < 90, SBP < 140). **Updated: 5/26/03**

For Patients with Stage 2 Hypertension (DBP >100 mm Hg, SBP >160 mm Hg), with Compelling Indications **Updated: 5/26/03**
- Institute a full nonpharmacologic program (as described above for prehypertension). **Updated: 5/26/03**
- Treat compelling condition(s) with appropriate drugs. **Updated: 5/26/03**
- If nonpharmacologic therapy and drugs for compelling indications have failed to lower the blood pressure to goal (DBP < 90 mm Hg, SBP < 140 mm Hg or DBP < 80 mm Hg, SBP < 130 mm Hg with diabetes or chronic kidney disease), then begin pharmacologic therapy with a thiazide–type diuretic (e.g., hydrochlorothiazide [HCTZ], 25 mg/day). If with continued monitoring, blood pressure does not reach goal, additional agents should be added. **Updated: 5/26/03**
- Monitor blood pressure closely to assure that goal is attained. **Updated: 5/26/03**

For Patients with DBP greater than 120 mm Hg or SBP greater than 210 mm Hg **Updated: 5/26/03**

- Consider emergency hospitalization, especially if there is evidence of acute target-organ injury (e.g., papilledema, retinal hemorrhages, heart failure, altered mental status).
- Patients with a similarly elevated pressure, but no evidence of target organ involvement, can be given oral labetalol in the office to acutely reduce pressure, started on a two- or three-drug regimen, and followed up in a few days.

Initiation and Advancement of Pharmacologic Therapy

- Begin pharmacologic therapy with a first-line agent, preferably a diuretic or beta-blocker.
- Choose agent based on consideration of patient's overall clinical situation (see below) and start with a modest dose (Table 26-1). In most cases this will be a thiazide diuretic (e.g., HCTZ, 12.5-25 mg/d). **Updated: 1/25/03**
- If pressure does not improve within 1 month of initiating drug therapy, increase dose (e.g., to HCTZ, 25 -50 mg/day) and recheck in 4 weeks. **Updated: 1/25/03**
- If there is no response despite increasing dose, then switch to another first-line drug from a different class (e.g., generic formulation of a beta–blocker, such as atenolol, 25 mg/day). **Updated: 1/25/03**
- If there is only a partial response, then the choice is either to further increase dose or to add a low dose of another first-line drug from a different class (e.g., add hydrochlorothiazide, 12.5 to 25 mg/d or a beta-blocker).
- Once pressure normalizes, recheck blood pressure at 3- to 6-month intervals.
- If a two-drug regimen using two first-line agents from different classes does not suffice, select a third drug from a new class. A particularly effective three-drug regimen is an ACEI, a thiazide diuretic, and a beta-blocker.
- Consider a sustained-release formulation if it is likely to increase compliance and reduce cost of a daily program. **Updated: 1/26/03**

Agents for Initial Use **Updated: 1/26/03**

- *Thiazides.* Consider for almost all patients, but especially useful in those likely to have volume-overload hypertension (e.g., the elderly, African-Americans, persons with nocturia or leg edema); provides effective low-cost therapy and enhances antihypertensive effects of beta-blockers, calcium channel blockers, and ACEIs. Limit doses to modest amounts (e.g., 12.5 to 25 mg/d of hydrochlorothiazide) to minimize adverse metabolic effects, particularly in patients with marked hypercholesterolemia, poorly controlled diabetes, symptomatic gout, cardiac arrhythmias, or severe underlying coronary disease. For monotherapy, use no more than moderate doses (e.g., 25 to 50 mg/d of hydrochlorothiazide). Regularly monitor serum potassium in persons with underlying heart disease.
- *Beta-blockers.* Appropriate for those with compelling indication of concurrent coronary artery disease or high cardiovascular risk including diabetes and congestive heart failure. Otherwise not as effective or as well tolerated in the elderly; among the most cost effective. Choose a relatively cardioselective preparation (e.g., atenolol or metoprolol). Prescribe generic formulations (e.g., metoprolol, atenolol) to keep costs low. Avoid in patients with severe bronchospasm or nonischemic heart failure. Add a small dose of thiazide if fluid retention develops or if enhanced pressure control is desired. **Updated: 5/26/03**
- *ACEIs.* Appropriate for those with compelling indication of diabetes, r heart failure, underlying coronary heart disease, and cerebrovascular disease, and with caution in chronic kidney disease. Otherwise useful choice in those with volume overload, underlying sexual dysfunction, depression, and intolerance to CNS effects of other antihypertensive agents. May be used alone or in combination with a diuretic or a beta-blocker, which enhance their effectiveness; contraindicated in pregnancy and in bilateral renal artery stenosis. Monitor renal function and serum potassium, especially in those with underlying renal dysfunction. Prescribe generic formulations (captopril, lisinopril) to minimize cost. **Updated: 1/26/03**

- *Calcium-Channel Blockers:* These agents are not a preferred class for hypertension. Consider as an alternative to thiazides and ACEIs in patients with volume overload hypertension (e.g., elderly, African-Americans) and in diabetics. Avoid use of short-acting preparations, because of concerns about increased risk of myocardial infarction and cardiac sudden death. Use cautiously in patients with conduction defects, especially if already taking a beta-blocker. Avoid if possible in patients bothered by peripheral edema; short-acting agents contraindicated in heart failure. If use unavoidable, consider an agent with the least known adverse peripheral vascular and cardiovascular effects (e.g., amlodipine). Prescribe a sustained-release preparation to minimize cost and cardiac risk and switch from a short-acting preparation to a long-acting preparation if patient already taking a calcium channel blocker. Obtain cardiac consultation regarding use in persons with known coronary artery disease. **Updated: 5/26/03**

CHAPTER 27 APPROACH TO THE PATIENT WITH HYPERCHOLESTEROLEMIA

MASON W. FREEMAN

INTRODUCTION

Over the last several years, evidence has accumulated demonstrating that treatment of hypercholesterolemia can reduce atherosclerosis and its attendant cardiovascular complications (see Chapter 15). These findings have heightened physician and patient awareness of the importance of hypercholesterolemia. The primary care physician needs to be capable of evaluating hypercholesterolemia and of designing and implementing a treatment program that effectively uses dietary treatment, exercise, weight loss, and, when necessary, cholesterol-lowering drugs.

PATHOPHYSIOLOGY

The production of atherogenic lipoproteins and the induction of atheromatous plaques by those lipoproteins involve distinct pathways. The presence of an elevated serum cholesterol level does not, by itself, guarantee the development of atherosclerotic lesions that will become clinically important any more than a normal cholesterol concentration ensures plaque-free coronary arteries. The formation and subsequent rupture of atherosclerotic lesions, leading to the acute coronary syndromes of unstable angina and myocardial infarction, depend on complex cellular and metabolic interactions. Serum lipids, inflammatory cells recruited to the sites of lipid deposition, the normal cellular constituents of the artery wall, and components of the blood coagulation system all contribute to the pathogenesis of atherosclerosis and its clinical consequences.

Lipoproteins

An understanding of lipoproteins and their metabolism helps guide physicians in evaluating and treating lipid disorders. To circulate in the aqueous environment of the blood, nonpolar lipids such as cholesterol and triglyceride are complexed with proteins and the more polar phospholipids into spheres called *lipoproteins*. The protein components of the lipoproteins are known as *apoproteins*, which play both structural and functional roles in the metabolism of lipid particles. Genetically inherited mutations in either the structure of apoproteins or the receptors that bind them account for many of the most severe forms of hyperlipidemia. The lipoproteins are usually divided into four major classes based on particle density, which is a reflection of their relative protein and lipid content: *chylomicrons, very-low density lipoproteins* (*VLDLs*); *low-density lipoproteins* (*LDLs*); *and high-density lipoproteins* (*HDLs*). There are also subdivisions and minor classes of lipoproteins (Table 27-1).

LIPOPROTEIN	PROTEIN	CHOLESTEROL	CHOLESTEROL ESTER %	PHOSPHOLIPID	TG
VLDL	10.4	5.9	13.9	16.2	53.4
IDL	17.9	8.5	22.5	21.7	31.4
LDL	25.0	8.6	41.9	22.9	5.5
HDL₂	43.6	5.2	20.3	33.1	2.2
HDL₃	54.5	1.9	19.1	25.0	1.4
Chylomicrons	1-2	1-3	3-4	3-6	84-95

Values are % composed by weight. VLDL = very low density lipoprotein; IDL = intermediate density lipoprotein; LDL = low density lipoprotein; HDL = high density lipoprotein; TG = triglyceride.

Table 27-1. Lipoprotein Composition

Chylomicrons. *Chylomicrons* derive from dietary fat and carry triglycerides throughout the body. They have the lowest density of all lipoproteins and will float to the top of a plasma specimen left in the refrigerator overnight. The chylomicron itself is probably not atherogenic, but the role of the triglyceride-depleted chylomicron remnant remains uncertain. Triglyceride makes up most of the chylomicron and is removed by the action of lipoprotein lipase. Patients deficient in this enzyme or its cofactors (insulin and apolipoprotein CII) have very high serum triglyceride levels and increased risk of acute pancreatitis.

VLDLs. *VLDLs* are also triglyceride rich and are acted on by lipoprotein lipase. Their function is to carry triglycerides synthesized in the liver and intestines to capillary beds in adipose tissue and muscle, where they are hydrolyzed. After removal of their triglyceride, VLDL remnants can be further metabolized to LDL. The atherogenicity of native VLDL is controversial, but the metabolism of VLDL to atherogenic lipoproteins is not in doubt. VLDLs serve as acceptors of cholesterol transferred from HDL, possibly accounting in part for the inverse relation between HDL cholesterol and VLDL triglyceride. The serum enzyme cholesterol ester transfer protein mediates the process.

LDLs. *LDLs* are the major carriers of cholesterol in humans, responsible for supplying cholesterol to the tissues, and the lipoproteins most clearly implicated in atherogenesis. LDL levels are increased in persons who consume large amounts of saturated fat and/or cholesterol, have defects in the LDL receptor (familial hypercholesterolemia), have defects in the structure of LDL apoprotein B, or have a polygenic form of increased LDL. When serum LDLs exceed a threshold concentration, they traverse the endothelial wall and can become trapped in the arterial intima. There, they may undergo oxidation or other modification, may be taken up by macrophages, and may stimulate atherogenesis. The association of serum total cholesterol with coronary heart disease (CHD) is predominantly a reflection of the role of LDL, because LDL cholesterol constitutes the bulk of serum cholesterol in most humans. Many well designed studies demonstrate that lowering the LDL cholesterol can dramatically reduce subsequent coronary events and all-cause mortality in hypercholesterolemic patients.

HDLs. *HDLs* are believed to function in peripheral tissues as an acceptor of free cholesterol that has diffused out of cellular membranes. The cholesterol is esterified and stored in the central core of the HDL and may be further metabolized. This reverse transport system may explain why patients with very high HDL levels have a reduced risk of developing CHD, even if their LDL levels are elevated. *Apolipoprotein AI* is the major apoprotein of HDL, and its level also inversely correlates with the risk of CHD. Women have higher levels of HDL cholesterol than men, in part because of their higher estrogen levels. Exercise increases HDL, whereas obesity, hypertriglyceridemia, and smoking lower HDL. The HDL cholesterol concentration is the single most powerful lipid predictor of CHD risk, but treatments designed to raise HDL cholesterol levels are limited and the significance of such interventions on coronary disease outcomes remains uncertain.

Dietary Influences

Dietary fat and cholesterol have a substantial influence on serum and LDL cholesterol levels. Saturated fat intake has a greater effect on serum cholesterol than does dietary cholesterol intake. For each increase in percentage of total calories contributed by saturated fats, serum cholesterol increases by a factor of 2.16, whereas the serum cholesterol increase is only 0.068 for each percentage increase in dietary cholesterol. This relationship is summarized in the equation of Hegsted:

Change in total cholesterol = 2.16 delta S − 1.65 delta P + 0.068 delta C

where delta S, delta P, and delta C are the changes in the percentage of total calories contributed by saturated fats, polyunsaturated fats, and cholesterol,

respectively. Fats are characterized by their constituent fatty acid composition. The fatty acids are characterized as saturated, polyunsaturated, or monounsaturated. The state of saturation refers to the number of carbon–carbon double bonds contained in the fatty acid.

Saturated Fatty Acids. Saturated fatty acids can raise LDL cholesterol, in part by altering the LDL receptor's catabolic activity. The long-chain saturated fatty acids common to the American diet—lauric (12 carbons), myristic (14 carbons), palmitic (16 carbons), and stearic (18 carbons)—have no double bonds and are not essential for human growth and development. Not all saturated fatty acids trigger rises in LDL cholesterol. For example, stearic acid and some shorter chain fatty acids (caproic and caprylic) do not. In the typical American diet, about one third of the saturated fat content of the diet derives from *meat* and meat products, whereas another third comes from *dairy products* and eggs, and 10% from baked goods. Vegetable oils also may contain saturated fat (see Appendix I), especially the so-called "*tropical oils*" (coconut and palm) and cocoa butter, which are commonly used in commercial food preparation. Even when unsaturated oils (see below) are used in processed foods, they usually undergo "*partial hydrogenation*," which adds back hydrogens to the carbon–carbon bonds, eliminating some double bonds and making the fatty acids more saturated. This saturation process is performed to make these oils more solid at room temperature, but it also makes them more hypercholesterolemic.

Monounsaturated Fatty Acids. Monounsaturated fatty acids are present in all animal and vegetable fats. The most common dietary form is *oleic acid*, plentiful in peanuts, almonds, olives, and avocados. Oils derived from these sources neither raise nor lower LDL cholesterol by themselves, although cholesterol and CHD risk fall if they are used as substitutes for saturated fat. Mediterranean diets rich in *olive oil* and other sources of monounsaturated fatty acids appear to be relatively nonatherogenic, even though they are not low in fat.

Polyunsaturated Fatty Acids (PUFAs). Polyunsaturated fatty acids (PUFAs), unlike saturated and monounsaturated fatty acids, are not synthesized by the body. They must be present in the diet and are referred to as *essential fatty acids*. The location of the first double bond from the methyl end of the molecule determines the nomenclature of the PUFAs. The major dietary fatty acids contain either an n-6 or n-3 first double bond. *Linoleic* and *arachidonic acids* are the common W-6 PUFAs, found in considerable quantities in *liquid vegetable oils* (sunflower, safflower, corn, and soybean). The W-3 fatty acids are represented by linoleic acid (found in canola oil and leafy vegetables) and the *omega-3 fish oils* (eicosapentanoic and docosahexanoic acids). The latter attracted considerable interest when epidemiologic studies found a link between their consumption and reduced rates of CHD mortality.

When vegetable oils rich in PUFAs are subjected to *partial hydrogenation* in commercial food processing, not only do some of their double bonds get converted to single bonds, but others shift from the "*cis*" configuration into the "*trans*" configuration, which increases their atherogenicity and associated CHD risk. Intake of such substances increases LDL cholesterol, lipoprotein(a) (LPa), and triglycerides and reduces HDL cholesterol. Data from The Nurses' Health Study suggest that replacing *trans* unsaturated fats in the diet with polyunsaturated fats can reduce CHD risk by nearly 60%, a much greater reduction than even that achieved by reducing overall fat intake.

Cholesterol. As the Hegsted formula indicates, dietary cholesterol has a much smaller effect than saturated fatty acids on raising total cholesterol. For every additional 100 mg of dietary cholesterol consumed per day, the serum cholesterol will rise by about 8 to 10 mg/dL. However, *organ meats* (e.g., brain, kidney, heart, sweetbreads) and *egg yolks* are concentrated sources of dietary cholesterol (see Appendix II) and can have a substantial impact on serum cholesterol levels. Although *shellfish* contain moderate amounts of cholesterol, they have relatively small amounts of saturated fat and are sources of W-3 PUFAs. Cholesterol is absent from food derived from plants. Plant stanols and sterols can actually block cholesterol absorption in the intestine, and a commercially available margarine containing the plant stanol sitostanol is now available as a cholesterol-lowering agent. It reduces serum cholesterol levels by up to 10% to 15%. Recently released National Cholesterol Education Program guidelines (Adult Treatment Panel III) encourage the use of these plant stanols in dietary programs aimed at reducing blood cholesterol levels. | **Updated:**
10/19/01

Other Dietary Factors. *Low-fat high-carbohydrate diets* can *reduce HDL* cholesterol and *increase triglycerides*. Especially in obese persons, increased total caloric intake may induce overproduction of VLDL triglycerides while reducing HDL cholesterol levels. Data from The Nurses' Health Study suggest that substituting carbohydrate for saturated fat in the diet may reduce CHD risk by about 15% but substituting carbohydrate for polyunsaturated fat may increase CHD risk by over 50%. There is no evidence that either *dietary carbohydrate* (whether simple sugars or complex ones) or *protein* significantly affects LDL cholesterol.

The *fiber* content of food has generated much interest. *Insoluble fiber* (typically cellulose found in wheat bran) has no cholesterol-lowering effect, although it is beneficial for lowering the risk of diverticular disease and colon cancer (see Chapter 65). *Soluble fiber* (pectins, certain gums, psyllium) has received much attention in the lay press stimulated by claims about *oat bran*, which contains the gum beta-glycan. Initial studies were encouraging, but subsequent data suggested the cholesterol decreases observed were no greater than those found with use of insoluble fiber and probably resulted from replacement of dietary fat in the diet rather than from a direct effect on lipid metabolism. When studied in patients already taking a low-fat diet, high soluble fiber intake appeared to lower serum cholesterol by a modest amount (3% to 7%).

WORKUP

Diagnosis. The diagnosis of hypercholesterolemia should always be based on *repeat measurements* of serum lipids, because combined analytic and biologic variations in serum lipids range from 10% to 20%. A single measurement should never be viewed as sufficient for a diagnosis of hypercholesterolemia. A *venous sample* processed in a laboratory meeting Centers for Disease Control and Prevention standards for cholesterol determination (see Chapter 15) is recommended.

While earlier guidelines often recommended a stepped approach to performing lipid analyses in patients, the ATP III guidelines now suggest that a fasting lipid profile be done at the initial assessment, whenever possible (Table 27-2). A *fasting* venous sample for determination of serum cholesterol, *HDL cholesterol*, and *triglycerides* constitutes the traditional lipid profile and this information is necessary to characterize a lipid disorder and design optimal therapy to treat it. If a fasting lipid profile cannot be readily arranged, then a practical alternative in persons at low CHD risk is to obtain nonfasting determinations of total cholesterol and HDL cholesterol and reserve for a full lipid profile only those persons with a nonfasting total cholesterol greater than 200 mg/dL or an HDL cholesterol less than 40 mg/dL (see Chapter 15). | **Updated:**

10/1/19

With measurement of total and HDL cholesterol and triglyceride levels, it is possible to *estimate the VLDL* level and *calculate* the *LDL cholesterol* concentration using the formula:

$$\text{LDL cholesterol} = \text{total cholesterol} - [\text{HDL cholesterol} + \text{triglyceride}/5]$$

The TG/5 factor represents a close estimate of VLDL cholesterol and derives from the observation that VLDL cholesterol is usually 20% of the serum triglyceride value. The validity of this formula for estimating LDL cholesterol has been confirmed by direct LDL cholesterol measurement and remains fairly accurate so long as the total triglyceride is less than 400 mg/dL. A *fasting* sample is required for accurate results, because chylomicrons appearing in the blood after a meal do not contain the same ratio of triglyceride to cholesterol found in VLDL. If the triglyceride level is greater than 400 mg/dL, the LDL cholesterol can be determined accurately only by methods available to a lipid research laboratory, although direct LDL assays of varying quality have recently become available for use on routine chemical autoanalyzers.

Excluding Secondary Causes. Before embarking on a treatment plan, one must exclude conditions that might secondarily lead to hyperlipidemia. The most important are *hypothyroidism, nephrotic syndrome*, and *diabetes* (Table 27-3), best screened for by a serum thyroid-stimulating hormone, urine dipstick for protein, and serum glucose, respectively (see Chapter 93, Chapter 104, and Chapter 130). Drugs can affect lipid levels as well, with LDL elevations occurring with *thiazide* use and triglyceride levels rising with *beta-blockers*. Postmenopausal *estrogen replacement* lowers LDL and increases HDL and triglyceride.

Table 27-3. Classification of Lipoprotein Disorders

Classification. The original *Fredrickson classification* scheme is of limited utility now that a better understanding of the genetics of these diseases has emerged. However, no unified classification of comparable simplicity has replaced it. For most clinical purposes, it is probably simplest to separate patients into three broad categories: those with *elevated cholesterol, elevated cholesterol and triglyceride, or elevated triglyceride* only. Table 27-3 summarizes the likely diagnoses under these broad categories. The possibility of a genetic disorder should be considered if extremes of any lipid level are encountered or if there is a history of premature CHD in the patient or family. Classification by risk stratification is also helpful for both patient and physician (see below and Table 27-4 and Table 27-5).

Table 27-4. CHD Risk Associated with Lipoprotein Cholesterol Abnormalities [a]

Lipoprotein-Cholesterol Level (mg/dL)		*Classification*
LDL cholesterol	<100 **Updated: 10/19/01**	Optimal **Updated: 10/19/01**
	100–129 **Updated: 10/19/01**	Near or above optimal **Updated: 10/19/01**
	130–159	Borderline high **Updated: 10/19/01**
	160–189 **Updated: 10/19/01**	High
	>190 **Updated: 10/19/01**	Very high **Updated: 10/19/01**
HDL cholesterol	>60 (and total cholesterol/HDL ratio >4.5) **Updated: 10/19/01**	Low
	<40 (and total cholesterol/HDL ratio >4.5) **Updated: 10/19/01**	Moderate-high
VLDL cholesterol	30–40 (or fasting triglycerides 150–200) **Updated: 10/19/01**	Low to borderline **Updated: 10/19/01**
	>40–100 (or fasting triglycerides 200–500) **Updated: 10/19/01**	High **Updated: 10/19/01**
	Triglyceride >500 **Updated: 10/19/01**	Very high **Updated: 10/19/01**

[a]Presence of additional CHD risk factors greatly increase risk for any level of lipoprotein cholesterol.

Table 27-5. CHD Risk Factors and CHD Risk Status

Risk Factors Other Than Elevated LDL Cholesterol Level
Age >45 for male; >55 or premature menopause for female without estrogen replacement
Family history of premature CHD (definite myocardial infarction or sudden death in first-degree male relative before age 55 or before 65 in female first-degree relative)
Current cigarette smoking
Hypertension (systolic >140 or diastolic >90)
Low HDL cholesterol (<40 mg/dL) **Updated: 10/19/01**
CHD Risk Status
Highest
Clinically evident CHD; other atherosclerotic disease (peripheral arterial insufficiency, symptomatic carotid artery disease); diabetes mellitus (DM) **Updated: 10/19/01**
No CHD or DM but two or more CHD risk factors in addition to hypercholesterolemia **Updated: 10/19/01**
No CHD or DM and fewer than two other CHD risk factors in addition to hypercholesterolemia **Updated: 10/19/01**
No CHD, DM, no risk factors
Lowest

PRINCIPLES OF MANAGEMENT

The goals are to reduce coronary morbidity and mortality. Both *primary prevention* (reducing risk of having a first coronary event) and *secondary prevention* (reducing risk of a new coronary event in a person with established CHD) are sought. The most impressive reductions in risk are achieved in patients at greatest risk (see below).

The growing appreciation of the importance of lipid abnormalities and the benefits of treating them have stimulated the National Institutes of Health to sponsor the third formulation of the Adult Treatment Panel (ATP III) guidelines of the National Cholesterol Education Program (NCEP). Many of the treatment recommendations generated by that expert panel are included below. The approach to treatment of hyperlipidemia is guided by an *assessment of total CHD risk*, not just the lipid abnormality. For a given degree of LDL cholesterol elevation, the threshold for initiation of therapy decreases and the intensity of therapy increases with increasing CHD risk. Dietary modification, complemented by exercise and weight reduction, is the core of the lipid treatment program, with pharmacologic therapy reserved for those at higher risk and for persons failing behavioral therapies. **Updated: 10/19/01**

Risk Assessment as a Guide to Selection of Therapy

With benefit from treatment of hypercholesterolemia closely linked to the degree of pretreatment CHD risk, a careful assessment of that risk is imperative to deciding whom to treat, when to treat, and how aggressively to treat. The CHD risk assessment should be a comprehensive one, extending beyond lipid levels to include consideration of *blood pressure, smoking, diabetes, family history of premature CHD, age, sex, and presence of established CHD or other atherosclerotic disease* (e.g., peripheral arterial insufficiency, symptomatic carotid disease). The increasing awareness of elevated HDL cholesterol as a factor in reducing CHD risk has led to its designation as a "negative risk factor." Conversely, an *HDL cholesterol serum level less than 40 mg/dL* enters the list of positive risk factors (Table 27-5).

A gradient of CHD risk has been defined by the NCEP expert panel, taking into account degree of LDL elevation and presence of other CHD risk factors (Table 27-4 and Table 27-5). For a given elevation in LDL cholesterol level, patients considered at highest risk are those with established CHD or other atherosclerotic disease, as well as patients with diabetes mellitus. Next come patients without CHD or diabetes mellitus who have two or more CHD risk factors, followed by those having no CHD and fewer than two CHD risk factors.

The NCEP treatment recommendations follow directly from the degree of estimated CHD risk. Dietary modification is the sole mode of therapy for patients at the lower end of the CHD risk spectrum, whereas pharmacologic measures are reserved for patients at higher risk or for those who fail dietary intervention (Table 27-6). Additional considerations include possible adverse effects of long-term pharmacologic therapy (an issue when dealing with young persons) and appropriateness of the patient for treatment (an issue in the frail elderly and seriously ill).

Table 27-6. Treatment Recommendations

Patient Category	Initial LDL Level (mg/dL)	LDL Goal (mg/dL)
Dietary Therapy		
No CHD, <2 risk factors	>160	<130 **Updated: 10/19/01**
No CHD, 2+ risk factors **Updated: 10/19/01**	>130	<130
With CHD or CHD risk equivalents **Updated: 10/19/01**	>100	<100
Add Drug Treatment		
No CHD, <2 risk factors	>190	<160
No CHD, 2+ risk factors **Updated: 10/19/01**	>130 **Updated: 10/19/01**	<130
With CHD or CHD risk equivalents **Updated: 10/19/01**	>130 (100–129 optional) **Updated: 10/19/01**	<100

Dietary Modification, Exercise and Weight Loss

Dietary modification remains the cornerstone of treatment, effective for both treatment and prevention of hypercholesterolemia. As suggested by the Hegsted equation (see above), the greatest contributor to hypercholesterolemia is the consumption of saturated fat, with excess cholesterol contributing to a lesser extent. *Reductions in total fat, saturated fat, partially hydrogenated unsaturated fatty acids*, and dietary *cholesterol* are recommended for all adults. Not only is it important to reduce total fat in the diet, but perhaps even more critical is *substituting* foods that provide *polyunsaturated and monounsaturated fats* for those rich in saturated and *trans* unsaturated fat.

In conjunction with exercise and weight loss (which contribute to reductions in lipid levels and ameliorate other cardiac risk factors), dietary modification provides an excellent nonpharmacologic means of improving the patient's lipid profile and reducing CHD risk. The adverse effects are nil, making it the safest of treatments for hypercholesterolemia and especially well suited for persons with only a modest increase in CHD risk (e.g., hypercholesterolemic young men and premenopausal women with no other CHD risk factors). Even for high-risk patients, diet is central to the treatment program, having an additive effect.

Efficacy. Decreases in intake of cholesterol and saturated fat in controlled settings can reduce total and LDL cholesterol by 15% to 30%, but the reductions average about 10% when similarly intensive dietary programs are prescribed for outpatient use. Although reductions in total and saturated fat are important, substituting polyunsaturates and monounsaturates for saturated and unsaturated fats appear to be as or even more important in reducing CHD risk by dietary intervention. Data from the Nurses' Health Study provide the best available estimates of expected changes in CHD risk from various dietary substitutions:

- Substituting polyunsaturated fat for saturated fat: 42% *decrease* in CHD risk (for every 5% of total calories);
- Substituting polyunsaturated fat for trans unsaturated fat: 57% *decrease* in CHD risk (for every 2% of total calories);
- Substituting carbohydrate for saturated fat: 17% *decrease* in CHD risk;
- Substituting carbohydrate for polyunsaturated fat and monounsaturated fat: 20% to 60% *increase* in CHD risk.

Note that not all substitutions are beneficial. Simply substituting carbohydrate for all fat might not be the best dietary strategy for reducing CHD, because beneficial polyunsaturates would also be eliminated as well.

The net effects of various dietary substitutions are related in part to their effects on CHD risk factors, including HDL cholesterol, LDL cholesterol, triglycerides, lipoproteins, and platelets and clotting factors. For example, substituting total fat intake with carbohydrate may produce a small (approximately 5%) reduction in HDL cholesterol, although the overall total-to-HDL cholesterol ratio still improves. Caloric and fat restrictions are also effective in lowering triglyceride levels, an effect enhanced by prohibition of alcohol. Reductions in CHD risk parallel the degree of cholesterol lowering and reduction of other risk factors.

Response to dietary modification is determined to some extent by the etiology of the hypercholesterolemia. When the phase I diet (see below) is prescribed for outpatient use in patients other than those with monogenic hypercholesterolemia, the total and LDL cholesterol levels fall by 5% to 15%. Typically, the total serum cholesterol level will fall to 140 to 160 mg/dL in normal individuals consuming a very low-fat (5% to 10% of total calories) diet. More modest but still useful reductions can be expected from less stringent diets. In the setting of metabolic ward study, there is wide variability in the magnitude of LDL cholesterol reductions achieved by lowering saturated fat intake, ranging from less than 5% to over 50%. Patients with severe monogenic hypercholesterolemias rarely respond to diet alone, whereas other individuals consuming a high-fat diet may demonstrate marked benefit.

Phased Approach to Dietary Modification. The phased approach, as exemplified by the American Heart Association's three-phase dietary plan, maximizes adherence. Total fat, saturated fat, and cholesterol intake are gradually reduced with partial replacement by polyunsaturated fats (which by the Hegsted equation have a modest cholesterol-lowering effect). Excess dietary saturated and trans unsaturated fats are supplanted by use of polyunsaturated and monounsaturated fats and by complex carbohydrates (fruits, vegetables, cereals, pasta, grains, and legumes).

Given the high prevalence of undesirable cholesterol levels in the U.S. population, it is recommended that all Americans adopt the *phase I diet* (Table 27-7):

	AVERAGE U.S. DIET	PHASE I	PHASE II	PHASE III
Total fat (as % total calories)	40-45	30	25	20
Saturated	17	10	<4	<3
Monounsaturated	18	10	<4	<7
Polyunsaturated	7	10	<10	<10
Protein (as % total calories)	15-20	15	15	15
Carbohydrate (as % total calories)	40-45	55	60	65
Dietary cholesterol, mg	500	300	200-250	100-150

Table 27-7. American Heart Association Three-Phase Dietary Plan

- *Total fat* as a percentage of total calories is *reduced to 30%* from an average 40% to 45%;
- *Saturated fat is reduced* to 10% of total calories;
- *Polyunsaturated fat is increased* to 10% of calories;
- *Dietary cholesterol intake is reduced* from 500 to 300 mg/d;
- *Protein* is held constant;
- The W-6 PUFAs found in vegetable oils should not exceed 10% of calories, because they may lower HDL cholesterol.

The phase I diet usually does not require a dramatic alteration in one's eating habits and can be readily adopted by most persons. It is important to note that much of the polyunsaturated fat found in "low-cholesterol low-fat" processed food products is usually partially hydrogenated, converting otherwise beneficial vegetable oils into the undesirable trans unsaturated configuration. Such processed food products should not be considered a substitute for saturated fat but neither should saturated fat be considered a healthier alternative to such products and trigger reverting back to lard-based or tropical oil-based processed foods.

The *phase II diet* (Table 27-7) entails more effort, because it goes beyond eliminating the obvious sources of fat and cholesterol. It is indicated for patients who do not achieve adequate results with a phase I diet and for patients at highest CHD risk (e.g., established CHD).

If just the phase I dietary interventions were widely implemented, the overall incidence of CHD in the population would probably drop significantly. The recommended percentages of fat intake in the diet must be translated into real menus and food recommendations if good compliance with these recommendations is to be realized. The counsel of a dietitian is often beneficial, particularly if a phase II diet is indicated. A good working knowledge of the fat content of common foods is essential for patient, family, and health care team (see Appendix III). A number of "heart healthy" cookbooks are on the market to help patients in their food choices and preparation. The use of faddish cholesterol cookbooks should be discouraged because these often do not promote sustainable healthy eating habits. Increasingly, restaurants are offering low-fat menu choices, and patients should be encouraged to select them.

Nonprescription Dietary Supplements. Nonprescription dietary supplements are no substitute for dietary reduction in total fat, saturated fat, and cholesterol. Nonetheless, they are popular with patients, even though they can be expensive. Preliminary data from prospective studies of *omega-3 fish oil* supplements are encouraging, but they are too limited to serve as the basis for dietary recommendations. Impairment of clotting has been noted with use of high doses.

The *antioxidant vitamins* (A, C, E, and beta-carotene) do not lower cholesterol levels , but because they are capable of increasing LDL resistance to oxidative change (a purported trigger of atherosclerosis), they have been suggested as a means of preventing atherosclerotic disease. Data from observational cohort studies suggested a possible reduction in CHD risk with use of vitamin E, but prospective large-scale randomized trials have failed to confirm any significant benefit. The discrepancy between observational and randomized study findings suggests the originally observed benefit was due to selection bias in the observational studies (healthier persons were more likely to take vitamins). There is no substantial evidence that use of vitamin supplements of A, C or beta-carotene reduces CHD events. At this time, the use of antioxidant vitamin supplements for CHD prevention is not recommended. Because most randomized trials of antioxidant supplements were conducted in persons at increased risk for CHD, there remains the question of benefit in lower risk persons, especially with use of vitamin E. Large-scale, long-term randomized controlled trials of vitamin E in lower risk persons are ongoing and the results should help clarify its value, if any, in preventing coronary events. **Updated: 07/07/03**

Garlic (one half to one clove a day) may produce a modest (5%) reduction in serum cholesterol, but powder and oil preparations have not demonstrated consistent significant benefit. Use of fiber preparations such as *psyllium* (10 g/d) also provide modest benefit, as does the soluble fiber in oat-containing cereals.

Exercise and Weight Loss. ATP III places continued emphasis on exercise and weight reduction as complements to dietary therapy and as essential components of a comprehensive nonpharmacologic program. They are helpful not only in correcting lipid abnormalities but also in reducing other CHD risk factors and total CHD risk. For example, exercise will raise the level of HDL cholesterol, decrease blood pressure, and increase efficiency of peripheral oxygen extraction (see Chapter 18). Weight loss efforts can lower fat intake, reduce risk of diabetes mellitus, and decrease myocardial work. **Updated: 10/19/01**

Drug Therapy

Dietary modification is not uniformly effective in achieving target reductions in LDL cholesterol or desired increases in HDL cholesterol. Addition of drug therapy to a diet and exercise program should be considered in high-risk patients whose lipid abnormalities remain inadequately controlled despite intensive dietary efforts. More widespread application of drug therapy remains controversial, with concerns persisting as to its cost effectiveness and risk-to-benefit ratio in patients at the lower end of the risk spectrum. Nevertheless, several recent studies of cholesterol-lowering drugs have shown impressive reductions in CHD morbidity and mortality in patients without established coronary disease (i.e., primary prevention studies) providing increased impetus for pharmacologic treatment of hyperlipidemias.

Effectiveness and Safety. The addition of drug therapy to a diet and exercise program can greatly enhance lipid-lowering results and lead to significant reductions in *nonfatal* and *fatal cardiac events* (i.e., myocardial infarction, revascularization, cardiac death). Reductions in *all-cause mortality* have also been demonstrated in lipid-lowering drug trials, particularly in higher risk populations. With intensive drug therapy, the rate of plaque progression falls, and modest *plaque regression* can be demonstrated in major coronary vessels and systemic arteries. There is now evidence that lipid-lowering medication (statins) also can reduce *risk of stroke* in persons with atherosclerotic carotid disease.

The reductions in CHD events have been noted in patients with established atherosclerotic disease (*secondary prevention*), who experience 30% to 40% reductions in coronary morbidity and mortality. In addition, benefit also accrues to persons with no clinical CHD and only moderate increases in CHD risk, whose reductions in rates of fatal and nonfatal coronary events with use of pharmacologic therapy (*primary prevention*) are on the order of 20% to 30%.

An early concern about an increased risk of cancer and violent deaths with use of some lipid-lowering agents has failed to materialize in major prospective, randomized, placebo-controlled studies. In four of the largest such trials conducted to date, collectively involving tens of thousands of patients (the 4S-Scandinavian, West of Scotland, AFCAPS/TexCAPS, and LIPID studies), no increase in rates of cancer or noncardiac deaths were observed. However, each class of drug therapies has important adverse effects that need to be taken into account when considering pharmacologic intervention (see below).

Candidacy for Pharmacologic Therapy. The risk-to-benefit ratio for pharmacologic therapy appears most favorable in patients at greatest CHD risk and least favorable in those at lowest risk. Because most data derive from studies involving *middle-aged men* and *postmenopausal women* with *established CHD* or *multiple CHD risk factors*, one must extrapolate to estimate effects in other populations. Treatment recommendations by NCEP are based on total CHD risk that includes lipid profile and associated cardiac risk factors.

In the *elderly*, high CHD risk is common. One might reasonably expect the benefit noted in high-risk middle-aged patients to accrue also to elderly persons at similar risk. Duration of therapy is less likely to be very prolonged, lessening risk of an adverse effect from long-term effect. These expectations remain to be proven, but

important emerging data (e.g., from the AFCAPS/TexCAPS trial) argue in favor of applying pharmacologic treatment to elderly patients.

Young men (age less than 35) and *premenopausal women* with no CHD risk factors other than hypercholesterolemia are best considered for nonpharmacologic therapy, because their short-term risk of CHD is low and the safety of long-term drug therapy is not established. For young persons at greater CHD risk (e.g., LDL cholesterol more than 220 mg/dL, potent CHD risk factors such as diabetes mellitus or strong family history of premature CHD), the potential gain from use of lipid-lowering medication may outweigh the risk, but there are no outcomes data yet available to confirm this. Again, the exercise of good clinical judgment is essential.

Available Agents. Design of a pharmacologic regimen must take into account the patient's degree of *CHD risk*, the nature of the *lipoprotein abnormality*, and the drugs' *mechanisms of action* and *side effects*. The best program is one that addresses and fits well into the patient's overall clinical state. A large degree of individualization is necessary. The range of available drugs is extensive, varying greatly in cost, effect on cholesterol fractions, efficacy, and side effects (Table 27-8).

Table 27-8. Drugs Used to Treat Hyperlipidemia

Name	Indications	Effects	Dosage	Side Effects	Relative Cost (Starting Dose)*
Bile and Sequestrants	↑ LDL	⁻ LDL	Cholestyramine 8–24 g/d	Constipation, heartburn, bloating	Cholest: 14.2
(cholestyramine, colestipol)		⁻ or no change HDL	Colestipol 10–30 g/d		Colest: 12.3
HMG-CoA Reductase inhibitors	↑ LDL; ↑ HDL	⁻ LDL; ↑ HDL; ⁻ VLDL (minor)		↑ Transaminases; myositis	
Atorzastatin			10-80 mg/d		7.2
Fluvastatin			20–80 mg/d **Updated: 10/19/01**		4.8
Lovastatin **			20–80 mg/d		9.0
Pravestatin			20-80 mg/d		8.3
Simvastatin			10–80 mg/d		14.7
Niacin (nicotinic acid)	↑ LDL ⁻ HDL, VLDL	⁻ LDL ↑ HDL ⁻ VLDL	1.5–8 g/d	Flushing, pruritus, PUD, hyperglycemia, rashes	1.0
Gemfibrozil	↑ VLDL	⁻ VLDL ↑ HDL ↑ LDL (if triglycerides high)	600–1,200 mg/d	? + gallstones potentiates warfarin	4.3
Fish oils (W-3 fatty acids)	↑ VLDL	⁻ VLDL ↑⁻ LDL	? 2–3 g or more of W-3 fatty acids/d	Platelet inhibition	0.5

*Initial dose.
**Cost is for non-generic formulation; generic formulation should be considerably less expensive when it becomes available.

HMG-CoA Reductase Inhibitors (The Statins). These agents have become first-line drug therapy because of their effectiveness, patient acceptability, and increasingly favorable safety record. They block the rate-limiting enzyme for cholesterol synthesis, HMG-CoA reductase. This inhibition decreases intracellular cholesterol and increases *clearance of LDL*. Serum LDL levels fall by 20% to 60%, depending on dose and preparation. They affect plaque regression, even when used alone. HDL levels generally stay the same or increase slightly. Statins also influence thrombotic and inflammatory mechanisms, effects whose importance remains to be elucidated, but may account for some of the surprising efficacy seen in persons with lesser degrees of increased CHD risk (see below).

Cost and Cost Effectiveness. *Cost and cost effectiveness* are important considerations in selecting statin therapy, because all these agents are expensive and use is likely to be measured in years. Although fluvastatin is usually the least expensive and pravastatin and simvastatin the most expensive, cost often depends on specific pricing contracts with large payors, making generalizations difficult. The statins differ principally in cost and potency, which parallel one another. The least potent, *fluvastatin*, is also the least expensive, followed by *lovastatin* and *pravastatin*, which are similar in terms of cost and potency. *Cerivastatin*, which was removed from the market in the summer of 2001 because of high rates of myositis and rhabdomyolysis, particularly when used in combination with gemfibrozil, is similar to the latter two in its ultimate LDL cholesterol–lowering effect, but is more potent on a milligram basis. *Simvastatin* and *atorvastatin* give the greatest cholesterol reductions at U.S. Food and Drug Administration–approved dosing levels, with atorvastatin having modestly greater efficacy at its maximum dose. **Updated: 10/19/01**

Although the major drawback to statin use is cost, cost savings from reduced rates of cardiac events, time lost from productive work, and premature death at least partly offset the high cost of treatment. The first statin released, lovastatin, should be available as a generic drug in early 2002. Its release may contribute to some reductions in statin pricing. Formal cost-effectiveness analyses are now appearing in the literature. Data from the Scandinavian Simvastatin Survival Study ("4S") examined cost per year of life gained and found statin therapy cost effective in men and women over a broad spectrum of ages and cholesterol ranges. The cost per year of life gained was less than half of that for other cost-effective preventive measures such as mammography. **Updated: 10/19/01**

Dosing. Starting dose for all these agents is 10 to 20 mg/d. The maximum dose is currently 80 mg/d for lovastatin, simvastatin, fluvastatin and atorvastatin and 40 mg/d for pravastatin. The shorter acting agents are best taken at night, the time of peak cholesterol synthesis, but all drugs work well even if taken once daily in the morning. **Updated: 10/19/01**

Adverse Effects: Asymptomatic *hepatocellular dysfunction* manifested by an increase in serum levels of hepatocellular enzymes (e.g., aspartate and alanine aminotranferases) is the most common adverse effect. Incidence ranges from about 3% for any elevation to less than 1% for elevations greater than three times the upper limit of normal. All such increases are reversible with cessation of therapy, which should be considered when liver enzyme levels continue to rise or reach more than three times the upper limit of normal. Transaminase monitoring is strongly recommended, with initial measurements made after 1 to 2 months of therapy, and follow-up measurements made at 6 months and 1 year. The lack of new onset of liver toxicity after 1 year of therapy has led many to advocate limited monitoring after 1 year.

Harmless elevations in *muscle enzymes* (e.g., creatine phosphokinase less than 10 times the upper limit of normal) occur in about 0.6% of cases and require no action. Myalgias without creatine phosphokinase elevations also occur with statin use, making routine monitoring of creatine phosphokinase of limited value. Symptomatic *myositis* is rare, but risk is increased when *niacin* is used in conjunction with statin therapy. In the setting of concurrent *gemfibrozil* use, *rhabdomyolysis* has occurred. Thus, joint use of a statin and a fibrate (either gemfibrozil or fenofibrate) should be done only with great caution and probably only by a lipid specialist. Because of an FDA warning against this combination, pharmacists will often not fill a prescription that places a patient on both drugs without first calling the physician. The withdrawal of cerivastatin from the market because of the complications arising from muscle breakdown will only likely increase the vigilance of pharmacists in responding to combination therapy prescriptions. **Updated: 10/19/01**

As noted earlier, initial concerns about an increase in non-CHD mortality (e.g., from cancer, suicide, or violence) were raised by early meta-analyses, but large-scale prospective studies of statins show no evidence for such adverse effects.

Choice of Agent. Although most experts believe that all of the statins will reduce coronary events in proportion to their efficacy in lowering LDL cholesterol, not all statins have been proven to do so. To date only simvastatin, pravastatin, and lovastatin have been shown in prospective studies to reduce coronary events and/or all-cause mortality. Not surprisingly, the drugs for which outcomes studies have been conducted are also generally priced higher than those for which data are not available. Whether this difference warrants their selection over the lower cost drugs remains a judgment call. Patients who require modest reductions in LDL cholesterol (less than 25%) can be started on any of the statins with the expectation that the reduction will be achieved. Those with marked LDL elevations and high overall CHD risk require more intensive therapy (more than 40% reductions) and are better served if started on a more potent statin such as simvastatin or atorvastatin.

Niacin. This agent is an effective and inexpensive first-line cholesterol-lowering drug. Its exact mechanism of action remains unknown, although it does affect fatty acid mobilization, *lowers LDL* and VLDL levels, and *raises HDL* levels. These changes can be dramatic, although the average LDL reduction is about 15% to 20%. Data from the Coronary Drug Project demonstrated decreased rates of new infarction and mortality in niacin-treated men with a prior myocardial infarction. Also, reduction in all-cause mortality appears to result from use in patients with established CHD. The combination of niacin plus colestipol has produced documented regression of atheromatous plaque in coronary arteries. Being a B-complex vitamin (nicotinic acid), niacin is available over the counter in nonprescription and in prescription formulations.

Adverse Effects: Niacin's principal adverse effects include a litany of side effects, resulting from the *large doses* required. Niacin can exacerbate *gout* and *diabetes*, elevate *liver enzymes*, and produce *rashes, nausea,* and *vomiting*. It also triggers acute prostaglandin-mediated vasodilation that can result in flushing and even postural lightheadedness. *Pretreatment with aspirin* mitigates this reaction. Dry skin and occasionally acanthosis nigricans may accompany niacin use. Lanolin cream helps the former, and prompt cessation clears the latter. Side effects can be minimized by starting with a dose of 100 mg three times daily, taken with meals. A gradual escalation of the dose to 1.5 to 3.0 g/d may be needed to achieve the desired results. Some studies have used niacin at doses as high as 8 g/d, but the frequency and severity of side effects would not be acceptable in clinical practice.

Preparations: Niacin is available in regular and *time-release* preparations, with the latter more expensive but much more convenient and better tolerated except for a higher incidence of *hepatic toxicity*. One should find a brand of niacin that is inexpensive and reliable, and it is suggested that patients take only that form. Transaminases (aminotransferases) should be monitored regularly, as well as glucose and uric acid levels. A new formulation of niacin that can be taken once a day and that induces significantly less flushing is available by prescription (Niaspan). It is significantly more expensive than the available nonprescription formulations.

Bile Acid Sequestrants (Cholestyramine, Colestipol, Welchol). These nonabsorbable agents have been first-line pharmacologic therapy for many years, with an established record of safety. They are very useful for patients who are not at great CHD risk but in whom diet alone fails to lower LDL cholesterol to target levels. Though not as cost effective as the statins or niacin, they are very effective when used in combination with them to treat high-risk patients with severe hypercholesterolemia. They bind bile acids in the gut and interrupt their normal enterohepatic circulation. The resultant shunting of cholesterol in the liver to bile acid production leads to a fall in total and LDL cholesterols. Welchol, which comes as a 625-mg pill, also binds biliary lipids in the gastrointestinal tract and has comparable effects on the serum cholesterol.

Adverse Effects: The bile sequestrants are nonabsorbable resins whose major *side effects* are gastrointestinal—*constipation, bloating, heartburn,* and *nausea*. A high-fiber diet or psyllium supplement and use of these agents just before a meal will usually ameliorate the gastrointestinal upset. The potential to *impede absorption of certain drugs* (e.g., digoxin, thyroxin, warfarin, tetracycline, phenobarbital) necessitates that bile sequestrants not be taken until at least 1 hour after or 4 hours before these other drugs. In rare instances, steatorrhea and malabsorption of the fat-soluble vitamins (A, D, E, and K) can occur. The usual starting dose is one scoop of the powdered form of the drug (4 g of cholestyramine, 5 g of colestipol) in a large glass of water twice a day. Dose can be increased to a total of three scoops twice daily. A newer formulation of cholestyramine, which is significantly less gritty (Lo-Cholest), can be tried if the texture of the generic drug formulation should prove unacceptable.

Estrogens. In postmenopausal women, estrogen replacement therapy is effective in *lowering* the levels of *LDL cholesterol* and *raising* those of *HDL cholesterol*, with attendant reductions in CHD risk. Because of the risk of endometrial cancer associated with unopposed estrogen use (see Chapter 118), a progestin is usually prescribed as well. The addition of progestin does not appear to significantly reduce the CHD benefit of estrogen replacement therapy, but confirmation by prospective randomized trial is needed. The HERS study showed no benefit of such hormone replacement therapy (HRT) on cardiovascular outcomes in women with established CHD. There was an increase in adverse events in the period of initiation of HRT, although in later stages there was a trend toward improved outcomes. Overall, no benefit was noted. This well-designed prospective study raises serious questions about the efficacy of HRT in protecting women against the complications of coronary artery disease. Most experts would not stop HRT in women with coronary disease, but far fewer would initiate it for this reason as a result of the HERS trial. The study did not address the issue of HRT in women without CHD, and data on this issue are still several years away. Data are also not available on the newer "designer estrogens" such as raloxifene, which also have a favorable effect on lipid profiles.

Fibrates (Gemfibrozil and Fenofibrate)

Because these drugs lower LDL cholesterol much less effectively than the statins, they are not considered first-line drugs for the treatment of hypercholesterolemia. Nonetheless, they do have specific uses. They *decrease VLDL* synthesis and enhance its clearance. They also *raise HDL cholesterol*, most prominently in those who have concomitant *triglyceride elevations*. The effect on LDL cholesterol is variable, although an 8% to 15% reduction can be seen in patients who do not have markedly elevated VLDL levels.

Both fibrate agents are generally well tolerated, but they can increase bile cholesterol content, raising the risk of gallstone formation and potentiating the effect of warfarin. The FDA has issued a warning about their use in combination with statins, because *rhabdomyolysis* has occurred when gemfibrozil and a statin are used concurrently. An earlier drug in this class, clofibrate, was taken off the market because of reports of *increased mortality* associated with its use. Although the FDA has approved both fibrates, these agents have yet to demonstrate a reduction in all-cause mortality. A VA gemfibrozil study of men with low HDL cholesterol did show improvement in coronary outcomes; HDL cholesterol rose, triglycerides fell, and LDL cholesterol stayed the same.

Probucol. This agent was formerly used as an LDL cholesterol-lowering drug, but it is no longer marketed for this purpose because more effective agents are now available. It is also not listed as a major drug for treatment of hypercholesterolemia. It *lowers LDL* cholesterol about 15% but frequently *decreases HDL* by 20% to 30%. The net effect is a more atherogenic lipid profile. However, probucol is an effective *LDL antioxidant* and decreases LDL uptake by macrophages, which theoretically could inhibit atherogenesis independent of any effect on LDL concentration.

Treatment Thresholds for Drug Therapy, Goals, and Monitoring

Treatment Threshholds. Current guidelines derive from the consensus views of the NCEP panel and, for the first time, reflect the data generated by the many lipid-lowering trials done in the mid to late 1990s. For those with *two or more CHD risk factors*, the NCEP recommends initiating drug therapy if the *LDL cholesterol remains above 130 mg/dL* after life-style modifications have been made, if the 10-year risk of a new CHD event is 10% to 20%. If two or more risk factors are present but the 10-year risk probability is less than 10%, an LDL cutpoint of 160 mg/dL is used. The 10-year risk probabilities are determined by a formula derived from Framingham Heart Study epidemiologic data. It is available at the National Heart Lung Blood Institute web page (http://www.nhlbi.nih.gov). For those with *fewer than 2 CHD risk factors*, drug therapy is definitively recommended for *LDL cholesterol levels above 190 mg/dL* and considered optional for those with values between 160 and 190 mg/dL.

Although epidemiologic data show a strong inverse relation between HDL level and CHD risk, there are no data yet from large-scale, randomized, prospective clinical trials showing that raising HDL cholesterol alone significantly reduces CHD mortality. However, treatment of patients with low HDL levels with statins does seem to lower CHD morbidity. Generally healthy middle-aged and elderly persons with *low HDL cholesterol* and "*normal*" *LDL* cholesterol demonstrate a significant reduction in risk of a first acute major coronary event (e.g., myocardial infarction, unstable angina) when treated with a statin drug (e.g., the AFCAPS/TexCAPS trial). Such findings suggest that even persons with modest increases in CHD risk—as manifested by advancing age and an isolated low HDL cholesterol—might benefit from pharmacologic therapy. The mechanism of the benefit may be other than the effect on HDL cholesterol, because in the AFCAPS/TexCAPS study, HDL cholesterol rose only 6%.

In view of recent data, lowering the threshhold for drug therapy below that recommended by the new NCEP guidelines could be justified on the basis of recent outcome studies, but the cost effectiveness of such an approach remains to be established. Since results are typically reported in terms of reduction in relative risk, the magnitude of the benefit to lower risk patients may sometimes appear inflated. Absolute risk certainly becomes an issue in younger patient populations, where a 20% to 30% reduction in relative risk may represent only a modest clinical achievement (i.e., if the absolute risk of having a CHD event over the next 10 years is only 2% a 20% reduction results in the absolute risk falling to 1.6%).

Treatment Goals. The ultimate treatment goal is *reduction in CHD risk*; the immediate one is reduction of LDL cholesterol. Target levels have been lowered, reflecting the improvement in outcomes associated with lower lipid levels. For *primary prevention* (no established CHD), the NCEP target is an *LDL cholesterol level less than 130 mg/dL, although ATP III now defines an optimal LDL as one that is less than 100 mg/dL. For secondary prevention* (established CHD), the goal is an LDL cholesterol level *less than 100 mg/dL.* The latest NCEP guidelines introduce the concept of *elevated non-HDL cholesterol* levels. Non-HDL cholesterol is determined by subtracting the HDL cholesterol value from the total cholesterol value. Patients with high triglyceride levels will have elevations in their VLDL cholesterol, which in turn contributes to a higher non-HDL cholesterol level. ATP III suggests for patients with high triglyceride levels substituting a non-HDL cholesterol goal in place of the LDL cholesterol goal and setting the cutpoint 30 mg/dL higher than the LDL cutpoint. The rationale is that the calculated LDL may not be accurate in patients with high triglycerides. This 30-point differential derives from the Friedewald formula, where VLDL cholesterol is represented by the triglyceride value divided by 5 (i.e., $150 \div 5 = 30$). So as the triglyceride level rises above 150 mg/dL the VLDL contribution to the non-HDL cholesterol will rise above 30 mg/dL.

Monitoring. This is performed by measurement of the LDL cholesterol level, beginning about 6 to 8 weeks after initiation of therapy and then every 3 to 4 months until control is established. Afterward, every 6 to 12 months is usually sufficient. More frequent monitoring for development of abnormalities in serum chemistries (e.g., liver enzymes) is indicated when using certain pharmacologic agents (see above).

Treatment in the Elderly

Prevalence of hypercholesterolemia is greatest in those older than 65 years of age. As in other age groups, elevations in total and LDL cholesterol are predictive of increased cardiovascular risk. However, the statistical risk relationship is not as strong as in younger patients, due in part to the frequent occurrence of other important risk factors in the elderly (e.g., diabetes, hypertension). Elderly patients may have other advanced diseases, making prevention of coronary disease appear irrelevant to their overall quality of life. But, in those who are vigorous and have a considerable life expectancy, primary and secondary prevention of CHD can be very important.

Several factors favor treatment. The coronary disease of women may be less advanced than that of men due to the protective effects of estrogens before menopause or due to use of postmenopausal estrogen replacement therapy. In addition, the benefits from secondary prevention of coronary disease by lowering of cholesterol exceed even the benefits of primary prevention. With the advent of better tolerated cholesterol-lowering medication, the risks of adverse effects and their negative impact on quality of life are declining. All these factors combine to recommend treatment of hypercholesterolemia in elderly patients.

Dietary Measures. Dietary therapy of hypercholesterolemia in the elderly is similar to that for all adults and should be carried out as the first step in treatment, though dietary measures do not always suffice by themselves. Carbohydrate should not replace most fat in the diet, rather polyunsaturates and monounsaturates should be increased. The W-6 polyunsaturated fatty acids found in vegetable oils should not exceed 10% of calories. For the elderly, modifications of the usual low-saturated-fat diet are needed to ensure adequate calcium intake for prevention of osteoporosis. Use of skim milk and low-fat and nonfat yogurts are examples of ways to *maintain calcium* intake while cutting down on saturated fat. Maintaining *adequate protein intake* is also essential, meaning that lean cuts of red meat ought to be allowed in addition to fish and skinless chicken to ensure palatability of the diet. *High fiber* is essential for good bowel function and cannot hurt the cholesterol-lowering effort.

Pharmacologic Therapy. Because dietary therapy alone frequently fails to achieve the goal of an LDL cholesterol lower than 130 mg/dL, drug treatment must often be considered.

Statin therapy is indicated when aggressive lowering of LDL cholesterol is needed. The statins have also proven useful for primary prevention in elderly persons with low HDL cholesterol and average LDL cholesterol. These drugs are well tolerated in the elderly, with minor diarrhea, myalgias, and occasional sleep disturbances being the most common problems. Minor transaminase elevations are common; they are usually asymptomatic and not a cause for discontinuation unless they reach three times normal. However, regular transaminase monitoring is required throughout the course of therapy. As noted earlier, initial concerns about an increased risk of malignancy have proven unfounded in large-scale, prospective, long-term, follow-up studies. Statins are recommended as first-line drug therapy for hypercholesterolemia in the elderly.

The *bile sequestrants* are safe but can cause considerable gastrointestinal upset, especially constipation. Increasing dietary fiber helps. Because sequestrants can impair drug absorption, their use in elderly patients must include instruction to take other medications at least 1 hour before or 4 hours after sequestrant use. Among the drugs that might be affected by sequestrants are warfarin, propranolol, digitalis preparations, thyroxin, and antibiotics. Low-dose sequestrants are a reasonable first choice for pharmacologic therapy.

Niacin is effective, although not always well tolerated. Its advantages over statins are its ability to also raise HDL cholesterol and its low cost. The incidence of side effects in the elderly is high, with flushing, gastrointestinal upset, dry mouth, and dry eyes being particularly annoying. The drug may exacerbate peptic ulcer disease, elevate transaminases, and trigger arrhythmias and hypotension. Multiple daily doses are usually required.

PATIENT EDUCATION

Regarding Diet and Exercise. The importance of patient education in the management of hyperlipidemia cannot be overemphasized, because treatment starts with alterations in the patient's eating and exercise habits (see Chapter 18 and Chapter 233). The first step in therapy should be a careful review of the rationale for treating hypercholesterolemia, followed by a discussion of basic dietary principles for lowering cholesterol. Consultation with a dietitian can be very helpful. Many patients are surprised to learn that dietary fat is more atherogenic than dietary cholesterol itself (witness the patient who eats his cholesterol-free potato chips with abandon). Reviewing the saturated fat and trans fat content of foods regularly consumed by the patient is quite worthwhile. At times, simply removing a few grossly offending foods from the diet (e.g., processed snack foods, cheese, grossly fatty meats, cold cuts, fried food) will ensure a good start to a change in eating habits. More comprehensive diet planning can be aided by discussion with the nurse or dietitian, facilitated by written material such as that produced by the American Heart Association. Periodic visits to check diet, weight, and cholesterol are excellent, although often overlooked, means of facilitating compliance and providing reinforcement.

Regarding Medications. Patients need to understand the rationale for their medical program and the details of its proper use and side effects. Some mistakenly believe their drug program is curative and stop treatment after a few months of therapy. Others harbor exaggerated concerns about adverse drug effects and stop medication prematurely. Cost is another factor that often limits compliance, necessitating a strategy that takes into account the patient's insurance coverage for medication. However, careful studies find that adequacy of insurance does not by itself explain the nearly 40% fall off in compliance that occurs over 5 years among patients prescribed lipid-lowering medication. Choice of agent, comorbidity, and socioeconomic status also play important roles, underscoring the importance of comprehensive and ongoing patient education.

INDICATIONS FOR REFERRAL

To the Dietician. Patients prescribed a dietary program should have a consultation with a *dietitian* if they are unclear about the food choices they should make or if compliance with the diet is problematic. Dieticians can provide educational materials, food preparation advice, and the periodic feedback that patients often need to permanently change their eating habits.

To the Lipid Specialist. Patients with high-risk lipid profiles who do not respond to diet plus one or two first-line drugs, those with extremes of any lipoprotein level, or a family history of premature coronary disease (before age 55 years) should be considered for referral to a physician expert in diagnosis and treatment of lipid disorders. Some genetic disorders are particularly refractory to standard therapies, and patients with these conditions will benefit from consideration of genetic links and more complex treatment regimens that are the province of a lipid specialist. Identification of affected family members can also be accomplished. Lipid research laboratories can often categorize specific genetic abnormalities through testing not routinely available in most clinical laboratories. Ultracentrifugation of lipoproteins, polymerase chain reaction amplification of DNA, and cell-based receptor and enzymatic assays can be used to help pinpoint the cause and screen other family

members for the problem. Although these more sophisticated tests may not yet translate into different therapeutic options, they often help clarify family questions about the risks of CHD in related individuals and are likely to influence therapeutic options in the years ahead.

THERAPEUTIC RECOMMENDATIONS

Effective reduction of CHD risk requires identifying and aggressively treating all CHD risk factors responsive to medical intervention, including smoking, hypertension, diabetes, and obesity (see Chapter 26, Chapter 54, Chapter 102, and Chapter 233). Focusing on hyperlipidemia alone is insufficient. In treating hypercholesterolemia, one should determine total CHD risk (see Table 27-4 and Table 27-5) and treat accordingly (see Table 27-6).

High Risk (Established CHD, Diabetes Mellitus, or other CHD equivalent; LDL Cholesterol 160 mg/dL plus Two CHD Risk Factors, or LDL Cholesterol greater than 190 mg/dL and No Other CHD Risk Factors)

- Start with dietary restriction of total fat intake to no more than 20% of calories, substituting polyunsaturated and monounsaturated fats for saturated fat, partially hydrogenated unsaturated fat, and cholesterol. Highly motivated individuals may avoid the need for life-long medication by strict adherence to phase II or phase III dietary programs, achieving LDL reductions of 40 to 80 mg/dL. Allow 4 to 6 months for implementation of dietary life-style changes. Even if dietary change does not bring LDL cholesterol down to desired levels, diet will enhance the effect from lipid-lowering therapy.
- Initiate pharmacologic therapy if goals for LDL cholesterol reduction have not been met by diet alone. For most patients, a statin preparation is the drug of first choice.
- Minimize cost of statin therapy by matching statin preparation with degree of LDL cholesterol reduction needed. For example, if an LDL cholesterol reduction of 30% to 40% is required, consider starting simvastatin or atorvastatin 20 mg/d (see above); if an LDL cholesterol reduction of less than 25% is needed, then any of the statins can be used and cost should determine choice.
- Consider niacin (average dose, 1.5 to 3.0 g/d) as an alternative choice, if LDL cholesterol elevation is accompanied by a low HDL cholesterol (less than 35 mg/dL). In postmenopausal women with this lipid profile, estrogen replacement therapy is an alternative to niacin.
- Consider adding a second agent in those with high CHD risk who fail to adequately respond to diet plus maximal doses of a single agent. The bile resins (e.g., cholestyramine or colestipol, one to two scoops twice daily) are well suited to combination programs. One should generally avoid the combination of a statin plus gemfibrozil because of the increased risk of rhabdomyolysis and the combination of a statin plus full doses of niacin because of increased risk of myositis.
- Aim for LDL cholesterol of less than 100 mg/dL for those with established CHD, DM, or other CHD equivalents and less than 130 mg/dL for all others.

Moderate Risk (LDL Cholesterol 130 to 159 mg/dL plus Two CHD Risk Factors or LDL Cholesterol 160 to 189 mg/dL and No Other CHD Risk Factors)

- Begin with dietary therapy. In patients with large intakes of saturated fat and cholesterol, the phase I diet can produce sufficient reductions in cholesterol of 20 to 40 mg/dL. More aggressive dietary fat restriction (phase II diet) may be needed in those who do not respond adequately. PUFAs should be increased moderately but to no more than 10% of total calories. The minimum goal is a reduction of LDL cholesterol to less than 130 mg/dL in those with two or more CHD risk factors and to well under 160 mg/dL in those with fewer than two risk factors.
- Drug therapy is usually not necessary but should be considered in those who fail to respond to dietary measures.

Modest Risk (Isolated Low HDL Cholesterol [Less than 40 mg/dL]; LDL Cholesterol Not Elevated)

- Prescribe nonpharmacologic measures that can increase HDL cholesterol, including aerobic exercise, smoking cessation, and weight loss if obese. Such actions can increase HDL by 5 to 15 mg/dL.
- Prescribe a phase I diet, in which saturated fat, cholesterol, and partially hydrogenated vegetable oils are restricted and replaced by monounsaturated and polyunsaturated fats.
- Do not recommend use of antioxidant vitamin supplements; there is no evidence of efficacy. **Updated: 07/07/03**
- Use clinical judgment in considering pharmacologic treatment if nonpharmacologic measures prove insufficient.
- Although the NCEP does not yet recommend pharmacologic correction of an isolated HDL cholesterol, pay attention to total CHD risk. In those with multiple cardiac risk factors and a low HDL cholesterol consider statin therapy for middle-aged and elderly persons; consider estrogen replacement therapy for the postmenopausal women; consider niacin as an additional option, especially for younger persons who tolerate the drug better than do the elderly; and always take into account HDL cholesterol level when designing a pharmacologic program for persons with LDL cholesterol elevation.

Elevated Triglycerides (Fasting Triglycerides More than 200 mg/dL)

- Because no consensus exists on need for treatment, exercise clinical judgment.
- Consider treatment in persons with elevated triglycerides in the setting of low HDL cholesterol (less than 40 mg/dL), as the latter may rise substantially with use of triglyceride-lowering drugs.
- To accomplish this goal, consider gemfibrozil (600 mg twice daily) or fenofibrate (67 to 201 mg/d).
- Such drugs can also be used to reduce the risk of pancreatitis in persons with very high triglyceride levels (more than 800 mg/dL).
- Substitute a non-HDL cholesterol level as the goal in place of the LDL cholesterol, setting the cutpoint 30 mg/dL higher than the LDL cutpoint. **Updated: 10/19/01**

All Patients

- Fully explain the condition and the rationale for the treatment program to ensure compliance; emphasize the importance of dietary modification, exercise, and compliance with any drug program that might be necessary. Customize the patient-education and treatment programs to the needs and capabilities of the patient.
- Address patient concerns, especially those regarding long-term use of lipid-lowering medications or dietary modifications. Enlist the services of a dietician if there are concerns or questions regarding dietary changes.
- Consider for referral to a lipid specialist patients with high-risk lipid profiles who do not respond to diet plus one or two first-line drugs, those with extremes of any lipoprotein level, or a family history of premature coronary disease (before age 55 years).

CHAPTER 28 OUTPATIENT MANAGEMENT OF ATRIAL FIBRILLATION

Atrial fibrillation (AF) usually presents in the office setting without hemodynamic compromise, making it amenable to outpatient management by the primary care physician. The first tasks are to ensure adequate rate control and identify and attend to underlying precipitants and etiologies (see   Chapter 25). Subsequent tasks are to determine the risk of embolization and to design a safe cost-effective program appropriate to the degree of risk. The principal treatment options are institution of chronic antithrombotic therapy in combination with pharmacologic rate control and proceeding to cardioversion followed by chronic antiarrhythmic therapy to maintain sinus rhythm. Because data from randomized prospective studies comparing these very different approaches with treatment are not yet available and because there is a wide spectrum of disease and stroke risk associated with AF, considerable clinical judgment and attention to the specific needs of the individual patient are required to manage AF safely and effectively. Regardless of approach taken, attention to stroke prevention is a critical priority that is too often inadequately addressed.

CLINICAL PRESENTATION AND COURSE

AF may be paroxysmal or chronic. Paroxysms typically occur in patients with lone atrial fibrillation, sick sinus syndrome, or Wolff-Parkinson-White (WPW) syndrome and during exacerbations of cardiomyopathic, valvular, and ischemic forms of organic heart disease. Advanced forms of these conditions often result in chronic AF. AF may also be triggered by hyperthyroidism. Although chronic fibrillation may be a manifestation of serious organic heart disease and represent an increase in overall risk, chronicity is not the prime determinant of embolic risk; the prime determinants are the presence of underlying heart disease and risk factors for thrombus formation.

Lone Atrial Fibrillation. Lone AF is characterized by the occurrence of atrial fibrillation in the absence of clinically evident heart disease or cardiovascular risk factors. In about two thirds of cases, the condition presents as isolated or recurrent episodes of paroxysmal AF; in the remainder, the AF is chronic. Survival rates and stroke risks are similar regardless of whether the lone AF episodes are paroxysmal or chronic. Lone AF may be annoying and sometimes frightening, but the key question is the risk of embolization that it confers. In patients younger than 60 years, survival and embolic risk are no different than that of a population of similar age; however, in patients older than 60 years there is nearly a fourfold increase in relative risk of stroke, probably due to the increased probability of underlying cardiovascular risk factors in older patients with seemingly "lone" AF. Thus, lone AF appears to pose little risk, but only if the patient is relatively young and has no other cardiovascular risk factors.

Apathetic Hyperthyroidism of the Elderly. Clinically inapparent hyperthyroidism may be mistaken for lone AF, because there may be little evidence of organic heart disease and the typical symptoms and signs of hyperthyroidism can also be absent. Sometimes, the clinical presentation more closely resembles depression or occult malignancy, with significant weight loss, marked apathy, and unexplained AF dominating the clinical picture. Diagnosis is made by ruling out underlying organic heart disease and finding the thyrotropin to be undetectable and the free thyroxin index or total triiodothyronine substantially elevated (see   Chapter 8 and Chapter 103). Treatment directed at the hyperthyroidism usually terminates the AF. Although uncommon, this eminently treatable form of AF should not be missed. Stroke risk is minimal if there is no accompanying organic heart disease.

Underlying Heart Disease. Patients with AF in the context of underlying heart disease have a much more serious problem. Not only is the risk of embolization significantly increased, but the AF may also lead to hemodynamic compromise. Chronic atrial fibrillation in such patients usually reflects serious cardiac pathology. In the Framingham study, onset of atrial fibrillation and heart failure were closely linked. Furthermore, the development of chronic AF corresponded with a doubling of cardiovascular mortality.

Some conditions that cause AF also manifest concurrent disease of the conducting system, further increasing risk. For example, patients with the tachycardia-bradycardia (sick sinus) syndrome have sinus node dysfunction, often in conjunction with arterioventricular nodal disease and lack of an adequate escape mechanism. Characteristic presentations include episodes of atrial fibrillation with a slow ventricular response rate and bouts of severe bradycardia leading to syncope or near-syncope.

Paroxysms of rapid AF and other supraventricular tachycardias are characteristic of WPW syndrome. In this condition, an accessory connection between the atrium and the ventricle (e.g., the Kent bundle) leads to preexcitation (short PR interval, delta waves) and a host of supraventricular dysrhythmias. The AF may be associated with a very fast ventricular response rate facilitated by rapid antegrade conduction over the accessory conduction pathway. There may be a widening of the QRS, mimicking ventricular fibrillation. In rare instances, the rapid ventricular response can degenerate into true ventricular fibrillation and sudden death. Fortunately, the risk of such serious ventricular dysrhythmias is very low in previously asymptomatic WPW patients, in part because the accessory pathways tend to lose antegrade conductivity over time.

An episode of AF in a patient with preexisting heart disease may be precipitated by such factors as acute heart failure, ischemia, fever, infection, hypoxia, or hypovolemia. Correction of the precipitant often results in at least a temporary return to sinus rhythm. If there is a valvular, cardiomyopathic, or ischemic process that continues unabated, the paroxysms of AF may become more frequent and prolonged, culminating in chronic AF. AF is particularly common in patients with mitral valve disease, due to rather early onset of increased left atrial pressure and size. AF is much less common in disease of the aortic valve; when it does occur, it signifies very severe advanced disease (see Chapter 33).

Alcohol has been implicated as a major precipitant of AF. Binge drinking may induce paroxysms of AF and ventricular dysrhythmias (so-called " holiday heart" disease). Although there may be no overt evidence of underlying heart disease, there is some debate as to just how normal the hearts really are of patients who experience alcohol-induced arrhythmias. Chronic alcohol abuse can lead to alcoholic cardiomyopathy, which may present as paroxysmal AF during binge drinking. As drinking continues, the cardiomyopathy progresses and the AF becomes more established. The condition is potentially reversible with total abstinence.

Systemic Embolization and Stroke. Both epidemiologic and prospective studies have documented an increased risk of systemic embolization and stroke in patients with AF. It used to be thought that increased risk applied only to patients with AF caused by rheumatic mitral valve disease (relative risk increased nearly 15-fold), but community-based studies have identified lesser but still significant increases (e.g., four- to fivefold) in stroke risk for all AF patients with   underlying heart disease. Independent predictors of high risk for stroke or systemic embolization in nonrheumatic AF patients include clinical congestive heart failure or systolic dysfunction, previous thromboembolism, systolic hypertension (more than 160 mm Hg), and age older than 75 years if female. Prospective transthoracic echocardiographic study confirms that left ventricular dysfunction is an independent predictor of stroke risk, and transesophageal echocardiographic (TEE) studies find that thrombus in the left atrium or left atrial appendage also powerfully predicts embolic risk.

Atherosclerotic risk factors (e.g., diabetes, hypertension) markedly increase the risk of systemic embolization and stroke in persons with AF, perhaps by contributing to development of complex atherosclerotic plaque in the transverse portion of the thoracic aorta, found in TEE studies to be an independent risk factor for embolic stroke.

Data from the Framingham study suggest that risk of stroke is greatest at the onset of AF, with more than 25% of AF-associated strokes occurring shortly after onset. In addition, patients with AF have twice the likelihood of having a recurrence of stroke within the first 6 months compared with patients with stroke and no AF.

Reduction in Cardiac Output: Risk of Death. The decrease in ventricular filling and loss of atrial contraction that result from AF lead to a fall in cardiac output and a rise in pulmonary capillary wedge pressure. When these are substantial, shortness of breath and reduced exercise tolerance may ensue. Rapid AF is especially likely to trigger hemodynamic compromise and heart failure. Cardiomyopathic changes are sometimes a consequence of rapid AF, further compromising cardiac output and exacerbating symptoms. Overall, AF increases the risk of death by as much as twofold.

PRINCIPLES OF MANAGEMENT

The first priorities are assessment of hemodynamic state and establishment of rate control, which requires identification and treatment of precipitants and underlying etiology. Then attention turns to determining the risk of systemic embolization and selecting an appropriate approach to stroke prophylaxis, be it chronic anticoagulation/rate control or cardioversion/chronic antiarrhythmic therapy or any combination thereof.

Assessment of Hemodynamic State and Establishment of Rate Control

Heart rate is an important determinant of hemodynamic state and myocardial oxygen demand. If there is any evidence of significant hemodynamic compromise (e.g., hypotension, congestive heart failure, ischemia), the patient must be immediately *hospitalized* and, in most instances, *urgently cardioverted*. Patients exhibiting no such compromise can be treated as outpatients. The goal is a ventricular response rate at rest of less than 85 beats/min and less than 110 beats/min after mild exercise (e.g., 10 situps or standing up 10 times from a chair). Heart rate may appear well controlled at rest when there is little adrenergic stimulation but rise markedly with mild effort; one needs to evaluate control both at rest and on exertion. For rate control, the drugs most often used in the outpatient setting are beta-blockers, calcium channel blockers, and digoxin.

Digoxin. Although still useful in properly selected patients (such as those with AF due to systolic dysfunction; see Chapter 32), digoxin should no longer be considered the cornerstone of pharmacologic therapy for AF, because the drug has several important shortcomings. It tends to be *ineffective* in slowing heart rate when vagal tone is low and adrenergic stimulation is high, as during *exercise, stress, fever, hypovolemia, hyperthyroidism, ischemia,* or *hypoxia*. Control may be fine at rest but inadequate in the setting of sympathetic drive. Moreover, in the absence of heart failure, digoxin neither restores *sinus rhythm* nor *maintains sinus rhythm* and does little to reduce the frequency and severity of paroxysmal AF episodes. This lack of efficacy is believed related to the drug's dependence on *vagal tone* for full effect and the high level of adrenergic stimulation common to situations that trigger paroxysms of AF or worsen rate control. Electrophysiologic studies show the drug actually shortens the atrial refractory period and may contribute to persistence of AF. By facilitating conduction through the bypass tract and shortening its refractory period, digoxin may exacerbate AF due to WPW syndrome. Careful case selection and close monitoring of therapy are critical to safe effective digoxin use (see Chapter 32).

Adverse Effects. The narrow therapeutic index for digoxin also discourages its use. Subtle dysrhythmic manifestations of digitalis toxicity in the setting of AF include *regularization* of AF, a manifestation of *junctional tachycardia*, and frequent *ventricular premature beats*. The latter should not be confused on electrocardiogram with the widened QRS complexes caused by the *Ashmann phenomenon* (prolonged relative refractory period in the beat after a long RR interval). Although ventricular response rate provides a "bioassay" of digitalis effect and makes frequent sampling of digoxin levels unnecessary, watching for changes in rhythm can be very informative. Whenever there is suspicion of digitalis toxicity, digoxin should be held and a serum level checked.

Beta-Blockers. Beta-blocking agents and calcium channel blockers have supplanted digoxin as the drugs of choice for rate control in AF, largely because of their superior efficacy in settings of high adrenergic stimulation. Beta-blockers slow ventricular response by increasing the refractoriness of the atrioventricular node and blocking the b-adrenergic effect of catecholamines on heart rate. Unlike digoxin, they do not require vagal tone to slow ventricular response rate, making them particularly useful when exercise, situational stress, hyperthyroidism, fever, hypoxemia, or ischemia is responsible for the tachyarrhythmia. Although negatively inotropic, beta-blockers may even be used with benefit (albeit cautiously) for AF in the setting of congestive heart failure (see Chapter 32).

Calcium-Channel Blockers. Like beta-blockers, a number of calcium-channel blockers have proven useful for AF rate control. *Verapamil* is the prototypical calcium-channel blocker used in AF; its ability to prolong the refractory period and the conduction time of arterioventricular nodal tissue reduces the ventricular response rate. *Diltiazem* acts similarly although not quite as potently; it is also less negatively inotropic. Unlike digoxin, calcium channel blockers do not require vagal tone to be maximally effective and consequently they control AF under circumstances that ordinarily would be refractory to digoxin (i.e., high sympathetic tone). Caution is required when using these calcium channel blockers in patients with underlying conduction system disease (e.g., sick sinus syndrome), because they may exacerbate heart block. The drug is contraindicated in WPW syndrome, due to its ability to enhance conduction through the accessory pathway (see below). Use of short-acting preparations in the setting of congestive heart failure is associated with an increased risk of cardiac death (see Chapter 32). In general, sustained-release formulations appear to be better tolerated than short-acting ones (see Chapter 26).

Etiologic Approach to Rate Control. Selection of the proper agent for rate control requires an etiologic diagnosis (see Chapter 25). Empiric therapy without regard for the underlying pathophysiology risks hemodynamic worsening. The importance of this principal is underscored by the approaches required to establish rate control in WPW syndrome, sick sinus syndrome, and hyperthyroidism.

WPW syndrome requires special mention because of the small but important risk of hemodynamic compromise associated with the disorder and standard approaches to rate control. WPW patients with very rapid ventricular rates and hemodynamic deterioration during an attack of AF should be hospitalized, promptly referred to a cardiologist, and treated with urgent *electrical cardioversion*. WPW patients with occasional bouts of AF that are well tolerated and self-limited require no treatment so long as the shortest RR interval during an attack is greater than 180 ms—a shorter interval is associated with an increased risk of ventricular fibrillation. No restrictions on activity are necessary. *Digoxin and calcium channel blockers should not be used*, because they encourage conduction through the accessory pathway by blocking conduction through the arterioventricular node. Future episodes of AF are prevented by the use of antiarrhythmic agents such as *amiodarone* or *radiofrequency ablation*. Inpatient electrophysiologic testing is used to help judge which agent is most likely to provide optimal control of ventricular rate during AF. *Beta-blockers* are sometimes helpful in protecting against recurrent episodes of AF but should also be subjected to electrophysiologic study before being used in patients with potentially serious attacks of AF. Cardiac consultation is essential.

Tachycardia-Bradycardia (Sick Sinus) Syndrome. Patients with the tachycardia-bradycardia form of *sick sinus syndrome* pose a therapeutic dilemma: Although their AF usually responds well to *beta-blockade, verapamil,* or *digoxin*, these therapies may seriously exacerbate episodes of bradycardia by further suppressing conduction through the arterioventricular node. Consequently, *pacemaker implantation* is often necessary for patients with symptomatic tachycardia-bradycardia syndrome.

Hyperthyroidism. AF caused by *hyperthyroidism* responds best to beta-blockade, although definitive treatment of the underlying thyroid disease (see Chapter 103) is essential to successful prevention of future episodes of AF. At times, elective cardioversion (see below) is necessary to restore sinus rhythm after successful treatment of the hyperthyroidism.

Assessment of Risk for Systemic Embolization and Approaches to Prophylaxis

Prevention of systemic embolization and stroke is a key therapeutic priority. Although there is agreement that AF increases the risk of stroke, there remains considerable variation of opinion about the best way to reduce stroke risk. A large-scale, prospective, randomized, clinical trial (the Atrial Fibrillation Follow-up Investigation of Rhythm Management) comparing cardioversion/maintenance of sinus rhythm with chronic anticoagulation/AF rate control is underway and should help provide guidance. In the meantime, considerable clinical judgment is required. Cost-effectiveness studies and decision analyses have tried to provide some guidance, but these studies are limited by their basic assumptions. Nonetheless, an emerging approach to treatment focuses on degree of stroke risk, with stratification helping to identify an appropriate set of therapeutic modalities. Also important are the patient's cardiovascular status, likelihood for successful cardioversion and maintenance of sinus rhythm, and ability to comply with and tolerate antiarrhythmic or anticoagulant programs.

Assessment of Stroke Risk. The *history, physical exam,* and pertinent laboratory studies (particularly *echocardiography*) are reviewed for important risk factors (see below) to help stratify the patient's degree of risk. Although not yet validated by prospective studies, such stratification has the potential to rationalized selection of treatment modality. It is also important to remember that embolic stroke risk is not solely a function of AF but also related to overall atherosclerotic risk, as manifested by complex plaque formation in the aortic arch.

High risk (more than 8%/yr) is a reasonable categorization for persons with *mitral stenosis* or other forms of *rheumatic valvular heart disease* and for those with *nonrheumatic heart disease* accompanied by *prior embolization* or *stroke* or evidence of marked *systolic dysfunction,* severe *congestive heart failure, significant left atrial mural thrombus,* or *female sex plus age more than 75 years.*

Moderate-to-high risk (5% to 8%/yr) might be the appropriate designation for those with less severe degrees of underlying heart disease and for those with *marked left atrial enlargement (more than 6.0 cm)* or other independent risk factors for stroke such as *diabetes, hypertension*, or *hypercholesterolemia.*

Moderate risk (3% to –5%/yr) has been suggested as a designation for patients with no risk factors other than *systolic hypertension* (more than 160 mm Hg). *Lone*

fibrillators older than 60 years of age might also be grouped in this category, because they manifest a similar degree of risk.

Low-to-moderate risk (1% to 3%/yr) has been confirmed by prospective study in AF patients treated with aspirin who manifest no evidence of congestive heart failure, systolic dysfunction, previous thromboembolism, systolic blood pressure more than 160 mm Hg, or age older than 75 years.

Low risk (less than 1%) might be the designation for those whose risk is similar to that of patients without AF, as occurs in *lone fibrillators younger than 60 years of age* truly devoid of any stroke risk factors or underlying heart disease.

Warfarin Anticoagulation. The demonstrated relationship between thrombus in the left atrium and risk of thromboembolism in AF provides a strong rationale for anticoagulation therapy. Several large-scale, prospective, randomized, controlled trials with long-term follow-up have demonstrated that warfarin anticoagulation significantly reduces the risk of systemic embolization and stroke not only in persons with rheumatic AF but also in those with nonrheumatic heart disease. Risk is lowered by nearly two thirds with application of warfarin anticoagulation. Modern well-monitored oral anticoagulation programs help ensure safety and minimize risk of major hemorrhage (see Chapter 83). Long-term warfarin anticoagulation represents one of the few well-established evidence-based approaches to stroke prophylaxis in AF. TEE studies suggest the mechanism is prevention of clot formation and resolution of preexisting clot.

Despite the important association between thrombus formation and stroke risk, oral anticoagulation is not the most potent of prophylactic measures in AF, falling short of cardioversion in many settings, but superior to aspirin. Consequently, although warfarin may be essential to prophylaxis in certain situations (e.g., previous embolization, cardioversion failure, inability to tolerate antiarrhythmics), it often does not suffice as monotherapy and may not be the treatment of first choice in many high-risk situations. In persons over the age of 75 years, oral anticoagulation becomes problematic, because its use is associated with an increased risk of hemorrhagic stroke that nearly cancels its prophylactic benefit. A low-dose warfarin program (PT INR less than 1.2 to 1.5) plus aspirin is not as effective as adjusted-dose warfarin that achieves a greater degree of anticoagulation (PT INR 2.0 to 3.0).

Short-term warfarin anticoagulation is prescribed for *elective cardioversion* to reduce the modest risk of embolization associated with the procedure. Treatment is usually begun 3 to 4 weeks before cardioversion (which allows for dissolution of any thrombus that is present and prevention of new thrombus formation) and continued for 4 weeks after cardioversion (which limits the risk of late embolization due to atrial instability and slow return of full atrial contractility). Patients with a very high risk of stroke are treated chronically with warfarin prophylaxis after cardioversion (those with lesser risk are given aspirin). The indications, optimal intensity, proper duration, and cost effectiveness of long-term postcardioversion anticoagulation remain to be determined. *TEE* can be used to detect left atrial thrombus and better determine need for a month of oral anticoagulation. TEE is especially useful in persons who have a relative contraindication to oral anticoagulation and also can obviate the need for delay in cardioversion. Persons with no thrombus on TEE have a very low risk of embolization; they require only a brief period of heparinization at the time of cardioversion. Although expensive and requiring skilled operators, the study may be worth performing to better estimate embolic risk in the patient with a relative contraindication to warfarin therapy.

Aspirin. Low-moderate risk patients with nonvalvular AF treated with aspirin (325 mg/d) experience a very low rate of embolic events, approaching that of patients without AF. Because aspirin is less likely to cause cerebral hemorrhage than warfarin, it is preferable in the low-risk setting. However, when used in higher risk patients, even in combination with low-dose warfarin, aspirin does not provide the same protection as does standard-dose warfarin. Some physicians use aspirin for stroke prophylaxis after cardioversion in persons of low-moderate moderate or low stroke risk, because of the high probability AF recurring.

Elective Cardioversion. An increasingly practical and safe approach to management of AF is to restore and maintain normal sinus rhythm. Not only can stroke risk be reduced in many AF patients by eliminating left atrial stasis, but the adverse hemodynamic effects of AF are also reversed, and exercise tolerance may improve as restoration of atrial contractility enhances cardiac output. Before the advent of safe effective means of cardioversion and maintenance of sinus rhythm, cardioversion followed by chronic antiarrhythmic therapy was fraught with a high risk of relapse and adverse proarrhythmic effects from drugs used to sustain sinus rhythm. As noted earlier, the relative efficacy of cardioversion compared with chronic anticoagulation remains unknown.

Candidacy. Patients experiencing *exercise intolerance* from the hemodynamic compromise associated with loss of atrial contraction should be considered for cardioversion. Other determinants of candidacy are degree of stroke risk and likelihood of remaining in sinus rhythm. A recent cost-effectiveness analysis found cardioversion superior to chronic anticoagulation when there was high or moderate-to-high embolic risk. The best predictors of successful cardioversion and sustained maintenance of sinus rhythm are *duration of AF* and *age*. AF of recent onset due to an acute stress (e.g., alcohol binge, pneumonia) often reverts spontaneously. At the other end of the spectrum, AF of more than 1 year is unlikely to cardiovert and hold as sinus rhythm, probably because of atrial fibrosis that occurs over time. Fibrosis is also believed to be at least part of the reason why age is a predictor of outcome. *Atrial size* is associated inversely with outcome, but often size appears to be more a reflection of AF duration than an independent predictor of success or failure. Nonetheless, a normal left atrial size is associated with a high probability of successful cardioversion and maintenance of sinus rhythm, whereas a left atrial diameter of more than 60 mm retains independent predictive value as a sign of poor outcome. Other factors that have been identified as predictors of poor outcome include advanced *mitral stenosis*, other forms of rheumatic heart disease, and chronic *congestive heart failure*; however, with the exception of these conditions, etiology is usually not a powerful predictor of responsiveness to cardioversion.

Mode of Cardioversion. Cardioversion may be electrical or chemical. *Electrical cardioversion* is the procedure of choice for urgently converting AF to sinus rhythm. It also has the highest success rate of any modality for restoring normal sinus rhythm. Pretreatment with antiarrhythmic agents is usually unnecessary and not deemed desirable because of its negative effect on atrial contractility. Anesthesia is often recommended. Any digoxin being used is withheld for 2 days before cardioversion, because there is an increased risk of ventricular dysrhythmias when the heart is countershocked in the presence of high digoxin levels. As noted above, the risk of embolization is a function of duration of AF and can be minimized by precardioversion oral anticoagulation and a month of warfarin after cardioversion (see above). Although many patients experience a prompt increase in cardiac output, up to a third do not because of chronic atrial changes associated with AF that may take up to a month to revert back toward normal.

Chemical cardioversion is a reasonable consideration for patients with recent onset of AF (less than 1 week), especially when there is no significant underlying myocardial disease. Single doses of a modern class *IC antiarrhythmic (e.g., flecainide 300 mg or propafenone 600 mg)* can restore sinus rhythm in over 75% of such patients. Because class IC antiarrhythmics may convert AF to very rapid atrial flutter with 1:1 conduction and cause acute hemodynamic compromise, chemical cardioversion is often supplemented with an arterioventricular nodal blocking drug such as a beta-blocker. Because class IC antiarrhythmics can suppress sinoatrial node function, patients may actually feel worse immediately after chemical cardioversion. As the suppressant effect wears off, cardiac output improves and patients begin to feel better. The newer class IC agents (flecainide, propafenone) have largely replaced *quinidine* for cardioversion, because single-dose therapy often suffices and these agents are more effective, although still associated with proarrhythmic risk (e.g., polymorphic ventricular tachycardias such as torsades de pointes). Moreover, they are negatively inotropic and should be used with caution if at all in persons with underlying myocardial or valvular impairment.

Maintenance of Sinus Rhythm. Because of the high likelihood of recurrence of AF (50% to 70%/yr), chronic antiarrhythmic therapy is often prescribed in persons at high risk of relapse (e.g., those with previous relapse, marked left atrial enlargement, advanced underlying heart disease, high voltage required for cardioversion). Of available agents, *amiodarone* is among the most effective (20% recurrence rate vs. 50% recurrence with most other drugs) and safest, with little to no proarrhythmic effect, no increased risk of sudden death, and no impairment of contractility. Low doses of the drug (e.g., 100 to 200 mg once daily) often suffice, and the agent can be used in the setting of heart failure. Side effects are numerous but usually not severe enough to warrant termination of therapy. Important adverse effects include *pulmonary toxicity* (interstitial changes related to total dose), *thyroid suppression* (due to the iodine in amiodarone), *acute gastrointestinal upset, chronic constipation, corneal cysts*, and *neurologic dysfunction* (tremor, ataxia, peripheral neuropathy). The drug *potentiates* the effect of *warfarin* and may cause minor *abnormalities in liver function tests*, but frank hepatocellular injury is rare.

Amiodarone has relegated previously used agents such as *quinidine* and *disopyramide* to secondary roles for maintenance of sinus rhythm. The proarrhythmic and gastrointestinal side effects of quinidine, as well as its suboptimal efficacy (50% relapse rate), discourage its use. Of greatest concern is quinidine's propensity to cause *QT prolongation* and polymorphic ventricular tachycardias (e.g., *torsades de pointes*), which are associated with increased risks of *syncope* and *sudden death*. Although amiodarone also increases the QT interval, it does not trigger torsades nearly as readily as the older drugs. Disopyramide has also been displaced as a first-line agent because of its disappointing efficacy, negative inotropy, and anticholinergic side effects. The newer class IC antiarrhythmics (e.g., *flecainide* and *propafenone*) are being explored for their possible role in maintenance of sinus rhythm, but they are negatively inotropic and have proarrhythmic effects, making them less than ideal for persons with underlying heart disease.

Beta-blockers are helpful for maintenance of sinus rhythm in cases where marked adrenergic stimulation is associated with precipitation or persistence of AF. Persons with underlying ischemic heart disease may be especially good candidates (see Chapter 30), and even persons with congestive heart failure may benefit when small

doses are used in conjunction with close monitoring.

Atrial pacing and implantable atrial defibrillation have been proposed as nonpharmacologic approaches to maintenance of sinus rhythm in persons who are unresponsive to other measures and tolerate AF poorly. Persons with sick sinus syndrome, who may already be candidates for pacemaker therapy, appear to be promising candidates for atrial pacing as a means of preventing recurrent AF. More prospective study is needed.

Ablation of the atrial reentrant circuit causing AF has been performed both surgically (the *maze procedure*) and by radiofrequency techniques during electrophysiologic study. Safety and long-term efficacy have yet to be established, but such procedures could conceivably prove useful in patients with frequent recurrences who tolerate their AF poorly and do not respond to other measures.

PATIENT EDUCATION

The young patient with paroxysmal AF who is free of underlying heart disease needs to be fully reassured to prevent cardiac neurosis and the unnecessary restriction of activity. Such patients should be instructed to quit smoking, avoid sleep deprivation, and limit use of alcohol and stimulants. They often will benefit from use of relaxation techniques (see Chapter 226) at times of stress. WPW patients whose episodes of AF are brief, infrequent, and well tolerated can also be reassured and encouraged to remain fully active. Patients with AF secondary to alcohol abuse and evolving cardiomyopathy need to be informed of the risk of alcoholic cardiomyopathy and strongly urged to abstain from alcohol. In addition, patients at risk for AF from any other cause should be advised to use caution in their social drinking, because excess intake may increase vulnerability to AF (see Chapter 25 and Chapter 228).

It is important to teach AF patients and family members to watch for signs of hemodynamic compromise, such as rapid heart rate, unexplained weight gain, worsening dyspnea on exertion, and decreased exercise tolerance. Patients often fear that long-term digoxin therapy will be habit forming or injurious to the heart; reassurance and education about its use are often much appreciated. However, they need to be aware of the symptoms and signs of digitalis toxicity (see Chapter 32) so that correction of the problem is not unnecessarily delayed.

INDICATIONS FOR ADMISSION AND REFERRAL

Patients unable to tolerate their AF due to congestive heart failure or ischemia should be immediately hospitalized. The same is true if the ventricular response rate is extremely rapid (more than 170 beats/min). Electrical cardioversion may be urgent. Hospitalization is also indicated for patients refractory to medical therapy and those with new onset of embolization. Patients who are candidates for elective cardioversion need at least a temporary stay, even if only for the day.

Referral is indicated for patients with refractory AF, suspicion of WPW syndrome, sick sinus syndrome, or AF resulting in hemodynamic compromise. Patients deemed possible candidates for elective cardioversion also should be referred for cardiac consultation.

THERAPEUTIC RECOMMENDATIONS

Rate Control

- Admit for consideration of urgent cardioversion any patient with evidence of hemodynamic compromise (i.e., acute or worsening congestive failure, ischemia, or acute embolization) or a very rapid ventricular response rate (more than 150 beats/min).
- Conduct a careful workup for identification and treatment of precipitants and underlying etiologies (see Chapter 25).
- Begin therapy for rate control if ventricular response rate at rest is more than 85 beats/min or more than 110 beats/min after mild exercise. Unless there is concurrent heart failure, start with a modest dose of a beta-blocker (e.g., atenolol 25 mg/d) or a calcium channel blocker (e.g., diltiazem, 30 mg four times a day, switching to a sustained-release formulation once an effective dose is established). In the setting of left ventricular systolic dysfunction, consider digoxin or very cautious low-dose use of a beta-blocker and avoid calcium channel blockers (see Chapter 32).
- In the setting of WPW and other preexcitation syndromes, refer for consideration of electrophysiologic study and ablative therapy; do not treat with digoxin or calcium channel blockers because of their tendency to enhance conduction through accessory pathways. Young patients with brief and infrequent bouts of AF due to WPW need not be treated if episodes are well tolerated and the shortest RR interval is greater than 180 ms.
- In the setting of sick sinus syndrome, use considerable caution in initiation of rate-control therapy because such patients are especially susceptible to symptomatic bradycardia; if marked bradycardia occurs upon initiation of such therapy, then refer for consideration of pacemaker implantation.
- If rate control is difficult to achieve, recheck for failure, ischemia, fever, hypovolemia, hypoxia, recurrent pulmonary embolization, hyperthyroidism, and WPW syndrome. Treatment should be directed at the underlying condition. Hospitalize and cardiovert if the AF is not well tolerated.

Stroke Prophylaxis

- For patients with underlying heart disease and AF of less than 48 hours' duration, consider immediate referral for elective cardioversion (either pharmacologic or electrical); precardioversion warfarin anticoagulation is not necessary so long as cardioversion is carried out within 48 hours of onset.
- For all patients with underlying heart disease and AF of more than 48 hours' duration or of unknown duration, begin oral anticoagulant therapy with warfarin as early as possible, unless there is a serious contraindication to warfarin therapy (see Chapter 83). Prescribed an adjustable-dose warfarin program that achieves a prothrombin time of 2.0 to 3.0 INR.
- For those at high risk for systemic embolization (e.g., prior embolization or stroke, systolic dysfunction, clinical congestive heart failure, significant left atrial mural thrombus, or female sex plus age more than 75 years), consider elective cardioversion. Also consider for elective cardioversion those with exercise intolerance or fatigue due to AF, intolerable symptomatic palpitations, or inability to take long-term oral anticoagulation. Screen out those with a high probability of unresponsiveness or relapse (e.g., AF more than 1 years' duration, marked left atrial enlargement, rheumatic etiology).
- Before elective cardioversion in persons with AF of more than 48 hours' duration, prescribe 3 to 4 weeks of adjusted-dose warfarin anticoagulation (to achieve a PT INR of 2.0 to 3.0).
- If it is deemed desirable to proceed directly to elective cardioversion without waiting 3 to 4 weeks for oral anticoagulation, then obtain a TEE to enhance determination of stroke risk. If no thrombus is detected in the left atrium or left atrial appendage, then it is reasonable to proceed directly to cardioversion.
- After cardioversion, whether preceded by warfarin or not, prescribe adjusted-dose warfarin for at least 4 weeks after restoration of sinus rhythm.
- After cardioversion in those with a high risk of AF recurrence (e.g., marked left atrial enlargement, advanced age, high amount of energy required for cardioversion), consider chronic adjusted-dose warfarin prophylaxis, especially if the patient has clinical features conferring high stroke risk. Alternatively, consider chronic antiarrhythmic therapy with low-dose amiodarone (e.g., 100 to 200 mg/d); monitor liver function tests and thyrotropin every 6 months.
- Refer those with frequent recurrences of AF that occur despite antiarrhythmic therapy for consideration of interventional approaches (e.g., atrial ablation, pacing, or defibrillator placement), especially if recurrences are not well tolerated hemodynamically.
- For those with clinical characteristics that make them poor candidates for elective cardioversion (e.g., AF more than 1 years' duration, advanced rheumatic valvular disease, marked left atrial enlargement), consider long-term adjusted-dose warfarin anticoagulation, especially if they have clinical features predictive of high risk for stroke.
- For AF patients with a low-to-moderate risk of embolic stroke (i.e., no congestive heart failure or significant systolic dysfunction, no previous thromboembolism, systolic pressure less than 160 mm Hg, and age less than 75 years), consider chronic aspirin therapy (e.g., 325 mg/d). Those with concurrent atherosclerotic risk factors are likely to benefit the most.
- Consider chronic aspirin therapy also for those who cannot take or refuse oral anticoagulation.
- Advise patients with paroxysms of AF from whatever cause to use alcohol only in moderation and avoid bouts of acute intoxication, because such bouts increase vulnerability for AF.

CHAPTER 29 MANAGEMENT OF VENTRICULAR IRRITABILITY IN THE AMBULATORY SETTING

ALLAN H. GOROLL

INTRODUCTION

The discovery of ventricular ectopy in the outpatient setting raises concerns about serious underlying heart disease and the possibilities of cardiac arrest and sudden death. At issue is how much danger the ventricular irritability poses, a critical determination because treatment is also fraught with risk. In some instances, pharmacologic suppression of ventricular irritability may actually increase risk of sudden death rather than reduce it. Management of ventricular ectopy is shifting from reliance on antiarrhythmic drugs to implantation of cardioverter-defibrillators, which have demonstrated promising results in preventing cardiac arrest and sudden death. Determining the optimal approach to management in this period of change requires close consultation with a cardiologist experienced in treating ventricular dysrhythmias. The primary care physician's principal tasks are to identify high-risk patients, arrange timely cardiac consultation, help patients choose the treatment option best suited to their needs, and monitor therapy. Knowledge of the relative benefits of antiarrhythmic drugs and implantable defibrillators is essential to therapeutic decision making. Close monitoring and long-term follow-up by the primary physician help to ensure safe and effective management.

CLINICAL PRESENTATION AND COURSE

Premature ventricular contractions (PVCs) are ubiquitous and commonly found among patients both with and without underlying heart disease. In studies of the general population, at least one PVC per routine electrocardiogram (ECG) was found in 1% of Air Force recruits, 4% of life insurance applicants, 7% of men older than 34 years of age, and 40% to 75% of normal persons subjected to 24 to 48 hours of continuous ambulatory (Holter) monitoring. The incidence and prevalence of PVCs increase with age and with exercise.

In the ambulatory setting, ventricular irritability usually presents in one of several ways: as an incidental finding on routine examination or ECG; as an ECG finding in a patient being evaluated for palpitations, dizziness, or syncope; or as a complication of underlying heart disease noted on resting ECG, exercise stress test, or Holter monitoring. *Frequent PVCs* are defined as more than 60 ectopic beats/h; *complex ventricular ectopy* is characterized by multiforms, repetitive forms, bigeminy, or R on T. *Ventricular tachycardia* (VT) refers to three or more PVCs in a row; in the *monomorphic* type, all QRS complexes are identical; in *polymorphic* VT (e.g., torsades de pointes), the QRS complexes are all different. *Nonsustained VT* refers to brief self-limited runs of VT; *sustained VT* persists in the absence of intervention. Prognosis is a function of the presence and severity of any underlying heart disease and the nature of the ventricular ectopic activity.

Benign Ventricular Arrhythmias

Initially, prospective studies of large populations of ambulatory men were thought to have shown a correlation between PVCs on routine ECG and subsequent sudden death; however, when these results were reexamined controlling for other cardiac risk factors, PVCs were not found to be an independent determinant of cardiac death in the general population. *Asymptomatic healthy* subjects, even those with frequent or complex PVCs, showed *no increased mortality* on long-term follow-up. Regardless of the presence and persistence of worrisome ventricular irritability, such patients have prognoses no different from those of other healthy people; there is no increased risk of cardiac death.

Other natural history surveys also emphasized that in the absence of hypertension, angina, history of myocardial infarction, heart failure, cardiomegaly on chest x-ray, or ECG signs of ischemia, left ventricular (LV) hypertrophy, or bundle branch block, people with PVCs are at no greater risk for cardiac death than the general population.

Potentially Adverse Ventricular Arrhythmias

In comparison with patients free of underlying heart disease, the situation is more worrisome for patients with a variety of cardiac problems, such as those recovering from a *recent myocardial infarction*. In the Coronary Drug Project study of over 2,000 survivors of myocardial infarction, the occurrence of even a *single PVC* on a routine ECG taken 3 months or more after the infarct was associated with a *doubling* of the *mortality rate* during the 3-year follow-up period. The features most predictive of mortality are *high frequency* of PVCs (more than 30/h over a 24-hour period) and presence of *complex* ventricular ectopy, especially repetitive beats (33 consecutive complexes). Prognosis is particularly poor in the setting of a *failing left ventricle* (ejection fraction less than 0.4). For patients with recent myocardial infarction, reduced ejection fraction, and nonsustained VT, the rate for cardiac arrest or sudden death approaches 20% at 2 years and exceeds 30% at 5 years.

In patients with a history of *remote myocardial infarction*, the frequency and complexity of PVCs also influence prognosis. The absence of ventricular irritability on a 1-hour ECG recording performed 3 to 9 months postinfarction is associated with a 6% risk of sudden cardiac death over 5 years, compared with 12% in patients with unifocal PVCs and 25% in those with complex ventricular ectopy. *Complex ventricular ectopy* (e.g., multifocal PVCs, nonsustained VT) has the strongest influence on risk for sudden cardiac death in this population (see below).

The situation is similar for patients with *other forms of heart disease* that cause myocardial scarring and abnormal wall motion. Patients with hypertrophic or congestive *cardiomyopathy*, hemodynamically significant *valvular disease, congenital heart disease* with ventricular hypertrophy, hypertensive *LV hypertrophy*, and revascularization or valve surgery have been found to be at significantly increased risk of sudden death if experiencing frequent or complex PVCs, especially in the context of a *reduced ejection fraction*. The ventricular ectopy is not merely a manifestation of the underlying heart disease but an independent predictor of prognosis.

Frequent or complex ventricular ectopy that occurs during the recovery period of exercise stress testing may have a worrisome prognosis. In a large-scale observational study from the Cleveland Clinic, patients who manifested frequent (7 or more beats per minute) or complex ventricular ectopy during the recovery period of exercise stress testing had an increased risk of death (adjusted hazard ratio, 1.5) that was independent of other cardiac risk factors. Ventricular ectopy that occurred during stress testing but not in the recovery period did not confer similar independent mortality risk when corrected for confounding variables. Patients with frequent ventricular ectopy during recovery had increased risk of underlying coronary disease and left ventricular systolic dysfunction. | **Updated: 03/26/03**

Malignant Ventricular Arrhythmias

Nonsustained VT. *Nonsustained VT* is a worrisome arrhythmia characterized by runs of VT that spontaneously revert to sinus rhythm within several beats. Unless there is hemodynamic compromise, nonsustained VT may be asymptomatic. In the context of *chronic coronary artery disease and LV dysfunction*, it represents a malignant form of electrical instability that is an independent risk factor for sudden death, increasing risk fivefold to 30% at 2 years. It has a more benign form, found in young patients with *no demonstrable heart disease* and characterized by resolution with exercise, no associated symptoms, and a regular relatively slow rate (less than 150 beats/min) with uniform cycle length and QRS morphology.

Recurrent Sustained VT. *Recurrent sustained VT* is a very dangerous ventricular arrhythmia, especially when it occurs in the context of *LV dysfunction*. Untreated, the 1-year mortality rate is about 40%; prognosis is poorest in symptomatic patients with compromised LV function. The arrhythmia is characterized by repeated episodes of VT, some of which may persist for up to several hours. Many patients become symptomatic due to a fall in cardiac output, which can lead to syncope, near-syncope, angina, or dyspnea. Coronary artery disease and cardiomyopathy account for almost 90% of cases. About 1% of postinfarction patients experience this arrhythmia during the first year of follow-up.

Torsades de Pointes. *Torsades de pointes* is a rapid polymorphic VT that often deteriorates into ventricular fibrillation. The characteristic feature is a QRS axis that

twists about the ECG baseline, going from positive to negative and back again. The arrhythmia occurs in the context of *QT interval prolongation*, be it congenital or acquired. This is a very malignant ventricular dysrhythmia most commonly seen as an *acquired* condition in patients with electrolyte abnormalities (especially hypokalemia, hypomagnesemia) and use of drugs that prolong the QT interval, including antiarrhythmics (e.g., procainamide, quinidine, disopyramide), antifungal agents (e.g., ketoconazole, itraconazole), antibiotics (e.g., macrolides), antihistamines (e.g., terfenadine, astemizole), and prokinetic agents (e.g., cisapride). Risk is increased when an electrolyte abnormality occurs during antiarrhythmic therapy or when several potentially etiologic agents are being used concurrently (e.g., an antihistamine and an antibiotic). In the *congenital form* of QT prolongation, patients are young and have no evidence of structural heart disease but may have a family history of early (before age 30) sudden death in first-degree relatives, a personal history of prior syncope (especially in the setting of stress) or deafness, and ECG findings of QT prolongation, T-wave alternans, and notched T waves in at least three leads.

In sum, the main determinants of adverse prognosis in patients with ventricular ectopy are the presence of underlying heart disease and a failing left ventricle. Each of these factors is an independent predictor of survival. The complexity of the ventricular ectopy is also a determinant of prognosis, especially in patients with heart disease and LV failure, where VT portends an especially high risk of cardiac sudden death.

Probability of Occult Heart Disease in Asymptomatic Persons with Premature Ventricular Contractions

As long as the asymptomatic patient with PVCs has no evidence of underlying heart disease, the prognosis appears fine, but what is the probability of occult heart disease in an otherwise apparently healthy patient presenting with frequent or complex PVCs? The best approximation is that risk is not high. In a study of such patients subjected to coronary catheterization and angiography, only one fourth were found to have significant coronary artery disease (defined as more than 50% luminal narrowing). The characteristics of the ventricular ectopy did not differentiate those with coronary disease from those without it. These asymptomatic patients were treated with modest doses of beta-blocking agents and had normal survival rates after 5 years of follow-up. On the other hand, patients with syncope of unknown origin who manifest complex ventricular irritability and signs of underlying heart disease have a high risk of further syncope and cardiac death, especially if they demonstrate inducible sustained VT on electrophysiologic study.

PRINCIPLES OF MANAGEMENT

The approach to management is undergoing a fundamental change as treatment shifts from traditional reliance on class I antiarrhythmic drugs (Table 29-1) to use of implantable cardioverter-defibrillators, beta-blockers, and class III antiarrhythmics. This shift derives, in part, from well-designed trials (e.g., Cardiac Arrhythmia Suppression Trial [CAST]; see below) revealing a paradoxical increase in risk of sudden death with use of antiarrhythmic agents, presumably a consequence of proarrhythmic drug effects. Equally important, prospective randomized trials find implantable cardioverter-defibrillators superior to antiarrhythmic agents in reducing rates of cardiac arrest and sudden death in very high-risk patents. Confirmation of these findings is still required as is clearer definition who benefits most from a cardioverter-defibrillator, but these findings have stimulated increasing reliance on defibrillator implantation in high-risk patients. Combination strategies are also being explored, such as cardioverter-defibrillator implantation supplemented by beta-blockade and a pharmacologic strategy of beta-blockade plus a class III antiarrhythmic agent.

CLASS (AGENTS)	ACTIVITY	ELECTROCARDIOGRAPHIC EFFECT	PROARRHYTHMIC
A (quinidine, procainamide, disopyramide)	↓PVC, ↓VT rate	↑QRS, ↑QT	Yes (torsade)
B (mexiletine, tocainide)	↓PVC	Nil	Yes
C (flecainide, moricizine)	↓PVC, ↓VT rate	↑QRS	Yes (VT, VF)
I (beta-blockers)	Improved survival	↑PR and ↓QRS	No
III (amiodarone, sotalol)	↓VT	↑PR and ↑QT	Yes (torsade)

Adapted from Nadas S, Singh B. Evolution, mechanisms, and classification of antiarrhythmic drugs. Am J Cardiol 1993;72:9J-19J, with permission.
PVC, premature ventricular contraction; VT, ventricular tachycardia; VF, ventricular fibrillation.

Table 29-1. Classes of Antiarrhythmic Drugs and Their Effects

During this period of flux in the treatment of ventricular irritability, it is essential that the primary care physician follow the literature for results of ongoing prospective trials and work closely with a cardiologist skilled in the management of ventricular dysrhythmias to ensure effective safe management. Because all therapies for serious ventricular ectopy are fraught with risk, it is essential to select carefully for treatment only those patients likely to benefit from intervention.

Candidacy for Treatment

Despite the increased risk of cardiac sudden death in patients with underlying heart disease manifest complex ventricular irritability, only those at highest risk appear to profit from antiarrhythmic measures. To date, prospective randomized trials of cardioverter-defibrillator implantation (e.g., MADIT, Antiarrhythmics versus Implantable Defibrillators [AVID] investigators, MUST) have demonstrated reductions in rates of cardiac arrest and sudden death in persons with;

- Resuscitation from near-fatal ventricular fibrillation;
- Sustained VT with syncope;
- Sustained VT plus a reduced ejection fraction (less than 0.40) and symptoms of hemodynamic compromise with VT (e.g., near-syncope, angina, dyspnea);
- Recent myocardial infarction associated with an ejection fraction less than 0.40, a history of asymptomatic nonsustained VT, and sustained VT on electrophysiologic study (EPS).

Of note, those with a reduced ejection fraction (less than 0.36), an abnormal signal-averaged ECG (a measure of increased risk for VT), and significant coronary disease showed no gain from defibrillator implantation (i.e., the CABG Patch study).

The spectrum of patients qualifying for treatment has been narrowed considerably by the finding that both antiarrhythmic agents (especially class I drugs) fail to reduce cardiac morbidity and mortality and may even increase risk of cardiac sudden death (see below). No longer are patients with underlying heart disease and complex ventricular irritability considered appropriate candidates for antiarrhythmic drug therapy if they are asymptomatic and have preserved LV function. Beta-blockade may be appropriate for such individuals, especially if they have coronary artery disease, but antiarrhythmic therapy is considered problematic. Under study is the combined use of beta-blockers (which do reduce mortality) and the class III antiarrhythmic agent amiodarone (which has very little proarrhythmic activity) for relatively high-risk patients with coronary disease who are not candidates for defibrillator implantation.

Some authorities rank inherited conditions associated with a high risk of life-threatening ventricular dysrhythmias and sudden death as indications for prophylactic treatment. *Congenital prolonged QT syndrome* and *hypertrophic cardiomyopathy* are the most important of these conditions. Common clinical features include a family history of cardiac sudden death or cardiac arrest in a first-degree relative under the age of 30 years and a history of stress-induced syncope. Reduction in mortality with prophylactic therapy remains to be established prospectively.

In sum, the realization that risk of sudden death may be exacerbated by pharmacologic antiarrhythmic therapy and that implantable cardioverter-defibrillators do not work for everyone with high-risk disease has greatly increased the threshold for treatment. At present, only patients with the most malignant forms of ventricular dysrhythmic disease (e.g., prior cardiac arrest; symptomatic or inducible sustained VT, especially in the context of recent myocardial infarction; and reduced ejection fraction) should be considered candidates for prophylactic treatment.

Identification of Candidates for Treatment

Clinical Features. Patients who present in the outpatient setting with complex ventricular irritability, especially nonsustained VT, should be evaluated thoroughly for *underlying heart disease and LV dysfunction* (see Chapter 25), because these features increase risk of cardiac sudden death. Conversely, those patients with heart

disease and a reduced ejection fraction should be checked for clinical features suggestive of VT, because of VT's potentially significant contribution to risk. Finding a history of syncope or near-syncope in a postinfarction patient can be a particularly important clue to VT, especially when the syncopal episode occurs with less than 5 seconds of warning, is accompanied by other symptoms of pump dysfunction (angina, dyspnea), and there are no major residual symptoms during recovery (a characteristic of less serious causes of syncope). Family history of sudden death before age 30 or stress-related syncope should raise suspicion of congenital prolongation of the QT interval and hypertrophic cardiomyopathy.

Electrophysiologic Study. EPS is an invasive procedure, requiring formal cardiac catheterization and an experienced staff. Inducibility of sustained VT correlates well with risks of clinically sustained VT, cardiac arrest, cardiac sudden death, and benefit from cardioverter-defibrillator implantation. Consequently, the study is often performed to identify candidates for defibrillator implantation. At present, those who should be referred for consideration of EPS include patients with asymptomatic nonsustained VT who have evidence of *underlying heart disease* and a *reduced ejection fraction* (less than 0.40). Nearly 40% of such patients will demonstrate inducible sustained VT and improved survival from defibrillator implantation. Others in whom EPS facilitates decision making are those with syncope of unknown origin who manifest clinical findings suggestive of a cardiac etiology (see above). Less compelling is the need for EPS in those with documented VT accompanied by *hemodynamic compromise* (syncope, near-syncope, angina, dyspnea). Studies are undergoing to better determine the indications for this very expensive and invasive procedure and simpler alternatives to predict outcome and benefit from therapy.

Ambulatory Monitoring. The importance of detecting VT has stimulated some to consider ambulatory monitoring to screen all potentially high-risk patients (i.e., those with recent myocardial infarction, hypertrophic cardiomyopathy, or congestive heart failure). However, except for those with syncope or a family history of early sudden death, such screening has not changed outcomes and is not recommended at this time.

Selection and Initiation of Therapy

Choice of Treatment. As alluded to earlier, implantation of a *cardioverter-defibrillator* is emerging as the best available approach to management of high-risk patients with life-threatening ventricular dysrhythmias. Emerging data from initial prospective, randomized, controlled trials (e.g., MAVID, MUST, AVID) that compare cardioverter-defibrillator implantation to *pharmacologic suppression* consistently find cardioverter-defibrillator implantation the superior treatment for reducing rates of cardiac arrest and sudden death. Although additional large-scale randomized trials directly comparing these two modes of therapy are needed to confirm initial findings, the observed benefits of are on the order of a 25% reduction in relative risk and a 7% reduction in absolute risk of cardiac arrest or sudden death at 5 years. All-cause mortality declines by a similar amount. Compared with patients treated pharmacologically, relative risk decreases by nearly 75% with cardioverter-defibrillator implantation. In some studies, all the treatment benefit observed was attributable to implantation therapy.

Implantable Cardioverter-Defibrillators. Currently available technology involves implantation of a pacemaker-sized device using procedures similar to those for pacemakers (e.g., subclavian or cephalic vein insertion, subcutaneous or submuscular left pectoral generator implantation). A complex right ventricular lead is used for sensing and pacing; a coiling of this lead delivers any needed shock. The unit discharges a high-voltage shock in response to detecting ventricular fibrillation or rapid VT and begins pacing when slower monomorphic VT is detected. Maximum output is up to 30 joules; amount needed for defibrillation is between 5 and 15 joules. Dual-chamber models better discriminate between ventricular and supraventricular tachyarrhythmias and allow dual-chamber pacing. Implantation is associated with a small risk of infection (2%); perioperative morality is less than 1%. Inappropriate shocks from mistaking supraventricular tachyarrhythmias for VT are the most common operational complication, occurring in about 20% of patients. Inappropriate firing can be terminated by placing a magnet over the device box, which should be done during any resuscitation efforts. Battery depletion is rare; battery life ranges from 5 to 9 years depending on the amount of discharging required. After implantation, there is no increased risk of endocarditis and no need for endocarditis prophylaxis.

Indications and Contraindications. Implantation is used both for primary and secondary prevention of life-threatening ventricular dysrhythmias (Table 29-2). The indications are in a state of evolution as the full scope of benefit continues to be updated by the results of ongoing prospective randomized trials. *Contraindications* include use for dysrhythmias triggered by a *self-limited event* (e.g., acute myocardial infarction, electrolyte or metabolic disturbances) and refractory disease necessitating frequent shocks in a person with less than a year of life expectancy.

Table 29-2. Indications for Cardioverter-Defibrillator Implantation for Ventricular Dysrhythmias

Effect on Quality of Life. Most patients adapt well, but the shock can be uncomfortable, described as similar to putting one's hand in an electrical socket. Frequent shocks can be very demoralizing and upsetting, necessitating additional measures (e.g., reprogramming, addition of pharmacologic therapy). About 15% experience brief syncope due to delay in cardioversion. The risk of a recurrence decreases with time, reaching a nadir 6 months after an episode. Consequently, most authorities recommend that patients who have a defibrillator implanted for primary prophylaxis do not drive for the first 6 months after implantation and for 6 months after every shock. A permanent ban on driving is absolute for those who drive commercially.

Precautions. Some forms of *electromagnetic exposure* are contraindicated, such as *magnetic resonance imaging*. Microwave ovens pose no hazard nor do airport security gates or brief passes of a handheld wand to detect metal objects, but security staff should be informed on the device's presence before passing through. Cellular digital phones do not interfere with operation of the device, but it is recommended that they are not carried or placed within 6 inches of the unit.

Concurrent Drug Therapy. *Beta-blockers* are widely used in patients with implantable defibrillators to reduce frequency of dysrhythmia- and tachycardia-induced shocks, especially in persons with underlying ischemic heart disease. Some cardiologists use *antiarrhythmics* to reduce the frequency of triggering arrhythmias, but use of these agents can cause drug-induced arrhythmias and raise the threshold voltage necessary to pace or defibrillate.

Beta-Blockade. Beta-blocking agents increase the fibrillatory threshold and reduce the risk of ventricular fibrillation and sudden death. These agents—sometimes referred to as *class II* antiarrhythmics—are safe and especially useful when the ventricular dysrhythmia is caused by underlying ischemic heart disease. They are among the few drugs proven to reduce mortality in patients with coronary artery disease (see Chapter 30). Not only do they reduce risk of sudden death, they also reduce overall mortality. Unlike other drugs with antiarrhythmic properties, the beta-blockers have no proarrhythmic effects. They are also useful for suppression of symptomatic ventricular irritability related to digitalis toxicity, exercise, emotional stress, prolonged QT interval syndromes, and tricyclic antidepressants.

These features make beta-blockers ideal for prevention of sudden death in patients with malignant ventricular irritability due to coronary artery disease and other conditions that respond to beta-blockade. At least some of the benefit associated with class III antiarrhythmics has been attributed to their adrenergic-blocking activity (see below). As noted above, beta-blockers are also being used in persons with cardioverter-defibrillators to reduce the number of shocks by suppressing the rate of VT and episodes of SVT. Combined use of a class III antiarrhythmic (e.g., amiodarone) with a beta-blocker is promising and currently being explored in prospective trials.

Antiarrhythmic Drugs. Although all antiarrhythmic drugs can suppress ventricular ectopy, their net effect on survival has been disappointing. At best, a slight reduction in overall mortality has been found (as with amiodarone in very high-risk patients), but more commonly the result is no benefit over placebo or even an increase in mortality (as found in CAST with use of class IC drugs). Consequently, drug therapy is increasingly relegated to a second-line role for prevention of cardiac arrest and sudden death in favor of cardioverter-defibrillator implantation. In addition, the practice of testing for and seeking to eliminate observable or

inducible ventricular irritability is being abandoned because it does not correlate with outcomes.

At the same time, new approaches to antiarrhythmic therapy are being explored. Use in combination with cardioverter-defibrillator implantation is being investigated as a means of reducing the number of shocks and improving survival. Advances in understanding the basic pathophysiology of malignant ventricular irritability and clinical data from prospective randomized trials are stimulating a shift from use of class I agents (e.g., quinidine, procainamide, disopyramide) to class III drugs (e.g., amiodarone, sotalol). There is exploration of combination drug regimens (e.g., amiodarone plus a beta-blocker) in which complementary modes of action are sought.

Indications for Therapy. Patients who present with symptomatic sustained VT or prior ventricular fibrillation arrest who cannot undergo or refuse cardioverter-defibrillator implantation are reasonable candidates for antiarrhythmic therapy. For asymptomatic patients with preserved LV function and frequent or complex PVCs or nonsustained VT, there is no evidence of survival benefit with use of antiarrhythmic agents. Patients unnerved by their PVCs (actually by the forceful compensatory beats), but otherwise asymptomatic, might be made more comfortable by beta-blockade or low-dose amiodarone. Drug therapy to suppress ventricular dysrhythmias may also be helpful in persons with implanted defibrillators who experience frequent shocks, but safety and impact on outcomes remains to be established. Pharmacologic treatment of ventricular irritability remains in considerable flux, necessitating close monitoring of the literature for results of long-term prospective trials currently underway to determine the best use of drug therapy.

Choice of Agent. Ability to suppress malignant ventricular ectopy used to be the principal criterion for choice of drug. The standard of care was to subject high-risk patients to EPS to see if a given drug could suppress inducible sustained VT. Only those agents demonstrating ability to do so were deemed appropriate for long-term use. The finding in the CAST study that suppressibility does not correlate with outcomes has led to abandonment of EPS study for choice of agent. In its place is empirical therapy, limited to well-tolerated agents proven to reduce rates of cardiac sudden death and all-cause mortality. Currently only the *beta-blockers* and the class III antiarrhythmic drug *amiodarone* meet these efficacy criteria, largely replacing the *class I agents* (*e.g., quinidine, procainamide, disopyramide*) as first-line drugs for life-threatening ventricular dysrhythmias. The class I drugs are now relegated mostly to supporting roles, such as reducing the frequency of shocks in persons with implantable cardioverter-defibrillators.

Amiodarone. *Amiodarone*, a class III antiarrhythmic, blocks a number of cellular ionic channels and also exerts noncompetitive antiadrenergic effects. When used in high-risk patients, the drug demonstrates a significant reduction (29%) in risk of arrhythmic sudden death and a more modest reduction (13%) in overall mortality. Empiric amiodarone therapy prescribed for cardiac arrest survivors has been shown capable of reducing mortality from 50% to 20% at 2 years. Despite being well tolerated, amiodarone has a number of adverse effects, most of which are dose and duration related. An important one is *pulmonary fibrosis*, usually preceded by a reversible patchy pneumonitis. Another complication is *corneal deposits*; these usually do not interfere with vision and disappear with discontinuation of the drug. *Gastrointestinal upset* (including constipation) is common as are minor increases in liver enzymes, but clinically significant *hepatitis* occurs in 4% of patients. Ataxia and tremor may also develop. The drug contains an iodinated segment that can interfere with thyroid metabolism and may lead to *hypothyroidism. Drug–drug interactions* are substantial: Amiodarone increases the serum levels of *digoxin*, *quinidine*, and *procainamide* and potentiates the effect of *warfarin*. Dose adjustments are necessary when amiodarone is used. Amiodarone prolongs the *QT interval*, and there is a small (1%) risk of torsades de pointes associated with its use. This rate is about a tenth of that seen with other antiarrhythmic agents. Effect on inotropy is minimal. Overall, the drug is reasonably well tolerated when used carefully by experienced clinicians.

Sotalol. *Sotalol* has a combination of nonselective beta-blocking affects and electrophysiologic features common to class III antiarrhythmics. These features make it a theoretically attractive agent, and indeed, it is effective in suppressing serious ventricular ectopy. However, at high doses it prolongs the QT interval, subjecting patients to the risk of torsades de pointes, especially if accompanied by hypokalemia or hypomagnesemia. The risk of torsades accounts for the failure of the drug to reduce mortality in some controlled trials.

Quinidine. *Quinidine* use, and most other class I agents, often continues in patients whose initiation of therapy for ventricular ectopy predates current standards; it does not prolong survival. Its association with *prolongation of the QT interval*, usually as a result of excessive dosing but occasionally as an idiosyncratic reaction to a single dose, increases the risk of serious VT (especially *torsades de pointes*), which can lead to ventricular fibrillation. " *Quinidine syncope*" is probably a manifestation of torsades de pointes. The drug *reduces digoxin clearance* and can double its serum concentration, necessitating reduction in digoxin dose when both are used simultaneously. The most common side effects are gastrointestinal (*nausea, vomiting, and diarrhea*). Other common side effects include *tinnitus* and *vertigo*. Hypersensitivity reactions are occasionally encountered; *rash, thrombocytopenia, hepatitis*, or *hemolytic anemia* may result.

Disopyramide. *Disopyramide* has many of the same electrophysiologic properties as quinidine plus a rather pronounced *negative inotropic effect*. Although disopyramide is relatively free of the troublesome gastrointestinal side effects associated with quinidine, it does have substantial anticholinergic activity, which commonly produces *urinary retention, constipation, blurred vision*, and *dry mouth*.

Procainamide. *Procainamide* acts similarly to quinidine and disopyramide. In addition, the drug can cause *arterioventricular block*. Chronic use of procainamide is associated with appearance of *antinuclear antibodies* in about 80% of patients; 20% to 30% of these patients develop a slowly reversible *lupuslike syndrome*. Rate of development of this syndrome is a function of acetylator phenotype; patients who slowly acetylate the drug are at greater risk. Concurrent use of amiodarone, ranitidine, or trimethoprim can increase the serum procainamide level.

Mexiletine and Tocainide. *Mexiletine and tocainide* are orally active *analogues of xylocaine*. Although they can suppress ventricular dysrhythmias refractory to other agents, their antiarrhythmic potency in crossover studies is about the same as quinidine, and like other class I agents, they occasionally worsen ventricular irritability. Of the two, mexiletine is the more negatively inotropic and also has modest suppressive effect on atrioventricular nodal conduction. Side effects are dose related and include tremor, ataxia, confusion, dizziness, nausea, and anorexia. Tocainide causes bone marrow suppression, with *agranulocytosis* reported in 0.2%. Rare instances of pulmonary fibrosis and pneumonitis have occurred.

Flecainide and Moricizine. *Flecainide and moricizine* are potent oral class IC (local anesthetic type) antiarrhythmic agents capable of suppressing sustained ventricular arrhythmias. However, randomized, prospective, controlled, clinical trials (CAST I and II) found these agents also had marked proarrhythmic effects, leading to increased rates of cardiac sudden death. These findings underscore the point that *suppression of ventricular arrhythmias does not predict increased survival*, at least in patients with prior myocardial infarction. The clinician should keep this fact in mind when reviewing claims of efficacy for antiarrhythmic drugs. The current role for these drugs is to reduce the frequency of shocks in persons with implantable defibrillators.

Radiofrequency Catheter Ablative Therapy. Catheter ablation is most successful in persons with VT who have no evidence of underlying structural heart disease (90% cure rate) and in those with VT involving a reentrant mechanism. Persons with VT due to coronary disease have a much lower response rate (less than 50%). The mapping component of the procedure can only be performed when there is hemodynamic stability during the induction of VT, a situation that is infrequent in persons with structural heart disease.

Diet and Exercise. There is no evidence that moderate intake of *caffeinated beverages* is harmful to patients with serious ventricular irritability. Although restriction of caffeine may cut down on the frequency of minor ventricular irritability, there is no evidence caffeine restriction has any effect on important outcomes. Promising data suggest a diet rich in *omega-3 fatty acids* may have an electrically stabilizing effect on myocardial cells; whether this translates into reduced risk of sudden death in high-risk persons is under study. In some forms of dysrhythmic heart diseases (e.g., severe ischemia, congenital form of QT prolongation), extreme exertion should be restricted because it increases the risk of symptomatic VT and cardiac sudden death.

Monitoring Therapy

For Patients Treated with a Cardioverter-Defibrillator. Monitoring such patients is relatively simple, because the devices have built-in monitoring and storage capacity. At the time of a visit to the cardiologist, the memory can be downloaded for study. The patient should be questioned about the number of shocks experienced and the number and type of any other symptomatic events. The device is "interrogated" for assessment of battery status and lead function.

For Patients Treated Pharmacologically. For patients taking antiarrhythmic agents, there are no clearcut guidelines for monitoring therapy. The previous standard of regularly repeated *EPS* or *ambulatory monitoring* has been invalidated by the lack of correlation between suppression of ventricular irritability and outcomes. Those taking pharmacologic therapy for control of bothersome symptoms related to VT (e.g., syncope, near-syncope, dyspnea, angina) should be asked to keep a diary of such symptoms and considered for transtelephonic continuous-loop ambulatory monitoring only if there is concern about the frequency or severity of episodes.

Even though pharmacologic treatment of ventricular irritability is still largely problematic, the primary physician can do much to ensure safety and minimize iatrogenic

complications. Monitoring *serum potassium* and *magnesium* and maintaining normal levels of these electrolytes are essential for reducing the proarrhythmic risk of torsades de pointes. When a digitalis preparation is used, it too needs careful monitoring in the setting of antiarrhythmic use. Renal and hepatic function determinations (*blood urea nitrogen, creatinine, transaminase*) bear watching, because they represent the principal routes of antiarrhythmic excretion. Drugs with potential for bone marrow suppression (e.g., tocainide) necessitate periodic checking of the *complete blood count*. Thyroid indices (e.g., *thyroid-stimulating hormone*) bear watching in patients taking amiodarone. Measurement of *serum drug levels* is an important aid to safe use of these antiarrhythmic agents. Proper interpretation of the data requires that levels be drawn long enough after the last dose so that one is not mistaking a peak serum level for a steady state one.

Monitoring the *ECG* for evidence of excessive dose and idiosyncratic reactions is also essential. Quinidine, procainamide, and disopyramide and some of the other class I agents can substantially *prolong the PR, QRS, and QT intervals* when serum levels are in the toxic range. Modest QT interval prolongation is to be expected and is a sign of therapeutic effect, but marked prolongation is an important sign of excessive dose and a need to withhold further medication. Marked prolongation of the QT interval also can occur idiosyncratically at the very onset of therapy in some patients taking quinidine; it should be checked. QT prolongation also needs to be watched for with use of class III agents, especially sotalol.

INDICATIONS FOR REFERRAL AND ADMISSION

Any patient found to have sustained VT complicated by symptoms of hemodynamic compromise (dyspnea, near-syncope, angina) should be emergently admitted to the hospital and referred to a cardiologist skilled in performing EPS and treating life-threatening ventricular irritability. The same pertains to a patient with acute syncope who presents with features suggestive of a serious cardiac rhythm disturbance (i.e., syncopal episode with less than 5 seconds of warning, other symptoms of pump dysfunction, no major residual symptoms during recovery). A bit less urgent is the case of asymptomatic nonsustained VT, but risk is still very high, and referral for consideration of EPS is indicated when there is a history of recent myocardial infarction and evidence of LV dysfunction. Asymptomatic patients with normal LV function who manifest complex ventricular ectopy other than VT are not candidates for treatment and do not require admission or referral, although cardiac consultation may be done for reassurance.

PATIENT EDUCATION

Patients and their families need to know the prognostic meaning of the ventricular irritability so that they can respond appropriately. Putting the problem in context avoids over- and underresponding. Any fears regarding a potentially serious arrhythmia can be lessened by reviewing available therapies and their ability to reduce the risk of sudden death. Full disclosure improves compliance by reinforcing the importance of therapy; patients are also more willing to put up with annoying side effects from the drugs and cardioverter-defibrillators. Those with cardioverter-defibrillators need to be fully informed about driving, cell phone use, and other precautions regarding electromagnetic interference (see earlier).

Patient education is also crucial to patients with harmless forms of ventricular irritability. Knowing that the palpitations and abnormal ECG have no implications for long-term survival is tremendously reassuring and can prevent development of a cardiac neurosis and unnecessary restriction of activity.

CONCLUSIONS AND THERAPEUTIC RECOMMENDATIONS

- The main independent determinants of prognosis in patients with ventricular ectopy are the presence of underlying heart disease and a failing left ventricle. The complexity of the ventricular ectopy is also a determinant of prognosis, especially in patients with heart disease and LV failure; VT portends an especially high risk of cardiac sudden death.
- Patients presenting with ventricular ectopy should be evaluated for underlying heart disease and LV dysfunction.
- Patients presenting with nonsustained VT in the setting of recent myocardial infarction and reduced ejection fraction should undergo EPS to test for inducible sustained VT, an indication for prophylactic measures.
- Patients presenting with syncope and clinical evidence suggesting a cardiac etiology are also candidates for EPS to test for inducible sustained VT.
- The principal goals of therapy are prevention of symptomatic sustained VT, cardiac arrest, and sudden death.
- Cardioverter-defibrillator implantation has become the treatment of choice for attainment of treatment goals in very high-risk patients.
- Evidence-based indications for treatment (Table 29-2) remain rather narrow, limited to specific groups of patients at extremely high risk of sudden death.
- Beta-blocker therapy is indicated for all patients with malignant ventricular irritability due to underlying coronary artery disease, especially for persons who have had a myocardial infarction.
- Antiarrhythmic drug therapy has been largely relegated to a second-line position because of its proarrhythmic potential and failure in most instances to achieve significant reductions in sudden death and all-cause mortality; best results have been found with use of class III agents manifesting antiadrenergic activity (e.g., amiodarone).
- High-risk patients who refuse or are not candidates for cardioverter-defibrillator implantation might be considered for amiodarone therapy.
- Because drug therapy is fraught with many potentially adverse effects, it should be undertaken only in conjunction with cardiac consultation. EPS testing for ability to suppress inducible VT is no longer recommended because results do not correlate with outcomes.
- Patients with symptomatic VT without structural heart disease are potential candidates for catheter radioablation.
- Under investigation are combination strategies such as cardioverter-defibrillator implantation plus an antiarrhythmic agent and beta-blocker use in conjunction with an antiarrhythmic agent.
- Patients with underlying heart disease, LV dysfunction, and sustained VT are at very high risk of sudden death and require prompt admission and cardiac consultation, especially if they experience arrhythmia-induced symptoms of hemodynamic compromise. Treatment is indicated for these patients and is best initiated in the inpatient setting, in collaboration with a cardiologist skilled in treating malignant ventricular arrhythmias. Outpatient assessment and initiation of therapy may be possible in asymptomatic persons with nonsustained VT, but prompt cardiac consultation is warranted.
- Monitoring should include checking for hemodynamic compromise (near-syncope, dyspnea, angina), number of shocks (in persons with defibrillators), ECG for QT interval prolongation and new dysrhythmias, and serum levels for potassium, magnesium, creatinine, transaminase, and drug concentrations (especially if taking antiarrhythmic drugs).
- Detailed patient education is essential to maximize compliance, safety, and quality of life.

CHAPTER 30 MANAGEMENT OF CHRONIC STABLE ANGINA

Several million Americans suffer from coronary heart disease (CHD), and more than 600,000 die each year from the condition and its complications. Even for patients with chronic stable angina—the form of CHD most commonly encountered in the office setting—the risk of death is high (2% to 12% annually). The array of treatment modalities is extensive, ranging from nitrates, beta-blocking agents, and calcium channel blockers to aspirin, angioplasty, and coronary bypass surgery. These medical and surgical approaches are complemented by aggressive treatment of underlying cardiovascular risk factors. The goals of therapy include symptom relief, improved exercise capacity and quality of life, prevention of infarction, and, ultimately, improved survival.

One must understand the limitations and indications for the vast array of therapeutic options. Design of the basic medical regimen and determining when interventional measures need consideration are among the important responsibilities of the primary care physician. Although long-term management of stable angina usually falls to the primary physician, a good working relationship with a consulting cardiologist is often helpful.

PATHOPHYSIOLOGY

Angina is a symptomatic manifestation of *myocardial ischemia*, occurring when oxygen demand exceeds available vascular supply. Most cases of chronic stable angina are related to fixed *atherosclerotic lesions* narrowing the major coronary vessels. A series of step-wise thrombotic events is believed to account for much of the atherosclerotic occlusion that occurs in the large epicardial arteries. These lesions may develop as a consequence of episodes of acute *thrombosis*, in which activated *platelets* and other elements of the clotting system appear to play major roles, triggered by reactive endothelial injury in areas of cholesterol deposition. Many, if not most, episodes of *acute coronary insufficiency (unstable angina) and infarction* are associated with acute thrombosis, often occurring at an ulcerated, eccentrically located, or ruptured plaque, not necessarily at a site of severe stenosis.

Restriction of coronary blood supply may also ensue from *coronary vasospasm*, believed related to loss of normal endothelial vasoregulatory activity. The coronary endothelium appears to cease production of vasoactive peptides and prostaglandins, leaving vascular smooth muscle unopposed and susceptible to spasm. It has been documented in patients both with and without underlying atherosclerotic disease and sometimes presents as *variant angina* (rest pain, ST-segment elevation). Prevalence is about 3% in patients undergoing coronary angiography with ergonovine stimulation, but the true prevalence is estimated to be far greater. Spasm is suspected of playing a role in acute myocardial infarction and triggering anginal episodes. *Cigarette smoking* and *hyperlipidemia* appear to interfere with normal endothelial activity. Precipitants include stress, cold, a-adrenergic stimulation in the setting of beta-blockade, abrupt nitrate withdrawal, ergonovine, cocaine use, and direct mechanical irritation from cardiac catheterization.

Aortic stenosis can lead to angina when hemodynamically significant valvular stenosis or calcific obstruction of a coronary ostia results in inadequate coronary perfusion (see Chapter 33).

Coronary microvascular dysfunction, characterized by inappropriately vasoconstrictive responses to autonomic and biochemical stimuli, can increase total resistance and reduce myocardial perfusion. The significance of these findings is still unclear, but they have been found with increased frequency among patients with the combination of atypical angina, an ischemic response to exercise stress testing, and a normal coronary angiogram. The terms "*microvascular angina*" and "*syndrome X*" have been applied to such persons. More study is needed, but the findings suggest a possible explanation for the ischemic chest pain of patients with *hypertrophic cardiomyopathy*. Diabetics with hyperinsulinism may also be at increased risk for microvascular disease.

There is a growing appreciation for the frequency and importance of *silent myocardial ischemia*, defined as objectively documented ischemia occurring in the absence of symptoms. On the basis of results from exercise stress testing and ambulatory monitoring, it is estimated that more than half of patients with chronic stable angina experience episodes of silent ischemia. Contrary to common belief, controlled studies find that the incidence in diabetics is no greater than in nondiabetics. Mechanism remains a subject of investigation, but it does not appear to be the result of less severe or less extensive ischemia.

Regardless of etiology, ischemic episodes are often triggered or aggravated by conditions that increase myocardial oxygen demand (e.g., *hyperthyroidism, fever*) or decrease oxygen supply (e.g., *severe anemia, respiratory insufficiency*). A circadian susceptibility to ischemic events has been identified, with the morning hours being the time of greatest risk. Mechanism(s) remains unknown, but the phenomenon can be blocked by beta-blockers or aspirin.

NATURAL HISTORY

Although the clinical course of some patients may extend over 15 to 20 years, most patients with chronic stable angina are at considerably increased risk of cardiovascular death. Among the factors strongly affecting prognosis are the *number* and *location* of *stenoses*. Combined angiographic data obtained before widespread use of bypass surgery reveal that patients with significant disease in one vessel have a mean annual mortality rate of 2.2%. This increases to a rate of 4.5% to 7.0% if the lesion involves the *left main* coronary artery. High-grade proximal stenosis of the left anterior descending artery has a prognosis similar to that of left-main disease and is sometimes referred to as a "*left-main equivalent*" lesion. With stenosis of two vessels, the mean annual mortality rate is 6.8%; the rate rises to 11.4% for *three-vessel disease.*

Prognosis also closely correlates with *severity of ischemia*, as measured by radionuclide or echocardiographic imaging and by electrocardiographic changes during exercise stress testing (see Chapter 36), regardless of whether the disease is symptomatic or silent. Other major independent determinants of increased risk are *left ventricular (LV) dysfunction* (see Chapter 32), *ventricular ectopy* (see Chapter 29), an intercurrent ischemic event within the last 6 months, and cigarette smoking. The onset of angina in a patient with hemodynamically significant aortic stenosis reduces mean survival to about 2 to 3 years (see Chapter 33).

Many *CHD risk factors* are powerful independent determinants of prognosis. *Smoking, diabetes mellitus, hypertension, hypercholesterolemia, low high-density lipoprotein cholesterol*, and *age* (45 years in men, 55 years in women) are well documented for their effect on prognosis in patients with stable angina due to atherosclerotic coronary artery disease. *Hyperhomocysteinemia* is emerging from epidemiologic studies as another potentially significant prognostic factor; however, a causal relationship between elevations in homocysteine and progression of atherosclerotic disease remains to be established.

The natural history of *coronary artery spasm* is highly variable, reflecting the heterogeneity of patients with this condition. An important variable is the presence of underlying atherosclerotic disease. If spasm occurs in the absence of fixed stenoses, the prognosis is relatively good (e.g., no mortality, 39% remission over 6 years). Some investigators even suggest that spasm may be a temporary condition; however, myocardial infarction, heart block, and malignant arrhythmias have been documented. The prognosis of patients with spasm in the setting of underlying coronary stenosis is a function of the coronary anatomy; patients with multivessel disease are at greatest risk. Whether risk is significantly enhanced by the presence of spasm is not yet known.

Risk Stratification. Patients can be classified as low, moderate, or high risk on the basis of stress testing and echocardiographic findings (Table 30.1) (see Chapter 21 and Chapter 36). Although individual patients may fall into the gray zones between categories, such risk stratification can help focus and guide treatment decisions.

Table 30.1. Risk Stratification for Patients with Stable Angina

PRINCIPLES OF MANAGEMENT

The ultimate goals are to reduce the risks of infarction and death. In patients with CHD, identification and aggressive treatment of atherosclerotic risk factors—*hypertension* (see Chapter 26), *hypercholesterolemia* (see Chapter 27), *smoking* (see Chapter 54), and perhaps *diabetes* (see Chapter 102)—can reduce cardiovascular morbidity and mortality. Under study is the effect of normalizing *homocysteine* on outcomes (see Chapter 31). The magnitude of risk reduction from such *secondary prevention* efforts can be impressive, exceeding that associated with primary prevention (see Chapter 31), although such efforts are often overlooked or mistakenly viewed as not productive. *Beta-blockers* and *bypass surgery* also provide effective secondary prevention in high-risk individuals, as does *aspirin* and *aggressive lipid-lowering* (see below).

The more immediate objectives are to control symptoms and enhance exercise capacity, which entail *improving blood supply* and *reducing oxygen demand*. Although drug therapy and interventional methods are the most heavily used treatment modalities (see below), attention also needs to be paid to conditions that increase oxygen demand and reduce oxygen availability. Among the former are *heart failure* (see Chapter 32) and *hyperthyroidism* (see Chapter 103). The latter include severe *anemia* (see Chapter 82), *chronic obstructive pulmonary disease* (see Chapter 47), and *interstitial lung disease* (see Chapter 46). An exercise program helps reduce peripheral oxygen demand (see Chapter 18 and Chapter 31). For patients with angina caused by hemodynamically significant aortic stenosis, *correction of the outflow tract obstruction* is indicated (see Chapter 33).

An effective management strategy needs to address the full spectrum of risk factors and precipitants and the relative benefits of medical therapy versus revascularization. To maximize patient safety, the aggressiveness of intervention should be proportional to the patient's degree of risk (Table 30.1). Knowledge of the treatment and outcome characteristics of available modalities is essential to program design. Often the choices are stated as if they are mutually exclusive, but even if revascularization is chosen, aggressive medical treatment of CHD risk factors remains the foundation of CHD management.

Medical Therapy: Nitrates

Although they have little demonstrable impact on survival, nitrates continue to be one of the cornerstones of CHD management. Their principal contributions are symptomatic relief and prevention of anginal episodes. Nitrates are vasodilators that work by releasing nitric oxide, which stimulates guanyl cyclase conversion of GTP to cyclic GMP, resulting in vascular smooth muscle relaxation. They act predominantly on the *venous capacitance vessels*, though they have a lesser effect on the *arterial bed*. Nitrates have no direct chronotropic or inotropic effects but decrease myocardial oxygen demand predominantly by *reducing preload* through a lowering of LV filling pressure and end-diastolic volume. Nitrates also have a favorable but lesser effect on *afterload*, modestly reducing systemic blood pressure. Regional myocardial perfusion may be improved by the ability of nitrates to *dilate epicardial coronary arteries* (including stenotic segments) and collateral vessels, but there is little effect on the smaller resistance arteries, thus preventing a steal phenomenon from developing (as seen with short-acting dihydropyridine calcium channel blockers). Nitrates are moderately effective in lessening coronary vasospasm. *Tolerance* to nitrates can develop if dosing intervals are too short (see below). Because nitrates and b-adrenergic blocking agents have complementary effects on myocardial oxygen demand, they are often used together (see below).

There is little question as to the efficacy of nitrates for relief of anginal pain and improvement in exercise tolerance in patients with stable coronary artery disease. In addition, nitrates remain the drug of first choice in patients with variant angina due to coronary vasospasm. However, the effect of nitrates on prognosis remains unknown. Most studies of survival involve multiple-drug regimens combining nitrates with beta-blocking agents; such studies do document improved survival in postinfarction patients, but most of the benefit appears attributable to beta-blockade.

Sublingual nitroglycerin (TNG) tablets provide short-term (up to 30 minutes) relief of anginal pain and improvement in exercise tolerance when taken prophylactically. Advantages include low cost, rapid onset of action (30 seconds to 3 minutes), safety, and proven efficacy for symptomatic relief. The drawback is its short duration of action. TNG must be taken sublingually because oral doses are denitrified and hepatically inactivated on the first pass through the portal circulation. Because the drug is volatile, it is best kept in a tightly capped amber vial, stored in a cool place. Once a bottle of TNG is opened, the contents remain maximally effective for up to 6 months. After that, it is best to assume the TNG has lost some of its potency and to prescribe a fresh bottle. Often, the patient using old TNG will notice less benefit and fewer of the usual side effects accompanying use of TNG (headache, burning under the tongue). Before concluding that a patient's failure to respond to TNG is due to disease progression or nitrate resistance (see below), it is important to be sure that "fresh" TNG is being used.

Aerosolized TNG spray delivers 0.4 mg of TNG to the surface of the tongue from a metered-dose aerosol canister; the drug is rapidly absorbed transmucosally. Onset and duration of action and efficacy of a single dose are similar to those of a 0.4-mg sublingual TNG tablet. Each canister contains about 200 doses. Canister-stored TNG will retain efficacy for up to 3 years. Cost per dose is substantially greater than for TNG tablets, but prolonged shelf life helps to reduce total cost to the patient. The spray is a reasonable alternative in patients who wear dentures or have dry mucous membranes. Proper use requires holding the canister close to the tongue, directing the spray at the tongue, not inhaling the spray, and closing the mouth after each dose.

Isosorbide dinitrate was developed to provide more sustained nitrate activity and better *anginal prophylaxis*. Single oral doses of 20 to 40 mg significantly improve hemodynamic parameters and exercise tolerance, and the effect persists up to 4 hours. Onset of action is 15 to 30 minutes and clinical duration of action, 4 to 8 hours. The optimal *dosage schedule* is two or three times a day, with an *eccentric pattern* (e.g., early morning, midafternoon) to minimize risk of nitrate tolerance (see below). Such eccentric schedules appear to strike the best balance between avoidance of tolerance and control of angina. A sustained-release form of isosorbide dinitrate with a 12-hour serum half-life is available but not recommended because of highly variable intestinal absorption and risk of nitrate tolerance (unless used only once daily).

Both *chewable* and *sublingual* isosorbide preparations are available and provide a more rapid onset of action (5 to 15 minutes), but duration of action falls to about 2 hours. It remains to be seen whether the faster onset shorter acting forms of isosorbide are so much better than sublingual TNG as to warrant their added expense.

Isosorbide mononitrate provides longer acting nitrate than isosorbide dinitrate. When given twice daily, it can provide up to 12 hours of antianginal activity. A large once-daily sustained-release formulation can give up to 12 hours of relief. Isosorbide mononitrate offers no significant advantage over generic isosorbide dinitrate for control of chronic stable angina, except convenience. The mononitrate costs 10 times more per day than the generic dinitrate preparation. The heavily promoted feature of reduced risk of nitrate tolerance with mononitrate use is probably true, but less expensive means of accomplishing this objective are available (see below).

Nitroglycerin ointment has been rediscovered as an effective method for providing long-acting anginal prophylaxis. Improved exercise tolerance and hemodynamic effects persist for up to 6 hours. Because the ointment can be messy and irritating to the skin if applied to the same area around the clock, it is best suited for nocturnal use.

Transdermal nitroglycerin patches can deliver nitroglycerin for 24 hours in a convenient-to-use form. Serum nitrate levels approach the peak level obtained with sublingual nitroglycerin. Initial round-the-clock improvements in symptoms and exercise tolerance decline after 7 to 10 days of continuous patch use, because the sustained high nitrate levels lead to *nitrate tolerance* (see below). Proper use requires a 10- to 12-hour period of *nitrate washout*, having the stable angina patient put

the patch on in the morning and remove it in the evening. Continued use of the patch is reasonable in those patients who show definite clinical benefit. If there is none, then the patch should be discontinued. In patients who have been using patches for months to years, termination is best conducted in a tapering fashion to avoid precipitation of a nitrate withdrawal syndrome.

Initiation of Nitrate Therapy. Determining the *proper dose* of a long-acting nitrate is achieved by monitoring the effect of the agent on heart rate, blood pressure, and exercise tolerance. Long-acting nitrate therapy should be introduced gradually; starting with too large a dose produces severe vascular headaches that force many patients to stop their medication. Beginning with a low-dose program (e.g., 5 mg of isosorbide three times a day) and advancing it slowly over 1 to 2 weeks, one can achieve substantial nitrate doses without significant headache. Patients with migraine headaches may be very intolerant of nitrates; combining nitrate therapy with a beta-blocking agent can often overcome this difficulty, especially if the beta-blocker is started first.

Dosage is increased until customary activity can be undertaken without pain, the heart rate at rest rises by 10 to 15 beats/min, or blood pressure falls to the point of causing postural lightheadedness. The development of headache is not a reliable therapeutic end point, because this side effect usually disappears with continuation of therapy.

Prevention of Nitrate Tolerance. *Nitrate tolerance* refers to the loss of hemodynamic benefit associated with continuous nitrate use over prolonged periods. It is believed to be related to sulfhydryl depletion in vascular endothelial cells. Tolerance is both dose and time dependent. In the outpatient setting, nitrate tolerance is seen after 7 to 10 days of continuous 5-mg transdermal TNG patch use and with as little as 30 mg of isosorbide given four times daily. The common denominator is insufficient time for adequate nitrate washout. Onset can be as rapid as 12 to 24 hours with use of intravenous TNG. Tolerance develops to both the peripheral and coronary vasodilator effects of nitrates. Prevention of tolerance appears to require a regimen that provides for rapid increases and decreases in nitrate levels over the course of the day and a daily nitrate-free period. A daily period of 10 to 12 hours off nitrate therapy is recommended to minimize the risk of nitrate tolerance. The least expensive approach is to prescribe an "*asymmetric*" *dosing* schedule for isosorbide dinitrate (e.g., 8 a.m., 2 p.m., 8 p.m.) in place of the standard "symmetric" program of every 6 or 8 hours. Alternatively, a once-daily dose of isosorbide mononitrate or applying a transdermal nitroglycerin patch for only 12 hours might achieve the same objective, but the cost is considerably greater.

b-Adrenergic Blocking Agents

Beta-blockers reduce the frequency of *angina* (especially that which is exercise induced) and improve *exercise tolerance*. These agents are among the few treatment modalities proven to prevent *cardiac sudden death* and prolong *survival* in patients surviving myocardial infarction, with 45% reductions in sudden death and 20% reductions in all-cause mortality demonstrated in long-term prospective trials. In patients with stable coronary disease, beta-blockers appear to reduce the frequency of silent ischemia and other coronary events. The benefits of beta-blockade are attributed to their lowering of myocardial oxygen consumption—they reduce *contractility, blood pressure*, and *heart rate*—and their raising of the *ventricular fibrillatory threshold*. In addition, a slower heart rate provides more time for *myocardial perfusion*, which occurs predominantly during diastole. Despite these proven benefits, beta-blockers continue to be underused especially the elderly.

Categorization. Beta-blockers can be categorized according to their relative cardioselectivity, lipid solubility, intrinsic agonist activity, and alpha-blocking capacity.

Cardioselectivity refers to the degree of preferential affinity for b_1-receptors, which predominate in the heart and are the principal target of antianginal therapy. Beta-blockers that lack cardioselectivity are more likely at low doses to cause side effects associated with b_2-blockade (bronchospasm, peripheral vasoconstriction, and inhibition of glycogenolysis; see below). Cardioselectivity fades as doses increase. At low to intermediate doses, cardioselectivity is demonstrated by *atenolol, metoprolol, acebutolol, betaxolol*, and *bisoprolol.*

Lipid solubility affects absorption, metabolism, serum half-life, and degree to which an agent crosses the blood–brain barrier. The more lipid soluble an agent is, the more rapid its absorption, the shorter its half-life, and the more likely its entry into the central nervous system (CNS). Lipid-soluble preparations are, for the most part, hepatically metabolized. The most lipid-soluble beta-blockers included propranolol, followed by metoprolol, and then pindolol; the least lipid soluble include atenolol and nadolol. Although it used to be thought that lipid solubility predicted degree of CNS side effects (depression, psychomotor retardation), this quality appears less important than cardioselectivity. An intriguing observation is that those beta-blockers best studied and proven to lower risk of sudden death are the lipid-soluble agents, suggesting to some that central adrenergic inhibition might play an important role in reducing the risk of sudden death.

Agonist activity is an intrinsic characteristic of *pindolol, acebutolol, carteolol, labetalol*, and *penbutolol*. At low doses, these drugs show some sympatholytic action and tend to cause less reduction in heart rate, contractility, and conduction than other beta-blockers. Consequently, they are worth considering in patients who develop symptomatic bradycardia with use of standard beta-blockers. However, as doses increase, these agonist effects are overpowered by the underlying beta-blocking activity.

Alpha-blocking activity is a feature of *labetalol* and *carvedilol*. This characteristic makes these agents useful in situations where potent afterload reduction is desired, as in hypertension and congestive heart failure. Labetalol combines nonselective beta-blockade with agonist activity and alpha-blocking action; it is used predominantly in hypertensive patients. Adverse effects include greater degrees of postural hypotension and sexual dysfunction than seen with most beta-blockers. Carvedilol offers nonselective beta-blockade in conjunction with alpha-blockade; in addition, it prevents upregulation of cardiac beta-receptors, reduces cardiac norepinephrine, and demonstrates antioxidant effects. The drug is U.S. Food and Drug Administration (FDA)-approved for use in heart failure, where it has been shown to reduce morbidity and mortality (see Chapter 32).

Adverse effects are directly attributable to the consequences of beta-blockade on a host of organ systems that require b-stimulation for normal functioning. Risk is greatest when there is underlying organ-system dysfunction. Heart failure, heart block, and severe bronchospasm are among the most worrisome of potential adverse effects, but risk can be minimized by careful prescribing and monitoring. In most instances, some degree of beta-blockade can be instituted, especially if cardioselective agents are used. Abrupt withdrawal of beta-blocker therapy can lead to rebound adrenergic stimulation and its attendant adverse consequences.

Heart failure may develop or worsen in patients with preexisting LV dysfunction. Not all patients with a reduced ejection fraction necessarily worsen; those with heart failure due to coronary disease may actually improve (see Chapter 32), but careful monitoring is essential. Concurrent use of other negatively inotropic drugs (e.g., verapamil, disopyramide) should be eliminated or at least minimized.

Heart Block. Patients with underlying conduction system disease may experience symptomatic *bradycardia* or *heart block* due to slowing of the sinoatrial node and atrioventricular conduction; sinus arrest may ensue in such patients. A preparation with some intrinsic b-agonist activity may be preferred if a beta-blocker is to be used in the setting of underlying conduction system disease. Close monitoring is critical to safe use in persons with underlying conduction system disease.

Coronary vasoconstriction is a theoretical concern in patients with coronary disease, especially in those with atherosclerotic disease complicated by vasospasm and in those with purely vasospastic disease. Clinically, it is rarely a problem. In fact, beta-blockers have actually proved useful in patients with variant angina, although they are usually prescribed in conjunction with coronary vasodilators such as nitrates or calcium channel blockers. The observed benefit of beta-blockers in settings of suspected coronary vasoconstriction is believed related to their favorable effects on platelet aggregation, oxygen demand, and other factors contributing to vasospasm or angina.

Peripheral vasoconstriction can occur with beta-blocker therapy, particularly in patients who suffer from vasospastic Raynaud's disease. However, as long as a low-dose cardioselective program is used, the Raynaud's patient can usually tolerate beta-blocker treatment. Similarly, patients with peripheral atherosclerotic arterial disease rarely suffer a compromise in limb perfusion when taking a beta-blocker (see Chapter 34).

Bronchospasm. By blocking b_2-receptors, nonselective beta-blockers (and all preparations when used in full doses) may trigger bronchospasm, the most serious side effect of beta-blocker use. Bronchospasm may occur in any patient with a history of bronchospastic disease, even if asymptomatic at the time of initiating therapy. Many regard asthma as a relative contraindication to beta-blocker use, but careful use is possible in patients with inactive or well-controlled bronchospastic disease, so long as doses are kept low and a cardioselective agent is used. Nonetheless, caution and careful monitoring of flow rates are advised, because even low doses of a relatively cardioselective agent can worsen bronchospasm in a patient with asthma.

Hypoglycemia. Beta-blockers will *blunt the adrenergic response* to hypoglycemia. This may impair patient recognition of a hypoglycemic episode in patients taking insulin or potent oral agents and, in theory, prolong the duration of hypoglycemia by inhibiting catecholamine-induced glycogenolysis and glucose mobilization. In actual practice, prolongation of hypoglycemia is rare, and diabetics have a very high risk of cardiovascular morbidity and mortality that is markedly reduced by

beta-blocker therapy. Consequently, beta-blocker use is not contraindicated in diabetics, even in those taking insulin, but careful dosing and cardioselectivity are required as are detailed patient education and careful program design (see Chapter 102).

CNS Effects and Depression. The CNS effects of beta-blockers are of considerable concern to patients and often a cause for discontinuation of therapy. Anecdotal reports of *cognitive problems, depression, sexual dysfunction, altered sleep, nightmares*, and *fatigue* appeared soon after propranolol became widely available. Their frequency is particularly high in the elderly with use of propranolol, but much less so with cardioselective agents. Some suggest that the incidence of CNS side effects could be substantially reduced by use of lipid-insoluble preparations (e.g., atenolol, nadolol, timolol), though the relative advantage of using lipid-insoluble beta-blockers remains a subject of debate. More important to avoidance of CNS effects appears to be use of a cardioselective agent. The issue of an increased *risk of depression* with beta-blocker use also remains unresolved, pending data from prospective, randomized, placebo-controlled trials. In one of the few well-designed studies—comparing atenolol to nifedipine in elderly hypertensive patients—atenolol was found to impair neither cognition nor mood. Pending further data, it appears that depression or other forms of CNS dysfunction are contraindications to beta-blocker therapy. Use of a cardioselective lipid-insoluble preparation is probably preferable in such patients, provided there is careful monitoring of mood, sleep pattern, and sexual and cognitive functioning.

Rebound. Abrupt *withdrawal* of beta-blockade can precipitate an exacerbation of *angina, acute coronary insufficiency*, or even *infarction*. It has been hypothesized that an "*upregulation*" *of beta-adrenergic receptors* results from long-term blockade and makes these patients more sensitive to unopposed b-adrenergic stimulation. Onset is characteristically within 2 to 6 days after abrupt cessation of therapy. Concern about withdrawal often occurs in the perioperative setting, where medications might have been held for surgery. About 10% of stable anginal patients experience a serious *rebound* in symptoms when beta-blockade is suddenly terminated. Infarction and death may occur. Those at greatest risk are patients on large doses who have achieved much benefit from beta-blockade. Withholding beta-blockers for up to 48 hours can be done without risking any increase in angina. Patients who experience an exacerbation usually do so 2 to 6 days after abrupt discontinuation of therapy. Tapering therapy over the course of 1 to 2 weeks can minimize a withdrawal reaction.

Lipids. Although beta-blocker use (especially of nonselective agents) may cause a modest increase in serum triglycerides and a small reduction in serum HDL cholesterol, there is no evidence that these effects are clinically significant. Moreover, both animal and human studies demonstrate beta-blocker inhibition of serum factors and vessel wall stresses important to atherogenesis.

Choice of Agent. The choice of agent should be based predominantly on cost, need for cardioselectivity, and duration of action. Generically available formulations (e.g., propranolol, metoprolol, atenolol) are one tenth to one thirtieth the cost of brand-name beta-blockers. Cardioselectivity deserves consideration in patients with asthma, peripheral vascular disease, or neuropsychiatric problems. Duration of action becomes important for maximizing compliance, which is facilitated by use of agents that can be administered on a once-daily or twice-daily basis. The combination of low cost, cardioselectivity, and prolonged duration of action make generic preparations of *metoprolol* and *atenolol* the preferred beta-blockers for most patients with coronary disease. An agent with some intrinsic b-agonist activity (e.g., generic *pindolol*) may be worth considering in anginal patients with conduction system disease or sinus node dysfunction bothered by symptomatic bradycardia when taking a beta-blocker without such activity. The presence of heart failure does not need to be a contraindication to beta-blocker use; both long-acting metoprolol and carvedilol have demonstrated ability to improve survival in patients with heart failure (see Chapter 32).

Initiation of beta-blocker therapy requires titration of dose against the *resting* and *exercise heart rates*. Lowering the resting heart rate to about 60 beats/min is usually considered evidence of sufficient beta-blockade but may not be a reliable indicator in elderly patients. A subset of patients do not achieve adequate control of their angina at this level of beta-blockade. Further increases in dosage (and a slower resting heart rate) may be necessary to prevent chest pain. Such bradycardia is often well tolerated hemodynamically. Typical target heart rates are 50 to 60 beats/min at rest, with an increase to 70 to 80 with moderate exercise and no more than 100 with vigorous exercise. The true measures of adequate therapy remain the suppression of angina and improvement of exercise tolerance. Times of maximum diurnal adrenergic activity (early morning and early evening) are the ones most important to cover with beta-blockade, because they are times when risks of cardiac events are greatest.

Angiotensin-Converting Enzyme Inhibitors

Angiotensin-converting enzyme (ACE) inhibition is emerging as an essential component of CHD management, not only in patients with *impaired LV function* but also in those with ejection fractions that are not reduced. In addition to inhibiting angiotensin-induced vasoconstriction, ACE inhibitors have shown ability to limit vascular smooth muscle proliferation, plaque rupture, and LV hypertrophy and to improve vascular endothelial function and fibrinolysis. Postinfarction patients with ejection fractions less than 0.4 achieve significant reductions in cardiac morbidity and mortality with ACE inhibitor use (see Chapter 32).

Now evidence is accumulating that even in the *absence of LV dysfunction*, ACE inhibition can significantly reduce cardiovascular *morbidity* and *mortality* independent of its effect on blood pressure. In the first large-scale randomized controlled trial to test this hypothesis (the Heart Outcomes Prevention Evaluation [HOPE]), reductions of 20% to 30% in relative risk were achieved in primary cardiovascular morbidity and mortality end points such as death, infarction, and stroke. The observed benefits were independent of aspirin use, beta-blockers, lipid-lowering agents, and antihypertensive drugs, suggesting a unique mode of action. Interestingly, there was no effect on rate of unstable angina. Although more data are needed to confirm these important findings, clinicians should consider ACE inhibition in patients with substantial CHD risk, even if LV function is preserved. Patients already taking ACE inhibitors should certainly continue with them in addition to any other medications prescribed for control of angina.

About 10% of patients experience an intolerable *dry cough* with ACE inhibitor use, which often leads to discontinuation of therapy. *Angiotensin II receptor antagonists* (e.g., losartan) are sometimes substituted; their effect on cardiovascular morbidity and mortality in CHD patients is unknown. Also unknown is the significance of any interaction between *aspirin* and ACE inhibitors, which are likely to be used concurrently in CHD patients; none was reported in the HOPE study. Surveys of primary care practices reveal considerable underuse of ACE inhibitors in CHD patients with LV dysfunction. The attention that is likely to be given to ACE inhibition because of the HOPE study is likely to change this behavior and extend the spectrum of ACE inhibitor use if confirmed by other large-scale randomized trials.

Calcium-Channel Blockers

Drugs in this class remain popular among many clinicians and patients for treatment of chronic stable angina, because they are generally well tolerated and effective for control of symptoms. They reduce the frequency of anginal episodes, prolong exercise tolerance, and decrease the need for nitroglycerin. They are especially useful in persons with coronary vasospasm. Although symptomatically beneficial, calcium channel blockers have yet to demonstrate any reduction in rates of myocardial infarction, need for revascularization, cardiac sudden death, or overall mortality. In addition, concerns have arisen about the safety of the short-acting preparations. Recent findings from several retrospective, prospective, and meta-analytic studies suggest increased risks (relative risk, 1.5 to 1.6) of myocardial infarction and cardiac death in patients taking short-acting calcium channel blockers. Moreover, risk of cardiac death is significantly increased when calcium channel blockers are used in the setting of LV failure (see Chapter 32). In fact, many of these agents are contraindicated when coronary disease is complicated by chronic heart failure. Pending the results of randomized trials of long-acting calcium channel blockers, many authorities currently recommend that calcium channel blockers are relegated to a secondary role in management of chronic stable angina. They suggest that use should be limited to patients who cannot tolerate beta-blockers or beta-blockade or who fail to achieve adequate control of symptoms with nitrates and beta-blockade.

Mechanisms of Action. These agents typically inhibit calcium transport via the "slow" or "L-type" calcium channels of the cellular membranes in myocardial, vascular, and nonvascular smooth muscle tissues. In the heart, calcium channel blockade reduces *inotropy* and slows *conduction*; in vascular tissue, the result is *vasodilation*, which may be accompanied by *reflex tachycardia*. Responses of vascular smooth muscle to angiotensin II and catecholamines are blunted. The net effects range from coronary and systemic vasodilation to decreases in myocardial contractility and conductivity. Coronary vasodilation improves perfusion in patients prone to coronary vasospasm. In most stable anginal patients, symptomatic benefit is believed to derive from a reduction in myocardial oxygen demand brought about by reductions in contractility, filling pressure (preload), and systemic blood pressure (afterload).

Classification. The different classes of calcium channel blockers are distinguished by their binding site within the L-channel and by their relative clinical effects on myocardial, conducting system, and vascular functions. They all cause vasodilation and a lowering of blood pressure, but the degree of pressure reduction varies as does the net effect on contractility and conduction.

Dihydropyridines. Nifedipine is the prototypical agent of this class. Those approved for use in stable angina include nifedipine, *nicardipine*, and *amlodipine*. At present, only amlodipine and the long-acting formulation of nifedipine are recommended for use, because of the concerns regarding safety of short-acting calcium channel blockers. Nifedipine is the most active vasodilator of all the calcium-channel blockers. Its main effect is arterial. Both coronary and peripheral arterial dilatation result, making this agent especially useful for patients with coronary vasospasm and hypertension (see Chapter 26). Although nifedipine is negatively inotropic, its net effect

on LV function is minimal because the drug induces a strong b-adrenergic reflex response to its arterial vasodilation. In some patients, a *reflex tachycardia* occurs with use of the short-acting preparation. Its potent vasodilating effects produce a higher incidence of *flushing, hypotension, dizziness, leg edema,* and *headache* than occurs with other drugs in its class. Also, unlike the others, nifedipine has no clinically significant suppressant effect on the sinoatrial or atrioventricular nodes, making it safe for use in patients with underlying conduction system disease. Nifedipine has been shown to be effective for symptomatic treatment of chronic stable angina and variant angina. Because of concerns about increased risk of sudden cardiac death and marked reflex tachycardia with use of short-acting dihydropyridines, only the sustained-release preparation of nifedipine is currently recommended for use.

Second-generation dihydropyridines (e.g., nicardipine, isradipine, felodipine, nisoldipine) are marketed predominantly as antihypertensive agents and promoted for their "vascular selectivity" because they do not affect atrioventricular or sinoatrial node activity. They are available in sustained-release formulations but are not FDA-approved for use in chronic stable angina. Like nifedipine, these induce arterial dilation and an initial reflex tachycardia, often necessitating concurrent use of a beta-blocker. Side effects are similar to those of nifedipine (flushing, peripheral edema, headache, lightheadedness). They are less negatively inotropic than earlier calcium-channel blockers, but they are still contraindicated in the setting of concurrent chronic heart failure. Amlodipine, promoted as the most "cardiofriendly" of the dihydropyridines, has the least effect on contractility, conductivity, and neurohumoral reflexes (no reflex tachycardia) and appears safe for use in the setting of LV dysfunction (see below).

Phenylalkylamines. Verapamil is the prototype in this class, which has the most pronounced net effects on myocardial contractility and atrioventricular conduction. Even though they effectively reduce afterload, they can precipitate heart failure in patients with underlying LV dysfunction and cause heart block in patients with conduction system disease, contraindicating their use in patients with severe LV failure or marked conduction system disease. This potent ability to slow atrioventricular conduction has made verapamil extremely useful for acute treatment of supraventricular tachycardias (see Chapter 28). Constipation and leg edema are consequences of its dilating effect on gastrointestinal and venous smooth muscle.

Benzothiazepines. Diltiazem is the prototype and among the better tolerated of the calcium channel blockers. Although it more closely resembles verapamil than nifedipine, its pharmacologic profile is unique. Compared with verapamil, it causes greater slowing of the sinoatrial node but has less influence on the atrioventricular junction, contractility, and vascular tone. In studies of its effects on mortality and reinfarction in postmyocardial infarction patients, there was no overall improvement in either mortality or reinfarction; those with LV dysfunction showed increased rates of adverse outcomes, suggesting that any possible benefit is limited to those with preserved LV function.

T-type Calcium-Channel Blockers. Mebefradil blocks not only the L-type calcium channel but also the T-type (transient) calcium channel. T-type channels are found in vascular smooth muscle and conduction system tissue but not in ventricular myocardium. The result is coronary and peripheral vascular dilatation, but no impairment of myocardial contractility. Mebefradil is effective for treatment of stable angina, but whether it will prove safe for use in the setting of concurrent heart failure remains to be established.

Adverse Effects. As noted earlier, increased risks of myocardial infarction and cardiac death have been reported in patient populations taking short-acting calcium channel blockers. The extent of risk remains to be defined. Proposed mechanisms include increased myocardial oxygen demand from reflex tachycardia and decreased coronary perfusion from acute drop in filling pressure. Calcium-channel blocker use also increases the risks of worsening heart failure, life-threatening arrhythmias, myocardial infarction, and death when used in patients with chronic LV dysfunction. The mechanisms responsible for these cardiac complications remain poorly understood. It was thought that the reflex tachycardia and negative inotropic effects of many of these agents were responsible, but even the use of sustained-release preparations and agents with little effect on the left ventricle have not lowered the risk. As noted, *heart block* and *sinoatrial node suppression* may occur with use of verapamil- and diltiazem-like agents.

Use and Choice of Calcium-Channel Blockers. Given the inability of calcium-channel blockers to reduce cardiac risk and ongoing concerns regarding their safety, the use of these agents should be limited to long-acting preparations in persons who fail to achieve adequate symptomatic control with beta-blockade and nitrates. Although all classes of calcium channel blockers have antianginal activity, selection of an individual agent needs to take into account cost, convenience, and the status of the patient's left ventricle and conducting system.

Cost and Convenience. From a cost-effectiveness perspective, calcium channel blockers do not rank highly. Even the generic sustained-release formulations are as much as 5 times the cost of generic beta-blockers; brand-name formulations are 10 to 25 times more expensive. The availability of many different sustained-release preparations facilitates compliance but at the expense of increased cost.

Use in the setting of LV dysfunction is discouraged, given the increased risk of sudden death and other adverse cardiac outcomes noted earlier. Negatively inotropic agents (e.g., verapamil, diltiazem) are especially important to avoid, but even agents without much negative inotropic effect have produced poor outcomes. *Only amlodipine* appears reasonably well tolerated in anginal patients with severe chronic LV dysfunction (ejection fraction less than 30%). Why it should be the best tolerated of the calcium channel blockers remains unclear, although it is among the least negatively inotropic. However, amlodipine does not improve survival and carries a 5% risk of inducing pulmonary edema, probably because of pulmonary vasodilation. Moreover, its cost is high. An *ACE inhibitor* (see above) might better contribute to outcome in this setting.

Use in the setting of conduction-system disease necessitates avoiding agents that suppress conduction system and/or sinus node function (e.g., verapamil and diltiazem respectively). Nifedipine and the second-generation dihydropyridines (e.g., amlodipine) are preferred. Moreover, their marked effects on noncardiac smooth muscle result in the highest incidence among calcium channel blockers of extracardiac side effects such as peripheral edema, flushing, and postural hypotension.

Antiplatelet Therapy and Oral Anticoagulation

With the increasing appreciation for the roles of platelets, clotting factors, and vascular reactivity in coronary artery disease comes renewed interest in the benefits of inhibiting platelet function and thrombus formation.

Antiplatelet Therapy. Of the conventional platelet inhibitors (e.g., aspirin, dipyridamole, sulfinpyrazone), only aspirin has proven effective in reducing cardiac risk. Aspirin prolongs survival in patients with *unstable angina* and reduces the risk of myocardial infarction in persons with *chronic stable angina*. In The Physicians' Health Study, participants with chronic stable angina demonstrated an 87% reduction in risk of myocardial infarction and a trend toward reduced risk of death from infarction; however, there was also a trend toward an increase in risk of hemorrhagic stroke. Aspirin therapy did not prevent the onset of angina.

New antiplatelet therapies are emerging. A promising approach for acute settings is use of *monoclonal antibodies* that block platelet *glycoprotein IIb/IIIa receptors*, which are important to platelet aggregation and thrombus formation. Initial studies show a 50% reduction in periprocedural infarction when used with angioplasty and reduced rates of infarction in the setting of unstable angina when added to a program of aspirin and heparin. Use in stable angina is not established; results of initial studies show results similar to those for aspirin.

Oral Anticoagulation. Meta-analysis of major randomized controlled trials of warfarin therapy in patients with CHD reveals significant reductions in myocardial infarction, stroke, and cardiovascular death with high-intensity (INR 2.8 to 4.5) oral anticoagulation. Risks of infarction and stroke are reduced with moderate intensity (INR 2.0 to 3.0) therapy. The benefits of high and moderate intensity anticoagulation approximate those seen with use of aspirin, but risk of bleeding is increased in proportion to the intensity of oral anticoagulation. Combining aspirin use with moderate intensity oral anticoagulation appears promising but remains to be confirmed.

Treatment of Cardiovascular Risk Factors and Precipitants

Risk Factors. An essential component of the management program is attention to cardiovascular risk factors. Patients with coronary disease have five times the risk of a coronary event. Secondary preventive efforts can improve quality of life, reduce risk of coronary events, obviate the need for revascularization, and prolong survival, especially those that address *hypercholesterolemia* (see Chapter 27), *hypertension* (see Chapter 26), *smoking* (see Chapter 54), *diabetes* (see Chapter 102), *exercise* (see Chapter 18 and Chapter 31), and *emotional stress* (see below and Chapter 31 and Chapter 226). The value of treating *hyperhomocysteinemia* remains to be established, and there continues to be much debate about the benefit of *hormone replacement* (see Chapter 31).

Risk factor reduction can be just as important to outcomes as properly implemented medical and surgical therapies, as evidenced by a randomized trial of aggressive lipid-lowering therapy compared with angioplasty in patients with mild-to-moderate stable angina. Lipid lowering was equal to if not better than angioplasty with

regards to reducing frequency of future cardiac events (Atorvastatin versus Revascularization Treatment study).

Precipitants. *Smoking* and *hypertension* are not only CHD risk factors but also potentially important precipitants of angina. The absorbed nicotine increases blood pressure and heart rate, thus increasing myocardial oxygen demand. Nicotine may also cause vasospasm, and the rise in carboxyhemoglobin from smoke inhalation cuts down on oxygen delivery. Even passive smoking (from being in a smoke-filled room) can reduce exercise tolerance in patients with stable angina. Cessation of smoking can be psychologically stressful and physically uncomfortable, but the immediate and long-term benefits greatly outweigh the short-term discomfort. The development of symptomatic coronary disease may provide a potent stimulus to smoking cessation; the effort often succeeds when the physician takes a strong interest in achieving it (see Chapter 54). Hypertension can exacerbate angina by raising myocardial oxygen demand through its effect on afterload.

Psychological stress is well recognized as an important precipitant, but only recently has it been appreciated how common stress-induced ischemia is in patients with coronary artery disease. Episodes of silent ischemia and symptomatic ischemia have been documented in stressful situations. Public speaking and difficult mental tasks can induce as much symptomatic and silent ischemia as exertion in patients with coronary artery disease. High levels of life stress and social isolation are independent predictors of death from coronary disease. The role of personality style, such as so-called type A behavior, remains a subject of debate, although the evidence from studies of mental stress suggests that coronary patients who have a low tolerance for frustrating circumstances might be expected to have an increased likelihood of ischemic stress responses.

Addressing the psychosocial stresses that the anginal patient encounters is critical. An adequate evaluation includes a thorough psychosocial history with emphasis on those factors contributing to stress and social isolation. Urging the hard-driving impatient person to change their personality style is counterproductive, but counseling them on means of coping with frustration and introducing them to simple *relaxation techniques* (see Appendix of Chapter 226) may be better appreciated. If acute anxiety or situational stress is known to predictably precipitate severe chest pain or significant silent ischemia, occasional prophylactic use of a *minor tranquilizer* may be warranted. However, frequent benzodiazepine use in the absence of a true anxiety disorder is strongly discouraged because it can lead to tolerance and even addiction (see Chapter 226); furthermore, tranquilizer use is no substitute for an adequate medical regimen. *Beta-blocker* therapy can be quite effective in limiting the adverse cardiac effects of anxiety by blocking the attendant adrenergic discharge.

Depression and *anxiety* are common responses to the diagnosis of coronary disease; they can impair not only the patient's psychological sense of well-being but also the physical responses to medical and interventional therapies. Moreover, anxiety is a risk factor for cardiac sudden death, and depression is more powerful predictor of heart disease than personality style. After a year of proper therapy for angina, any untreated anxiety or depression correlates more closely with exercise capacity and functional status than the severity of the underlying coronary disease. Despite receiving and complying with proper antianginal regimens, patients with these psychological states manifest more physical incapacity than patients free of active depression or anxiety. The close link between these states and functional status makes it imperative to check for and treat anxiety and depression (see Chapter 226 and Chapter 227) at the time of initial CHD workup and again during implementation of the antianginal program. Patients who fail to respond to what seems to be a properly instituted cardiac regimen should be evaluated for an underlying affective disorder.

Other precipitants that should be checked for and addressed include severe *anemia* (see Chapter 82), *hyperthyroidism* (see Chapter 103), *heart failure* (see Chapter 32), and *hypoxemia* due to lung disease (see Chapter 46 and Chapter 47). All are capable of worsening both symptomatic and silent myocardial ischemia in the context of underlying coronary disease. Neither *coffee* nor *caffeine* consumption has been shown to increase the risk of coronary disease, although an oft-quoted epidemiologic study found a minor trend toward increased risk in patients consuming more than four cups of decaffeinated coffee per day.

Exercise can significantly improve functional status and directly and indirectly improve important outcomes by improving skeletal muscle efficiency, decreasing heart rate and blood pressure, and enhancing moral well-being (see Chapter 18 and Chapter 31).

Designing the Medical Regimen

Criteria for Inclusion. With such a vast array of available medical therapies, the first priority is to ensure that the medical program includes those measures proven to enhance major outcomes. The goal is not only to eliminate anginal pain but also to reduce the risks of myocardial infarction, need for revascularization, and cardiac death. Consequently, *beta-blockade, aspirin*, and *aggressive control of cardiovascular risk factors* should be incorporated whenever possible into the medical regimen. In persons with LV dysfunction (and possibly in those with preserved LV function), an *ACE inhibitor* is essential to maximizing survival. In addition, any *precipitating factors* must be identified and addressed, because they can have major effects on response to treatment. The program should include an *exercise program* to enhance functional status. Surveys of CHD patients in primary care practices often find underuse of therapies with proven benefit (e.g., beta-blockers, ACE inhibitors). A common error is to focus on relief of angina and ignore overall cardiovascular risk; patients are prescribed nitrates and calcium channel blockers, but not beta-blockers, ACE inhibitors, aspirin, and treatment that aggressively reduces cardiovascular risk factors.

Evidence to guide selection of treatment modalities for patients with stable angina suffers from the tendency of investigators to concentrate their efforts on postinfarction populations. A number of recommendations for patients with stable angina are extrapolations from postinfarction studies (e.g., the mortality benefit of beta-blockers). More long-term studies using cardiac events and mortality as outcomes are needed to validate these recommendations for anginal patients who have not infarcted. Pending such data, it seems reasonable to extrapolate the medical recommendations to this population, especially because most measures are well tolerated, relatively inexpensive, and safe. To withhold them might risk losing an opportunity to improve outcomes. Extrapolation of revascularization recommendations is not another story, because the risks associated with interventional therapy are much higher (see below).

Commonly Used Combinations of Antianginal Agents. Combining *nitrates* with *beta-blockers* usually achieves good symptomatic control at low cost and takes advantage of the positive contribution of beta-blockers to major outcomes. In general, *calcium channel blockers* should be relegated to a second-line role and avoided in the setting of LV dysfunction. Nonetheless, they may add a degree of symptomatic relief when added to a program of beta-blockade in persons free of conduction disturbances and LV dysfunction (most calcium channel blockers are contraindicated in heart failure; see Chapter 32).

The combination of *nitrates plus a calcium channel blocker* is occasionally worth considering in very symptomatic patients who cannot tolerate beta-blockade (e.g., those with severe bronchospastic disease). The calcium channel blocker should be one that blunts reflex tachycardia (e.g., diltiazem, verapamil). Such a program may be particularly effective in patients with stubborn vasospastic disease, but it must be undertaken with care because of the potential for hypotension and worsening angina.

Adding a *calcium channel blocker* to a program of *beta-blockade* and *long-acting nitrates* is sometimes useful, especially in persons with suspected vasospasm or a need to decrease doses of the other agents due to bothersome side effects.

Combined use of a beta-blocker and a calcium channel blocker often requires reduced doses of both agents due to the risks of adversely affecting contractility, chronotropy, conduction, and blood pressure. Concurrent use of potent arterial vasodilators (e.g., alpha-blockers, centrally acting vasodilators) is to be avoided due to the risk of serious hypotension. Care is also required when combination therapy is used in conjunction with digoxin, because of potential for further suppression of conduction through the atrioventricular node.

Revascularization

Revascularization provides the opportunity to improve coronary blood flow, control of angina, and exercise tolerance. In high-risk patients, risk of infarction is reduced and long-term survival is enhanced. The principal revascularization modalities are *percutaneous transluminal angioplasty* (PTCA) and *coronary artery bypass graft* (CABG) surgery. Both procedures have become among the most commonly performed invasive therapies in the nation, with over 500,000 performed annually. Considerable debate has surrounded the indications for their use, because of widespread uncritical use before randomized study. The indications for CABG have become much clearer with completion of major multicenter studies of long-term survival. Meanwhile, the indications for PTCA continue to expand as the technology improves and controlled data emerge. Outcomes from *directional atherectomy* remain disappointing because of unacceptably high complication rates due to debris and endothelial damage associated with the procedure.

Angioplasty. PTCA was developed as an alternative to surgical revascuariztion for patients who remain unacceptably symptomatic despite medical therapy yet do not have high-risk disease (Table 30.1), which is an absolute indication for CABG. Angioplasty involves passing a balloon catheter into a stenosed vessel and inflating the balloon at the site of the narrowing to widen the lumen. It requires coronary angiography and, when performed on a critical artery, surgical standby, given the risk of sudden vessel occlusion from manipulation leading to infarction. A *high-grade proximal stenosis* (70%) that is smooth, concentric, less than 0.5 cm in

length, and noncalcified is considered the lesion most amenable to PTCA treatment. The immediate success rate for PTCA in patients with favorable lesions is in excess of 85%. The insertion of a wire-mesh *stent* with PTCA improves patency and reduces the risk of restenosis. Rapid advances in stent technology have led to their widespread application; well over a half-million stenting procedures are being done annually, both for initial treatment of stenoses and for restenosed vessels. Although PTCA with stenting has become commonplace, its cost effectiveness and long-term impact on cardiovascular morbidity and mortality remain to be established. Of note, use of medical therapy does not appear to decline after PTCA, despite a decline in angina.

Benefits. Symptomatic low-risk patients receiving PTCA demonstrate better symptomatic relief and exercise tolerance at 6 months of follow-up than do those treated medically, although there is a small risk of periprocedural myocardial infarction. Patients randomized to PTCA versus CABG achieve nearly equivalent outcomes for cardiac morbidity and mortality at 5 years (86.6% vs. 89.3%), but over half of those treated with PTCA require a repeat revascularization within 1 to 3 years; up to one third eventually come to bypass surgery. Risk of Q-wave infarction is higher for CABG in the short run, but equals out over time. Among subgroups, diabetics may do better with CABG compared with PTCA.

The long-term safety, efficacy, and cost effectiveness of PTCA compared with medical therapy and bypass surgery remain to be defined. The literature should be followed closely, as there will be much data forthcoming, especially on use of PTCA with stenting in higher risk patients such as those with left-main and left-main-equivalent disease. Sorely needed are large-scale, randomized, controlled trials comparing PTCA, CABG, and medical therapy with regards to long-term cardiovascular morbidity and mortality. To date, the end points of many studies have been limited to symptom relief, exercise tolerance, quality of life, and short-term risks of restenosis, complications, and cardiac events; more data are needed on long-term outcomes. The hope is that the technologic advances afforded by PTCA with stenting will result in superior outcomes and expand its indications. Whether this mode of revascuzriztion will prove a cost-effective alternative to surgery and to medical therapy remains to be demonstrated. The currently high rates of restenosis (see below) make repeat revascularization procedures more likely; this needs to be factored into the calculation of relative costs and benefits and discussed with patients as they choose between treatment alternatives.

Risks. The risk of *restenosis* with PTCA alone is substantial (e.g., 25% to 40% at 6 months) but can be reduced by nearly 50% by stent use. Because stent placement can trigger *acute thrombosis* (heralded by angina) or *subacute thrombosis* (manifested by acute infarction or death), the procedure is followed immediately by 2 to 4 weeks of potent antiplatelet therapy. Currently prescribed regimens include *aspirin* plus *ticlopidine, clopidogrel* (which lacks the marrow-suppression risk of ticlopidine), and *abciximab* (which blocks platelet glycoprotein IIb/IIIa receptors). Trials are ongoing to determine the optimum program. With antiplatelet therapy, the rates of stent-related acute and subacute thrombosis are markedly reduced (e.g., less than 0.5% and less than 1.5%, respectively). Other periprocedural risks include *bleeding* and *vascular injury* that require urgent surgical repair (1%), coronary *artery perforation* (less than 1%), *infection* (rare), and contrast-induced nephropathy (0 to 44% depending on presence of underlying kidney disease).

After 6 months of patency, the reappearance of angina usually represents progression of another lesion that was not dilated rather than late restenosis. Nonetheless, in-stent restenosis (more than 50% reduction in lumen diameter) remains a concern and can occur in up to 20% to 30% of patients. Most patients remain asymptomatic, but those that do redevelop angina pose a difficult challenge because treatment is problematic. Intimal neoproliferation is believed to be a contributing factor; methods to minimize it are being sought (e.g., local application of radiation).

Costs. Angioplasty represents a multibillion dollar health care expenditure in the United States annually. Per patient, total costs of PTCA plus stenting can reach thousands of dollars. Although the cost of a PTCA-plus-stenting procedure remains a fraction of that for CABG, it still represents a substantial expenditure, especially if it needs to be repeated. Moreover, medical therapies that prolong survival are often continued, negating major cost savings from reduction in medication use. Cost-effectiveness data are needed.

Indications. For those anginal patients who have unacceptably symptomatic *single- or two-vessel disease without LV dysfunction*, PTCA represents a reasonable *alternative* to medical therapy and to bypass surgery. At present, *moderate-risk patients* with considerable angina are typically offered PTCA as the *initial treatment* because it can be more effective than medical therapy for relief of anginal symptoms; *low-risk patients* can be offered PTCA if they *fail medical therapy*. For patients with preserved LV function who respond well to medical therapy and demonstrate good exercise tolerance, medical therapy is currently preferred, given the good prognosis it affords, especially in conjunction with aggressive lipid lowering.

Contraindications. In addition to local anatomic considerations (stenosis near a branch point, diffuse occlusive disease of a vessel, involvement of a smaller vessel), there are a number of other settings in which PTCA does not appear successful. In patients with *left-main* or *three-vessel disease*, the risk of PTCA is greater than that of CABG, which remains the treatment of choice in patients who can undergo surgery (see below). As with bypass surgery, high rates of restenosis have occurred in patients with *variant angina*, making this form of revascularization ill advised in patients with vasospastic disease.

Coronary Artery Bypass Graft Surgery. Surgical revascularization is the treatment of choice in persons with *high-risk disease* (Table 30.1). It not only improves symptoms and functional status but prolongs survival and reduces risk of infarction.

Benefits. Three landmark studies established CABG as the treatment choice for high-risk patients. In the Veterans Administration (VA) study of bypass surgery in patients with stable angina, those with *left-main disease* randomized to surgery experienced significant improvements in rates of *infarction* and survival (average annual mortality fell from more than 10% to 3%). Also benefiting were markedly symptomatic patients with *three-vessel disease* and *LV dysfunction* but not those with normal LV function and disease limited to two vessels. The Coronary Artery Surgery Study included patients with less serious illness (no left-main disease or severe angina); again, only high-risk patients—those with three-vessel disease and LV dysfunction—showed a statistically significant improvement in rates of infarction and cardiac death. The European Coronary Artery Surgery Study confirmed improved survival in patients with left-main disease and found that benefit also accrued to those having *three-vessel disease* with *preserved LV function* and to those with *two-vessel disease* that included a high-grade proximal stenosis of the left anterior-descending coronary artery ("*left-main equivalent*" anatomy). *Late graft occlusion* has reduced some of the apparent advantages of surgical therapy that were noted enthusiastically in earlier reports. Use of the left internal mammary artery for grafting reduces the rate of late graft occlusion to 15% at 10 years. Risk factor modification remains important, even after bypass surgery.

Patients with less severe multivessel disease (Table 30.1) do not experience a survival benefit with revascularization but may achieve *symptom relief* when medical therapy proves inadequate. At issue is whether surgery or angioplasty is the preferred approach to revascularization in such patients. Meta-analyses find the rates of survival and cardiac events to be similar (except for diabetics, who do better with CABG), as are the effects on symptoms, but PTCA patients are nearly 10 times much more likely (risk approaching 50%) to require a repeat revascularization procedure within 3 to 5 years.

Risks. In major centers, the perioperative complication rates for elective CABG in high-risk patients include mortality (2%), infarction (2.5%), arrhythmia (10%), major bleeding requiring reoperation (2%), stroke (1%), and embolization (1%). Higher complication rates are found in hospitals that do relatively fewer bypass procedures per year.

Indications. In sum, bypass surgery is superior to medical therapy for prevention of infarction and prolongation of survival in stable high-risk anginal patients (i.e., those with significant *left-main, proximal left-anterior descending*, or *three-vessel disease*, especially if accompanied by *LV dysfunction*). Patients at less risk who continue to be limited by their angina despite a full medical regimen and aggressive treatment of risk factors are also reasonable candidates for revascularization. CABG is the preferred revascularization procedure for diabetics and those patients who are reluctant to undergo a repeat revascularization procedure within the next 5 years.

Contraindications. Most studies of surgical therapy for patients with *coronary spasm* show disappointing results (e.g., higher rates of mortality and nonfatal infarction). In such patients, surgical therapy should be considered only when medical therapy has failed and spasm has been documented in or about an area of fixed critical stenosis and not in other vessels or distally.

Identifying Candidates. Exercise stress testing and echocardiography are the best noninvasive means of screening and identifying potential candidates for revascularization (see Chapter 20 and Chapter 36). Those demonstrating a large amount of myocardium at risk and/or a reduced ejection fraction are candidates for angiography.

Overall Strategy: Choosing between Initial Medical Therapy and Revascularization

A practical management strategy supported by currently available evidence assigns the patient to initial medical therapy or revascularization on the basis of estimated

risk and degree of incapacity as determined by stress testing, echocardiography, and severity of symptoms:

- *Low-risk patients* (mild-moderate angina, normal ejection fraction, small amount of myocardium at risk, probable single-vessel disease): Medical therapy, with revascularization reserved for those incapacitated by angina despite full medical therapy and aggressive risk factor reduction.
- *Moderate-risk patients* (moderate severity of angina, moderate amount of myocardium at risk, probable two-vessel disease, normal ejection fraction): Initial revascularization (PTCA or CABG) if very symptomatic; if not, a trial of medical therapy and aggressive risk factor reduction.
- *High-risk patients* (moderate to severe angina; large amount of myocardium at risk; three-vessel, left-main, or left-main-equivalent disease; reduced ejection fraction): CABG plus ACE inhibitor therapy.

Regardless of the initial mode of therapy, all patients require aggressive treatment of CHD risk factors, because of the major contribution to outcome that accrues with smoking cessation, control of hypertension, and reduction of lipids.

Patient Education

Patient education is pivotal, both to ensure proper compliance with what can be a rather complex medical regimen and to maximize functional status. An understanding of the rationale behind the medical regimen will facilitate its effective use. Counseling about prognosis and allowable activity can prevent unnecessary restriction of activity, relieve fear, and improve life-style. Of particular concern to many patients is the safety of engaging in *sexual intercourse.* The issue should be addressed openly and directly, even if the patient does not take the initiative to raise the subject. Failure to do so can lead to marital problems, depression, and a worsening of symptoms. Guidelines for engaging in sexual activity are similar to those for any other form of physical exertion. The oxygen demands of intercourse among married middle-aged partners are about the same as those for climbing a flight of stairs. If intercourse takes place among unaccustomed partners, the physical and emotional stress may be considerably greater and the oxygen requirements increased substantially. If patients have serious concerns as to how much activity they can safely tolerate, an exercise test may be of value for reassurance, especially if they are needlessly limiting themselves.

With advances in medical therapy and revascularization technology, patients now have an expanded choice of treatment options. In circumstances where outcomes are similar, the advantages and disadvantages of PTCA versus CABG versus medical therapy need to be reviewed so that a treatment program well tailored to the patient's needs and preferences can be designed. Many of the racial differences noted in rates of revascularization among whites and blacks in the United States appear to be a function of familiarity rather than preference. Patient education is essential to ensuring that there is not inappropriate underutilization. Despite obtaining cardiac consultation, many patients will ask the independent opinion of their primary care physician whom they view as knowing them best. This role necessitates keeping well informed on the risks and benefits of treatment options for stable angina.

Indications for Admission and Referral

Admission is required when the anginal pattern is increasing in frequency or severity or is becoming harder to control. Episodes that are starting to last more than 15 minutes and beginning to occur at rest and with exertion suggest progression to *unstable angina*, with its attendant increase in risk of acute infarction. Hospitalization may also be of benefit to judge the adequacy of a medical regimen and to check on compliance when a patient with stable angina reports insufficient relief of symptoms. Referral to a cardiologist for consideration of coronary angiography and angioplasty is indicated when maximum medical therapy has failed to control symptoms and when left-main or severe three-vessel disease is suspected. The same is true if tight aortic stenosis is a consideration (see Chapter 33).

THERAPEUTIC RECOMMENDATIONS

General Measures for All Patients (including Those Undergoing Revascularization)

- Identify and aggressively treat all major CHD risk factors, particularly hypertension (see Chapter 26), hyperlipidemia (see Chapter 27), and smoking (see Chapter 54).
- Check for and correct any concurrent precipitating or aggravating factors, such as heart failure (see Chapter 32), severe anemia (see Chapter 82), hyperthyroidism (see Chapter 104), hypoxemia (see Chapter 47), and critical aortic stenosis (see Chapter 33).
- Screen for and treat psychosocial factors that can adversely effect outcomes, including anxiety (see Chapter 226), depression (see Chapter 227), situational stress, and social isolation.
- Begin low-dose enteric-coated aspirin (81 mg/d).
- Consider ACE inhibitor therapy; initiate if the patient has a reduced ejection fraction (less than 0.4) (see Chapter 32), consider for the CHD patient with preserved LV function and multiple CHD risk factors (e.g., diabetes, hypertension).
- Determine patient's prognosis and degree of CHD risk by ascertaining amount of myocardium at risk through stress testing (see Chapter 36) and by assessing LV function through echocardiography or radionuclide scanning (see Chapter 32 and Chapter 36). Use the risk categorization to guide further program design.
- Thoroughly review with patient and family the rationale and proper use of therapies; encourage monitoring response to treatment; counsel on allowable activity, encourage exercise as tolerated, and help avoid self-imposed unnecessary limits on activity.
- Begin a gentle exercise program (e.g., walking 20 minutes three times a week) and a more intensive program for the highly motivated; obtain an exercise stress test first (see Chapter 31).
- Promptly admit any patient with unstable angina or markedly worsening LV dysfunction and obtain cardiac consultation.

Low-risk Patients (Mild-to-Moderate Angina, Normal Ejection Fraction, Small Amount of Myocardium at Risk, Probable Single-vessel Disease)

- Prescribe as needed TNG, 0.4 mg, for symptomatic relief of anginal episodes; instruct the patient to rest at the time of pain and to take a second and a third TNG if the pain does not resolve within 5 minutes of each TNG dose. Advise maintaining a fresh supply of TNG and discarding any bottle that has been open for more than 6 months or any tablets that fail to cause sublingual burning or head throbbing.
- Prescribe prophylactic use of sublingual TNG if angina is predictable and short-term (less than 30 minutes) protection will suffice (e.g., before carrying bundles, climbing stairs or a hill).
- Begin beta-blockade with a generic formulation of a long-acting cardioselective agent (e.g., atenolol 25 to 50 mg/d or metoprolol 25 mg twice daily); adjust dose to ensure adequate beta-blockade (heart rate less than 60 beats/min at rest, less than 100 beats/min with vigorous exertion). If beta-blockade must be terminated, do so only in a tapering fashion over 1 to 2 weeks; have the patient reduce activity during this time.
- If anginal control is not sufficient with the above measures but the patient responds well to TNG, then add a long-acting nitrate to the program (e.g., isosorbide dinitrate, beginning with 5 mg three times a day and advancing slowly over 1 to 2 weeks in increments of 5 mg per dose); dose in asymmetric fashion (8 a.m., 2 p.m., 8 p.m.) to minimize risk of nitrate tolerance.
- Consider a trial of calcium channel blocker therapy (e.g., long-acting diltiazem 90-120 mg/d, amlodipine 5 mg/d) only if the patient continues to be unacceptably symptomatic despite full doses of nitrates and beta-blockers. Use only a long-acting formulation. Monitor conduction and LV function, especially when using in combination with a beta-blocker. With the exception of amlodipine, do not use if there is underlying heart failure or clinically significant conduction system disease.
- Consider referral for angiography and possible revascularization only if the patient continues to be unacceptably limited by angina despite full compliance with the above medical regimen plus aggressive treatment of CHD risk factors.

Moderate-risk Patients (Moderate Angina, Moderate Amount of Myocardium at Risk, Probable Two-Vessel Disease, Normal Ejection Fraction)

- Give trial of full medical regimen as outlined for patients with low-risk disease. If it provides adequate control of symptoms, then continue indefinitely in conjunction with very aggressive and comprehensive treatment of CHD risk factors and precipitants.
- If exercise tolerance and functional status remain impaired, then refer for angiography and determination of candidacy for revascularization.
- If candidate for revascularization, assess patient's preference for PTCA vs CABG.

High-risk Patients (Moderate-to-Severe Angina; Large Amount of Myocardium at Risk; Suspected Three-Vessel, Left-Main, or Left-Main-Equivalent Disease; Reduced Ejection Fraction)

- Refer immediately for angiography and consideration of CABG.
- Recommend CABG for those found to have left-main, left-main equivalent, or three-vessel disease, especially if complicated by LV dysfunction. (Some proximal

LAD lesions might be suitable for PTCA plus stenting.)

CHAPTER 31 CARDIOVASCULAR REHABILITATION AND SECONDARY PREVENTION OF CORONARY HEART DISEASE

ALLAN H. GOROLL

INTRODUCTION

The major goals of cardiovascular rehabilitation and secondary prevention of coronary heart disease (CHD) (i.e., prevention in patients with established disease) are to improve functional capacity, reduce the risks of future cardiac events (e.g., infarction, revascularization, cardiac arrest), and prolong survival. The results of major long-term randomized controlled trials indicate that these goals can be achieved cost effectively through concerted application of preventive therapies. Some modalities are medical (e.g., aspirin, beta-blockers, angiotensin-converting enzyme [ACE] inhibitors), and others are interventional (e.g., revascularization). Those that address risk factors have the unique capacity to stabilize and even induce regression of the atherosclerotic process, yielding some of the greatest reductions in risk when applied aggressively.

Because some interventions require changes in the patient's life-style, the influence of the primary physician is critically important. One needs to know what interventions are effective and how to tailor a secondary prevention program to the needs and capabilities of the individual patient. Upon experiencing a myocardial infarction (MI) or receiving a diagnosis of coronary artery disease, most patients become highly motivated to live a more healthy life-style, providing an excellent opportunity to effect important changes in diet and exercise as part of a comprehensive program of risk reduction through secondary prevention.

CARDIAC REHABILITATION: EXERCISE AND LIFE-STYLE MODIFICATION PROGRAMS

Goals. A program of cardiovascular rehabilitation usually begins in the hospital at the time of a acute cardiac event and continues in outpatient setting after discharge. The major goals of the *inpatient phase* include prevention of physical deconditioning, patient education regarding coronary risk factors, and interventions aimed at preventing psychological disability resulting from the anxiety and depression that frequently follow an acute coronary event. In the *early outpatient convalescence phase*, the goal is to return the patient to the level of physical conditioning that existed before the cardiac event. The *late convalescence/physical training phase* is designed to enhance the patient's physical conditioning. The goal of the maintenance or follow-up phase is to encourage life-long adherence to good health habits. The rehabilitation effort combines an exercise program with dietary modification and aggressive treatment of risk factors.

Phase I: Early Rehabilitation. This phase begins *during hospitalization* for an acute coronary event. Physical deconditioning is avoided by initiating a program of low-level activity as soon as possible after clinical stability has been achieved. In practice, low-level activity can begin safely as soon as the third day after admission for an uncomplicated MI, as soon as symptoms have been controlled in patients admitted for medical therapy of angina, and as soon as the patient who has undergone coronary artery bypass surgery can walk. Initial activity should consist of *slow walking* (60 to 80 steps a minute); the heart rate should not exceed 15 to 20 beats/min above the resting level (or 10 to 15 beats/min above the resting value in patients receiving *b*-adrenergic blocking agents). An alternative low-level activity program can be initiated during hospitalization with a *stationary bicycle ergometer* in the free-wheeling mode, where the systemic oxygen consumption is only 1.3 times resting oxygen consumption. This low level of activity is comparable in intensity with slow walking and is quite safe for most patients. Either mode effectively prevents skeletal muscle deconditioning and atrophy. Low-level activity also improves morale; patients believe they are contributing positively to the recovery process. Before hospital discharge, most patients should be observed by their physician while *climbing a flight of stairs.* This will provide confidence that such tasks can be performed safely and will often uncover specific questions about what should and should not be done during the first weeks at home.

Submaximal exercise testing before hospital discharge has been recommended and is performed routinely in many centers. A treadmill exercise test to a 5-met level has been found to be safe even when performed within 10 days of an uncomplicated MI. Successful completion of an exercise test before discharge from the hospital helps to restore patient confidence and suggests that the recovery process is proceeding smoothly. The information obtained has prognostic implications and may be useful in patient management. A negative submaximal test predicts an excellent prognosis during the subsequent year, whereas a test that is positive for ischemic electrocardiographic changes with or without anginal symptoms predicts a poorer outcome. In the latter instance, a more aggressive medical approach, coronary angioplasty, or coronary artery bypass surgery may be indicated (see Chapter 30). Exercise testing can also be effective in exposing latent ventricular dysrhythmias and may help in selecting patients whose long-term prognosis may benefit from *b*-adrenergic blocker therapy (see Chapter 29 and Chapter 30). In addition, the procedure helps in deciding which patients can safely undergo early discharge. Radionuclide scintigraphy in conjunction with submaximal exercise testing may sharpen risk stratification after MI, especially if the resting electrocardiogram is abnormal, prohibiting an electrocardiographic stress test (see Chapter 36).

Phase II: Early Convalescence. It begins at the time of hospital discharge and continues for 3 to 6 weeks. Because evidence from experimental animal models suggests that high-level physical activity soon after MI may promote infarct expansion and possible ventricular aneurysm formation, the prescribed activity level remains relatively low during phase II. Exercise intensity is regulated by monitoring peak heart rate, which should not exceed the level achieved during the predischarge submaximal exercise test. If the predischarge exercise test disclosed ischemic electrocardiographic changes, anginal symptoms, or ventricular dysrhythmias, then the heart rate during exercise training sessions should be maintained below the heart rate at which any of these pathologic events was observed. The exercise training modalities used during phase II, as in phase I, usually consist of *walking* and *stationary bicycling.* The process of educating the patient and the family about coronary risk factors is an important component of phase II (see below).

Phase III: Late Convalescence/Physical Training. The program is designed to increase the patient's level of physical conditioning. Based on a *maximal exercise test* performed 3 to 6 weeks after discharge, the exercise prescription is rewritten to provide a greater *physiologic training* effect. This test allows the patient's heart rate and blood pressure responses to exercise to be quantified and provides another screening test for latent myocardial ischemia and ventricular dysrhythmias. The exercise training modalities used during phase II can be broadened during phase III to establish a balanced exercise program that will have long-term patient appeal. Upper extremity conditioning may be added, especially in patients for whom upper extremity work is important to daily activity. During phase III, efforts to modify risk factors continue. These include *dietary interventions* to lower the total serum cholesterol and low-density-lipoprotein cholesterol concentrations, raise high-density-lipoprotein cholesterol concentration, and achieve ideal body weight (see below and Chapter 27 and Chapter 233). *Hypertension control* (see Chapter 26) and *smoking cessation* (see Chapter 54) are critically important. *Management of psychological stress* and *depression* should also be addressed (see Chapter 226 and Chapter 227), particularly as the patient returns to work. A well-balanced cardiac rehabilitation program attends to all these factors and should involve the patient's family as well.

Phase IV: Maintenance/Follow-Up. The goal is to encourage life-long adherence to the healthy habits established during phase III. Follow-up visits at 6- to 12-month intervals are important. Blood pressure and pulse measurement, serum lipid levels, and even repeat maximal exercise tolerance tests can provide useful feedback to the patient and indicate areas that may require life-style change to minimize coronary risk. Further research is needed to improve our understanding about the most effective methods of achieving permanent life-style modification.

Mechanisms of Benefit from Exercise. Regular physical exercise may benefit patients with coronary artery disease by a number of mechanisms. Among these is the "*physiologic training effect.*" Because of the increase in peripheral oxygen extraction by working skeletal muscles and the increase in cardiac stroke volume that constitute the training effect, the cardiovascular system of the trained subject is able to deliver a given quantity of oxygenated blood to the peripheral tissues at a lower heart rate. Because systemic arterial pressure also tends to be somewhat lower during exercise in the trained state, the rate-pressure product (heart rate × systolic arterial pressure), which correlates closely with myocardial oxygen consumption under most physiologic conditions, is often substantially lower than in the untrained state. The benefit to the patient with ischemic heart disease is obvious; it becomes possible for the trained patient to exercise to a higher level before reaching the critical rate-pressure product at which myocardial ischemia develops. *b*-Adrenergic blockers benefit patients with angina pectoris in a similar fashion, by reducing heart rate and blood pressure during exertion. Unlike exercise training, however, beta-blocking agents also tend to *reduce the maximal cardiac output* that

can be achieved during exertion and thereby also decrease maximal oxygen consumption and exercise capacity.

Exercise training may benefit patients with cardiovascular disease by other physiologic mechanisms as well. Aerobic exercise training results in *dilatation of large coronary arteries*, and this effect may diminish the hemodynamic compromise from existing coronary artery lesions. Some evidence also suggests that exercise training may improve collateral blood flow to ischemic zones. Coronary blood flow under conditions of maximal coronary vasodilation may also be increased. Whatever the mechanism, myocardial perfusion has been observed to increase by 25% to 50%. Another important beneficial effect is an *increase in high-density-lipoprotein cholesterol* concentration (see [Chapter 15](#)). Potentially important protective mechanisms of aerobic exercise include an *increase in fibrinolytic response* to occlusive stimuli in the trained state and an *increase in the myocardial ventricular fibrillation threshold*, rendering it less vulnerable.

Effects of Programs on Morbidity, Mortality, and Quality of Life. Cardiac rehabilitation programs for secondary prevention reduce all-cause mortality, cardiovascular mortality, and fatal reinfarction by 20% to 25%. The best effect is on sudden death, which declines by over 35%. Quality of life also increases as patients regain confidence and develop a better sense of physical well-being. Because the data derive from comprehensive exercise rehabilitation programs that also incorporate such efforts as smoking cessation, dietary modification, and stress reduction, it is difficult to know the precise proportion of benefit due to exercise alone.

Cost Effectiveness. Cardiac rehabilitation programs are cost effective. Their cost effectiveness is achieved by reductions in rates of rehospitalization, length of stay, and charges per hospitalization.

Program Design: How Much and What Type of Exercise? *Motivating the Patient.* Views about the amount of exercise needed to reduce cardiovascular risk are undergoing considerable change. The classic assumption was that one must achieve a physiologic training effect to obtain health benefits and that such a training effect requires *aerobic (endurance) exercise* (running, jogging, fast walking, cycling, rowing, cross-country skiing, swimming) performed at least *four times a week for at least 30 minutes a session*, resulting in a heart rate of 70% to 85% of a predicted maximum. However, significant reductions in coronary risk do not require attainment of maximum cardiopulmonary fitness. Moderate degrees of exercise may provide nearly equivalent results. Persons with low baseline levels of activity demonstrate the greatest improvement in outcomes with exercise training, even if exercising only moderately (e.g., walking 3 to 4 miles/h). Epidemiologic data suggest that simple informal exercise carried out as part of everyday life (e.g., walking, stair climbing, working in the yard) confers survival benefit. The current consensus recommendation for the inactive person is to *accumulate a total of 30 minutes* of moderate exertion over the course of the day rather than to put in 30 minutes of exercise at a single session.

The *traditional approach* to determining the proper intensity of exercise for a cardiac rehabilitation program is to *calculate 70% to 85% of a measured maximal heart rate*. The measured maximal heart rate is usually based on the results of an exercise stress test. The mode of exercise used for exercise testing should be specific to the type of exercise planned for the training program (e.g., treadmill testing for a walking/jogging program, bicycle ergometer testing for a cycling program). Some authorities suggest other methods of calculating the target heart rate, but in practice, the traditional calculation is generally the most efficient. This exercise intensity translates to approximately 60% to 80% of maximal oxygen consumption. The relationship between heart rate and oxygen consumption is not influenced by *b*-adrenergic blockade. This point is important in cardiac rehabilitation, because many patients receive a beta-blocking agent as part of their post-MI therapeutic regimen (see [Chapter 30](#)). Such patients require a formal graded exercise test under the influence of a beta-blocker if they are going to be taking a beta-blocker while engaged in an exercise training program.

The current consensus regarding the approach to exercise is shifting from an emphasis on maximizing intensity to *maximizing compliance*. For previously inactive patients, this translates into a program of a *moderate degree of exercise*, usually prescribed as starting with *walking at a rate of 3 to 4 miles/h* for 30 minutes each day. This more practical and sustainable approach to exercise training is designed to increase long-term compliance and extend participation in exercise programs beyond the meager 25% who currently engage in them for cardiac rehabilitation.

Program Implementation. Only a fraction of coronary patients who would benefit from a well-designed exercise/rehabilitation program actually undergo it. Part of this results from most programs being institutionally based, requiring travel to and from the site. The original basis for this "on-site" requirement was concern about cardiac events during exercise and the need for on-site medical supervision. Although the rate of sudden death in medically supervised programs is extremely low, home programs supplemented by occasional institutional visits and regular nurse follow-up by can also be carried out safely, provided there is careful patient selection (e.g., no ischemia or dysrhythmias on stress testing, good functional capacity, frequent exercising, good reliability). Those who should be closely supervised are those who exercise infrequently and manifest poor functional capacity at baseline. Physician enthusiasm, provision of close supervision, and adoption of a moderate exercise program rather than one that stresses more intensive exertion all help the patient to get started and continue. Most important to compliance is design of a program that the patient likes to do and finds doable (see [Chapter 18](#)).

RISK FACTOR REDUCTION

As noted earlier, exercise is but one important component of a comprehensive program of secondary prevention of coronary artery disease. The benefits to survival from aggressive risk factor reduction are as large as any intervention in secondary prevention of coronary disease. Unlike other modalities of secondary prevention, they directly address the atherosclerotic process.

Risk Factor Reductions of Proven Benefit. Effective treatment of *hypertension* (see [Chapter 26](#)), *hypercholesterolemia* (see [Chapter 27](#)), and *smoking* (see [Chapter 54](#)) can reduce cardiovascular morbidity and mortality by 25% to 50%. In many instances, atherosclerotic progression can be halted, and in about 25% of cases, plaque regression may be observed, particularly with aggressive lipid-lowering efforts. Control of *obesity* (see [Chapter 233](#)) and diabetes (see [Chapter 102](#)), although not directly proven to reduce cardiovascular risk in themselves, are critical to effective control of key CHD risk factors (e.g., lipids, blood pressure).

Less appreciated is the importance of recognizing and treating anxiety and depression. These psychosocial factors are important determinants of future adverse CHD events. Effective treatment can markedly decrease event rates and mortality from sudden death by up to 50% and improve functional status. Depression is often overlooked or simply accepted as a "natural consequence" of having a major ischemic event; however, patients exhibiting major depression after an acute ischemic event (MI or acute coronary insufficiency) may benefit significantly from antidepressant therapy, especially if they have a history of depression. In the largest placebo-controlled prospective trial to date, SSRI treatment (sertraline) started a month after acute MI or unstable angina in persons exhibiting major depression produced a 40% reduction in the incidence of subsequent major cardiovascular events. Results were statistically most significant in persons with a history of depression. SSRI therapy produced no adverse effects on ejection fraction, QT interval, or ventricular irritability. (Use of tricyclic agents may be more problematic in the setting of ischemia.) Recognition and treatment of depression are essential to achieving the best possible outcomes in patients with recent infarction or unstable angina (see also [Chapter 226](#) and [Chapter 227](#)).

Updated: 8/23/02

Risk Factor Reductions of Potential Benefit. There is considerable interest in the contributions of *homocysteine reduction* to the secondary prevention of CHD. Previously, hormone replacement therapy (HRT) also fell into this category because it appeared to be protective in healthy women, but large-scale prospective study has failed to confirm epidemiologic findings.

Updated: 8/22/02

Homocysteine Reduction. Epidemiologic data indicate a dose-dependent association between plasma homocysteine and risk of cardiovascular disease. To date, the association appears independent of other cardiovascular risk factors; however, it remains to be proven by prospective randomized trials that decreasing homocysteine levels will reduce cardiovascular risk. Despite the absence of a proven benefit, many physicians currently screen for and treat CHD patients with homocysteine elevations, even moderate ones, because treatment is safe and simple. *Folic acid* supplementation with or without *vitamins B_6 and B_{12}* will lower homocysteine levels by nearly 25% in 2 to 6 weeks, even in persons who are not deficient in these vitamins. The higher the pretreatment homocysteine level and the lower the folate stores, the greater the reduction in homocysteine.

Doses of folate more than 0.4 mg/d usually provide no additional benefit, but lower doses are not very effective. Folate given to a B_{12}-deficient patient can aggravate the B_{12} deficiency, mask its hematologic features, and lead to neurologic impairment (see [Chapter 79](#)). Such consequences lead many to add oral B_{12} (0.5 mg/d) to the daily program or to check serum B_{12} level before beginning folate therapy. Vitamin B_6 is safe to use so long as the daily dose (which averages 25 to 50 mg/d) does not exceed 400 mg/d, a dose associated with sensoryneuropathy.

Relatively inexpensive *measurement* of plasma homocysteine is becoming available; accuracy is facilitated by fasting, and sensitivity is enhanced by methionine loading, which stresses the involved metabolic pathways. Ongoing prospective trials should help determine the usefulness of lowering homocysteine and the need for

screening CHD patients for this condition. At this time, screening and treatment of homocysteine elevation cannot yet be recommended in persons with CHD.

Hormone Replacement Therapy. Because *menopause* is a risk factor for CHD, HRT has been examined as a possible means of achieving primary and secondary prevention of CHD events in women. Although epidemiologic data suggested a strong association between HRT use in postmenopausal women having CHD and reduced risk of further coronary events (nonfatal infarction and cardiac death), a disappointing landmark prospective study of the question (the Heart and Estrogen/Progestin Replacement Study) failed to confirm this benefit. Consequently, initiating a program of estrogen plus progesterone in older postmenopausal women with CHD for secondary prevention of CHD is not recommended.

MEDICAL THERAPIES

Besides risk factor reduction, one needs to consider pharmacologic interventions that can enhance survival and reduce rates of cardiac events. Evidence-based modalities include beta-blockade, ACE inhibition, and antiplatelet therapy. Some dietary interventions appear very promising.

Beta-Blockade. *b*-Adrenergic blockade significantly reduces the total mortality rate and the incidences of recurrent infarction and sudden death in patients who have had a recent MI. Rates of reduction in mortality range from 26% to 39%; reinfarction rates fall by 23% to 28%. Concerns for adverse effects often factor into prescribing decisions and probably contribute to the low rates of postinfarction beta-blocker utilization (30% to 60%) seen in community-based practice. Underutilization is especially common in elderly patients. The major trials excluded individuals at increased risk for adverse effects of beta-blockade, such as patients with severe pulmonary disease, marked congestive heart failure, insulin-requiring diabetes mellitus, and the elderly. Observational studies find no increased risk from use in such "high-risk" patients and no compromise in benefit. In fact, high-risk groups actually demonstrate a higher absolute reduction in risk because of a higher baseline mortality rate. Pending data from randomized prospective studies, it is recommended that all postinfarction patients are given a trial of beta-blocker therapy shortly after infarction and that those with relative contraindications to such therapy have the trial conducted under close supervision, starting at low doses (e.g., 12.5 to 25 mg/d of atenolol) and titrating upward as tolerated until beta-blockade is achieved. Because early morning and early evening are times of greatest adrenergic stimulation and cardiac risk, it is important that a beta-blocker program ensure adequate beta-blockade during these critical periods.

Angiotensin-Converting Enzyme Inhibition. ACE inhibition is emerging as a major approach to reducing CHD mortality and reinfarction risks in postinfarction patients. Initially found effective in postinfarction patients with left ventricular dysfunction (ejection fraction less than 0.4), ACE inhibitor use has more recently demonstrated clinically significant reductions (20% to 30%) in morbidity and mortality for CHD patients with preserved left ventricular function (Heart Outcomes Prevention Evaluation [HOPE] study), including those who have not suffered infarction. Not only is survival improved, but so are the rates of infarction, stroke, and need for revascularization. Proposed mechanisms of action include not only inhibition of the angiotensin-renin-aldosterone system, but also the ability to limit vascular smooth muscle proliferation, plaque rupture, and left ventricular hypertrophy and to improve vascular endothelial function and fibrinolysis. All CHD patients should be considered for ACE inhibitor therapy. Choice of ACE inhibitor and optimal dose have not been established, but there appears to be little difference among ACE inhibitors, suggesting that benefit may be attained with any drug in this class, starting at a modest dose (e.g., generic captopril 25 mg bid, generic lisinopril 10 mg/d; the HOPE study used ramipril 10 mg/d). It is unknown whether angiotensin-II-receptor antagonists will provide the same protection.

Antiplatelet Agents and Oral Anticoagulants. Modest but significant reductions (20%) in death and reinfarction are achieved with *long-term aspirin therapy* in CHD patients. Aspirin has also been found efficacious in preventing MI among patients with unstable angina. Long-term prophylactic therapy with aspirin should be strongly considered for patients with acute MI and unstable angina.

Therapy with warfarin is not routinely prescribed in postinfarction patients, because although results may be slightly better than with aspirin, there is an increased risk of major bleeding. The Anticoagulants in the Secondary Prevention of Events in Coronary Thrombosis trial demonstrated a 50% reduction in risk of reinfarction; however, intensive anticoagulation was required (INR 2.8 to 4.8), raising the risk of hemorrhagic complications. Combination therapy with lower dose warfarin plus aspirin is being studied.

Antiarrhythmic Therapy. There is no evidence for a protective effect with use of antiarrhythmic drugs; the marked proarrhythmic effects of potent class I agents appear to negate their ability to suppress malignant ventricular irritability. Only *beta-blockers* and *implantable defibrillators/cardioverters* have demonstrated a clearcut beneficial effect in reducing risk of sudden death in high-risk patients. Whether class III antiarrhythmics such as amiodarone when used alone or in conjunction with other agents will prove useful remains unknown (see also Chapter 29).

DIETARY MEASURES AND SUPPLEMENTS

Diet. The role of a *low-saturated-fat low-cholesterol diet* is well established for CHD prevention. It remains an essential part of a lipid-control program essential to aggressive risk factor reduction (see Chapter 27). Of increasing interest for CHD prophylaxis is a diet rich in *omega-3 fatty acids*. A 30% reduction in overall mortality has been observed in MI survivors who twice weekly consumed fish rich in these fatty acids. Purported mechanisms include beneficial effects on atherosclerosis and clotting. In addition, others find a stabilizing effect on myocardial cell membrane channels that appears to raise the threshold for dysrhythmias, perhaps accounting for the association between reduced rates of sudden death and fish consumption. Data from major prospective observational studies, such as the Nurses' Health Study, support the view that it is the intake of fish rather than confounding factors that is responsible for the benefit observed with fish intake. Moreover, serum levels of omega-3 fatty acids correlate strongly with risk of cardiac sudden death. A once- or twice-weekly serving of an oily fish, such as salmon, mackerel, fresh tuna, lake trout, sardines, or herring, is recommended. Whether such benefit also derives from use of fish oil tablets remains unproven, and intake of such tablets may exacerbate warfarin anticoagulation. So enjoy the fish. There is no evidence that restriction of *caffeinated beverages* is necessary.

Vitamin Supplements. Being "natural," these substances are currently very popular among patients, stimulated by enthusiastic reports in the lay press of their possible "antioxidant" benefits in atherosclerosis. In addition to *folic acic* and *vitamins B$_6$ and B$_{12}$* for treatment of *homocysteine* elevations (see above), *vitamins E, beta-carotene*, and *C* have all received mention as possibly beneficial agents, supported by initial epidemiologic data.

Vitamin E has received the most attention because of suggestive epidemiologic data; however, findings from randomized placebo-controlled trials have failed to confirm a significant benefit. An antioxidant program of vitamin E, vitamin C, beta carotene, and selenium not only failed to lower risks of coronary stenosis and coronary events in persons with known coronary disease, but when used in combination with a program of statin and niacin, blunted the beneficial effects of lipid-lowering therapy (the HATS trial). Similarly disappointing results have been observed in prospective studies of individual antioxidants (e.g., vitamin E, beta-carotene) in persons with coronary disease. With beta-carotene, not only was risk of a CHD event not lowered, but risk of lung cancer worsened. When taken with vitamin A, beta-carotene increased the incidence of cardiovascular mortality and all-cause mortality. Contrary to popular opinion, these results suggest that antioxidant vitamin therapy should not be used in persons with known coronary disease, either as sole therapy or in combination with lipid-altering agents.

REVASCULARIZATION

Surgical revascularization (coronary artery bypass and graft) produces long-term reductions in risks of reinfarction and CHD mortality that approach 40% in patients with *high-risk disease* (moderate-to-severe angina; large amount of myocardium at risk; suspected three-vessel, left-main, or left-main-equivalent disease; reduced ejection fraction).

For patients with *lesser degrees of risk*, coronary artery bypass and graft does not reduce risk compared with medical therapy but does improve functional status and quality of life in patients who remain unacceptably symptomatic despite full medical management. *Angioplasty* is replacing bypass surgery as the preferred means of revascularization for anginal control in such cases (see Chapter 30). Although enthusiastically embraced by the interventional cardiology community for treatment of CHD, it remains to be demonstrated by prospective randomized controlled trials what impact angioplasty will have on rates of reinfarction, cardiac arrest, and death.

Even after successful revascularization that eliminates angina, most patients continue to use antianginal medications at nearly the same rate or greater than they did before revascularization, negating some of the cost benefit to be expected from revascularization. Perhaps this is out of fear of stopping a seemingly successful program. Those agents that do improve prognosis (e.g., beta-blockers, aspirin, ACE inhibitors) should certainly be continued; however, drugs such as nitrates and calcium channel blockers that are taken for symptomatic relief yet have no demonstrably beneficial effect on cardiovascular morbidity or mortality should be phased

out.

In some centers, patients with acute non-Q-wave infarctions are sent routinely for immediate angiography and prompt revascularization. However, such patients who have no clinical or laboratory evidence of ongoing ischemia or heart failure can be managed just as successfully with regular medical therapy, reserving angiography and revascularization for those who develop ischemia or failure or who later manifest evidence of high-risk disease by stress testing. In fact, mortality 1 year postinfarction is lower with conservative therapy than with immediate revascularization. Even after 2 years of follow-up, no survival advantage for immediate revascularization can be found.

PATIENT EDUCATION

The patient who has suffered an acute coronary event is among those in greatest need of health education and individualized life-style counseling. Patient and family are apt to be depressed and frightened by the diagnosis of "coronary disease," believing the prognosis to be grim and fearing invalidism, especially if an infarction has occurred. They need to be informed that in the vast majority of uncomplicated cases, a return to job and regular activity is the rule rather than the exception and that there is much that they can do to greatly improve their prognosis.

Prognosis. *Prognosis* is a major concern of the patient and family and should be reviewed, not only with the intent of being accurate and realistic but also with an eye toward communicating the significant improvements in prognosis that are achievable by a comprehensive program of secondary prevention. Most published survival rates derive from prospective epidemiologic studies and do not reflect the effects of secondary-prevention programs. Average annual mortality in the Framingham Study was 5% for men and 7% for women. Patients at greatest risk for late cardiac death were those with persistent "malignant" ventricular irritability (see Chapter 29), azotemia, previous infarction, persistent congestive failure, angina, or advanced age. Once congestive heart failure ensued, 50% were dead within 5 years. Risk of postinfarction angina in the Framingham Study was 2.9% for men and 9.6% for women. Risk of heart failure was 2.3%. Many complications of infarction are a function of the degree of myocardial damage. This is consistent with the observation that prognosis correlates with extensiveness of disease, a finding also supported by angiographic studies (see Chapter 30). As noted above, 1-year survival can be estimated from a limited treadmill exercise test done before discharge.

In reviewing prognosis, it is essential to review the reductions in risk associated with implementation of secondary preventive measures (Table 31-1). On average, each element of the program has the potential to reduce risk by 25% to 50%, providing a very substantial improvement in outcomes if implemented. This is a very important and highly motivating message that needs to be conveyed and goes far beyond the common perception that revascularization is the only thing that can be done. In reality, revascularization has a relatively small role in improving prognosis for most patients.

MEASURE	REPORTED REDUCTION IN CHD MORBIDITY/MORTALITY (%)
Lipid lowering	7–76
Exercise	20–25
Smoking cessation	50
Hypertension control	8–38
Stress management	10–65
Aspirin	25
Beta-blockade	20
Coronary artery bypass (in high-risk patients)	39
Angiotensin-converting enzyme inhibition	20–30
Angioplasty	0–?

Counseling. *Counseling* needs to begin in the predischarge period. Realistic concerns and excessive fears of incapacitation may dramatically alter self-image and diminish self-respect. The most effective way of dealing with such fears is to specifically elicit and address the patient's and the family's concerns and discuss the plan for recovery and rehabilitation and its impact on quality of life and survival. Specific statements concerning *exercise capacity* can be based on graded treadmill stress testing during the recovery period. Knowing what one should and should not do during various stages of the recovery process can help reduce some of the anxiety that accompanies having heart disease.

Activity guidelines should be given. Unsupervised activities during the first month after an MI should require no more than 3 mets (see Table 18-1). By the time 6 to 8 weeks have passed, tasks requiring up to 5 mets will be safe for most patients, provided a gradual increase in activity has not been interrupted by symptoms or complications. Specific guidelines, tailored to the patient's personal occupational and recreational interests, are essential.

Some concerns may not always be verbalized by the patient. One such concern is the safety of resuming *sexual activity*. Often, there is fear of sudden death during intercourse. The safety of sexual activity should be routinely discussed with the patient and spouse, even if the topic is not initially raised by them. Sexual intercourse with a familiar partner requires about 3 to 5 mets. Thus, sexual activity can be safely resumed by most patients as early as 4 weeks post-MI. During the early return to full sexual activity, the patient should be advised to avoid coital positions that require sustained isometric exercise, such as upper torso weight-bearing with the arms.

The period after an acute coronary event is also a time when patients are particularly receptive to counseling about changes in *life-style* that reduce coronary risk, such as smoking cessation (see Chapter 54) and dietary change (see Chapter 27). The primary physician is ideally suited to take advantage of this opportunity. A balanced cardiac rehabilitation program offers a very positive response to a very frightening event. In many instances, the results are extremely gratifying, with a patient who is healthier and more fit than before the acute coronary event.

CHAPTER 32 MANAGEMENT OF CHRONIC CONGESTIVE HEART FAILURE

ALLAN H. GOROLL

INTRODUCTION

Chronic congestive heart failure (CHF) ranks among the most serious of cardiac problems encountered in office practice and is one of the most prevalent. Advances in the understanding of CHF's pathophysiology, its detection, and the advent and timely application of increasingly effective therapies now provide the primary physician with the opportunity to significantly reduce the cardiac morbidity and mortality associated with the condition. The growing appreciation of both systolic and diastolic dysfunction and their respective roles in CHF have led to more precisely targeted therapy. Diuretics, angiotensin-converting enzyme (ACE) inhibitors, and digitalis are the cornerstones of treatment, with ACE inhibitors markedly improving prognosis when used in timely fashion. Primary care physicians need to ensure that their CHF patients are prescribed ACE inhibitors, a practice that remains only partially implemented.

A carefully designed program tailored to the patient's underlying pathophysiology helps to maximize outcomes and prevent such complications as prerenal azotemia, drug- or electrolyte-induced dysrhythmias, and dehydration. Successful management of CHF in the outpatient setting also requires identification and correction of treatable underlying causes and elimination of precipitating factors. Because multidrug regimens are often necessary, thorough patient and family education are essential to limit complications and prevent unnecessary hospitalizations that result from poor compliance or drug toxicity.

PATHOPHYSIOLOGY, CLINICAL PRESENTATION, AND COURSE

Pathophysiology. The "congestive" manifestations of CHF—leg edema, orthopnea, paroxysmal nocturnal dyspnea, rales, jugular venous distention—represent elevations in right or left ventricular filling pressures. Traditionally, filling pressure elevations have been viewed as a consequence of *systolic dysfunction* producing a backup of blood into the pulmonary and systemic venous systems. The hallmark of systolic dysfunction is a *reduced ejection fraction*.

An increasing appreciation for the role of *diastolic dysfunction* in CHF has emerged. As many as 40% of patients presenting with congestive failure appear to have reasonably well-preserved systolic function (ejection fraction more than 0.45) but suffer from diastolic dysfunction, manifested by increased resistance to diastolic ventricular filling. Diastolic dysfunction has been demonstrated in the setting of valvular, hypertrophic, ischemic, and cardiomyopathic diseases. Mechanisms include impairment of diastolic myocardial relaxation, valvular dysfunction, loss of myocardial dispensability, ventricular remodeling, and intracellular calcium overload. Diastolic dysfunction has also been noted in the setting of volume overload.

Heart failure triggers a number of compensatory neurohumoral mechanisms, which ultimately become troublesome. The initial fall in cardiac output activates the *renin-angiotensin-aldosterone axis*, leading initially to *fluid retention and sympathetic discharge*, which temporarily help preserve cardiac output but at the cost of an increase in preload and afterload. Abnormalities in release of atrial natriuretic peptide, prostaglandin metabolism, and neurohumoral regulation contribute to volume overload. Eventually, the resultant venous hypertension and increased left ventricular work affect the failing heart, which cannot tolerate such increases in work, and cardiac output drops. Normal hearts respond to increased venous return via the Frank-Starling mechanism to increase cardiac output, but not the failing heart. The result is increased pulmonary and systemic hypertension and no improvement in cardiac output. The progressive decrease in cardiac output and rise in venous pressure trigger further neurohumoral activity, and a vicious cycle is established. Late changes effected by these compensatory mechanisms include myocardial and vascular *remodeling* and *fibrosis*.

Clinical Presentation. A *preclinical phase* of CHF often precedes onset of symptoms. As many as half of CHF patients may manifest moderate to severe degrees of diastolic and/or systolic dysfunction echocardiographically in the absence of obvious symptoms. Regardless of etiology, once symptoms ensue, the clinical manifestations of CHF are quite stereotyped and reflect the magnitude of the fall in cardiac output and the rise in pulmonary and systemic venous pressures. Initially and in mild cases, the patient may complain of *fatigability, dyspnea on exertion*, or unexplained *weight gain*. There may be few overt physical signs of failure, but chest x-ray often shows *redistribution* of pulmonary venous flow to the upper lung fields and/or *cardiomegaly*. Fatigue becomes increasingly prominent as cardiac output falls. As pulmonary congestion increases, dyspnea worsens, *orthopnea* is noted, and *paroxysmal nocturnal dyspnea* may be reported. At this stage, *rales* become evident on auscultation of the lungs, but their absence does not rule out the presence of CHF. Sometimes failure-induced *bronchospasm* dominates the pulmonary examination. In severe cases, the chest film will show *interstitial pulmonary edema*. In chronic CHF, right-sided or bilateral *pleural effusions* are common. *Ankle edema, jugular venous distention*, and *hepatojugular reflux* are indicative of elevated systemic venous pressure; if CHF is predominantly left-sided, these findings may not be present. An S_3 *gallop* is among the most specific physical signs of failure, but it is often difficult to hear. If left ventricular dilation becomes very marked, a *mitral regurgitant murmur* may become evident. Pedal edema is one of the least specific signs of CHF; in the elderly, isolated pedal edema is more likely to be a result of venous insufficiency (see Chapter 22). **Updated: 03/07/03**

Partially treated CHF may present with atypical manifestations. For example, potent diuretic therapy may eliminate most congestive manifestations, whereas pump function remains depressed. Dyspnea, orthopnea, leg edema, rales, and even radiologic signs of CHF (see below) may be absent, and fatigue might dominate the clinical picture.

Clinical Course. Because congestive failure is not a single disease, it does not have a uniform natural history. Clinical course and response to therapy depend on the nature of the underlying etiology and the state of the myocardium at the time of presentation. For example, the appearance of CHF in a patient with aortic stenosis is an ominous prognostic sign associated with a mean survival of no more than a year or two. However, if the valve is replaced before irreversible myocardial decompensation has occurred, the prognosis is altered dramatically (see Chapter 33). Cases of CHF caused by alcohol abuse, thiamine deficiency, hypertensive heart disease, and hyperthyroidism also have favorable outcomes if detected and treated early. However, if uncorrected, they lead to cardiomyopathic changes and accelerated mortality.

The Framingham Study has provided interesting epidemiologic data concerning CHF in the community setting before the advent of echocardiography and vasodilator therapy. The annual incidence rate for development of failure was 2.3 per 1,000 for men and 1.4 per 1,000 for women. The major causes were hypertension in one third of the patients, hypertension in combination with coronary disease in another one third, isolated coronary disease in about 10%, and valvular disease in another 10%. Sixty percent of patients had a serious noncardiac illness along with CHF. Five-year survival rates, regardless of cause, were only 50%. Later studies have shown significantly improved survival rates associated with the use of ACE inhibitors, even in patients with advanced disease (see below).

Several factors have been examined for their correlation with prognosis. Community-based study reveals diastolic dysfunction to be a strong prognostic indicator of all-cause mortality (hazard ratios of 8 to 10 for persons with diastolic dysfunction compared to those with normal diastolic function). Another prognostic factor is increase in *plasma norepinephrine* level, correlating strongly with mortality risk and superior to pulmonary wedge pressure, cardiac index, mean arterial pressure, and heart rate. The high catecholamine level is thought to represent autonomic compensation for falling cardiac output, though such a compensatory mechanism is not without its own risks, especially for patients with underlying ischemic or hypertensive disease who cannot tolerate the increase in afterload. **Updated: 03/07/03**

DIAGNOSIS AND MONITORING OF HEART FAILURE

Early clinical diagnosis of heart failure may be difficult, because clinical manifestations are often absent in the presence of echocardiographically overt diastolic or systolic dysfunction. In addition, the symptoms of CHF (many of which are manifestations of compensatory mechanisms) can be nonspecific and at times misleading, leading to both overdiagnosis and underdiagnosis. In a study of patients on digitalis therapy for supposed CHF, 40% did not fulfill basic diagnostic criteria for the condition. Left-sided heart failure can be particularly difficult to detect clinically. The advent of cardiac Doppler ultrasound has greatly enhanced ability to detect heart failure in its earliest stages.

Clinical Diagnosis

Right-Sided Heart Failure. *Right-sided heart failure* is defined clinically as a right atrial pressure greater than 6 cm H$_2$O, manifested by a *jugular venous pressure less than 6 cm H$_2$O*. The presence of ankle edema in the absence of jugular venous distention does not constitute a diagnosis of right heart failure. On the other hand and as noted earlier, the absence of ankle edema and jugular venous distention do not necessarily rule out right-sided heart failure, especially in the patient taking diuretics.

Left-Sided Heart Failure. Left-sided heart failure is more difficult to diagnose solely on clinical grounds. By themselves, most findings on history and physical examination are neither very sensitive nor specific, but in conjunction with other evidence they can be quite helpful. A story of orthopnea and paroxysmal nocturnal dyspnea is suggestive, as are *basilar rales* on pulmonary examination. The finding of a *third heart sound* (S_3) is among the more specific of signs for systolic dysfunction, but it is often difficult to elicit and is sometimes present in elderly hypertensive patients with a normal ejection fraction. In the absence of definitive radiologic evidence of pulmonary edema, the diagnosis of left-sided heart failure is best supported by the finding of upper zone redistribution and one of the other historical, physical, or laboratory findings just noted. In the absence of upper zone redistribution, the presence of any three other findings (e.g., S$_3$, cardiomegaly, and basilar rales) constitutes reasonable evidence for the diagnosis.

Laboratory Diagnosis

Identification of Congestive Heart Failure. The *chest x-ray* remains an excellent readily available test for diagnosis of CHF. Characteristic findings include upper zone flow redistribution, cardiomegaly, prominent interstitial markings, Kerley "B" lines, and perihilar haziness. Patients who develop CHF only during exertion may not show interstitial changes on a chest film done at rest, although cardiomegaly and upper zone redistribution may be present. The *electrocardiogram* can be useful for detection of left atrial enlargement, which in conjunction with cardiomegaly by chest film has diagnostic value as do the electrocardiographic findings of left ventricular hypertrophy and ischemia.

Cardiac ultrasound, particularly with Doppler enhancement, has become the test of choice for assessment of suspected CHF. The test allows for measurements of *ejection fraction* and *chamber size* and for detection of *valvular* and *wall abnormalities*, extending information obtained by clinical assessment and chest x-ray. The finding of left ventricular dilatation in persons without myocardial infarction is an independent risk factor for CHF and the detection of subclinical disease. Doppler ultrasound is the test of choice for detection of diastolic dysfunction (a poor prognostic indicator) and essential to diagnosis in those CHF patients who present with normal systolic function (ejection fraction > .45). By being able to detect both systolic and diastolic dysfunction before symptoms develop or in the context of nonspecific symptoms, Doppler ultrasound provides an opportunity to improve outcomes by enhancing early, accurate diagnosis of heart failure. The ultrasound is also essential to identification of the patient's underlying pathophysiology and etiology, which are essential to design of an effective treatment program.

Determining the Underlying Pathophysiology. *Echocardiography* with *Doppler* assessment of flow allows for detection of both systolic and diastolic dysfunction. In CHF patients with systolic dysfunction, the ejection fraction is reduced (less than 0.45), whereas the ejection fraction may be preserved (more than 0.45) in the setting of diastolic dysfunction. Doppler techniques help confirm the diagnosis of diastolic dysfunction by identifying abnormal diastolic flow across the mitral valve. The ability of the cardiac ultrasound study to detect left ventricular hypertrophy, hypertrophic and restrictive cardiomyopathic changes, ischemia, and pericardial disease makes the study an excellent choice for etiology of diastolic dysfunction.

Monitoring

Once the diagnosis of heart failure is made and its underlying pathophysiology determined, assessment shifts to monitoring. Simple measures often suffice, including patient weight, symptoms (particularly exercise tolerance), physical examination, blood urea nitrogen (BUN), creatinine, and chest x-ray. Repeated use of elaborate diagnostic technology for monitoring is usually unnecessary, raising the cost of care without improving outcomes.

PRINCIPLES OF MANAGEMENT

Searching for and Treating a Reversible Underlying Etiology. Searching for and treating a reversible underlying etiology is the first task of management. All too often, many cases are encountered at the time irreversible myocardial damage has occurred, but when a treatable cause is present and detected early, there is an opportunity for definitive measures to bring about a successful outcome. *Coronary artery disease* (see Chapter 30), *valvular disease* (see Chapter 33), *alcohol excess* (see Chapter 228), *hypertension* (see Chapter 26), *hyperthyroidism* (see Chapter 103), and *hypothyroidism* (see Chapter 104) are examples of conditions requiring etiologic therapy. A stereotypic approach to treatment that ignores etiology may lead to loss of a unique therapeutic opportunity and even be counterproductive.

Attending to Precipitating Factors. Attending to precipitating factors is another priority. Acute *ischemia* (see Chapter 30), *severe anemia* (see Chapter 82), *high fever* (see Chapter 11), *atrial fibrillation* and other *supraventricular tachycardias* (see Chapter 28), *pneumonia* (see Chapter 52), *pulmonary embolization* (see Chapter 35), *excess salt intake, marked obesity* (see Chapter 233), *and excess exertion or emotional stress* may worsen or precipitate failure in patients with decreased myocardial reserve. Excessive doses of beta-blockers (see Chapter 30) or other negatively inotropic agents (e.g., *verapamil, disopyramide*) may also bring on CHF. A careful search for these factors is essential.

Treating Pathophysiologically. Loop diuretics directly address volume overload. ACE inhibition counters the dysfunctional response of the angiotensin-renin-aldosterone system to poor systemic perfusion, reducing both preload and afterload; digoxin provides an inotropic boost to hearts manifesting systolic dysfunction. Combination therapy utilizing a loop diuretic, ACE inhibitor, with or without digoxin has become the standard of treatment. When properly applied, such therapy has the potential to reduce cardiac morbidity and mortality across a wide range of patients. Beta-blockade and spironolactone have promising adjunctive roles: Selective use of beta-blockers blunts excessive sympathetic stimulation, and small doses of spironolactone inhibit the marked aldosterone effects of severe disease.

Diastolic dysfunction requires attention first to its underlying etiology (e.g., hypertension, left ventricular outflow tract obstruction, ischemia, valvular regurgitation, myocardial disease, pericardial disease). Supportive therapy includes maintenance of normal sinus rhythm, rate control if the patient is in atrial fibrillation, and careful use of diuretics and ACE inhibitors, avoiding too precipitous a fall in preload that might compromise cardiac output. Nitrates are sometimes used in place of ACE inhibition. Beta-blockers may also contribute, particularly in patients with underlying ischemic heart disease or hypertrophic cardiomyopathy; venodilating calcium channel blockers are sometimes considered, but their use in heart failure can be problematic (see below).

Systolic dysfunction also requires addressing the underlying cause (e.g., ischemia, hypertension, cardiomyopathy, valvular disease). The combination of diuretics, ACE inhibitors, and digitalis serve as first-line agents, improving contractility, reducing afterload, and eliminating excess volume. Low doses of a beta-blocker may actually improve the ejection fraction, and spironolactone helps reverse the adverse physiology of advanced heart failure by inhibiting aldosterone.

Diuretics

Rationale for Use as Initial Therapy. Diuretics are an important *initial therapy* when there is evidence of volume overload. The degree of compensatory fluid retention in CHF is typically excessive, leading to pulmonary congestion and/or peripheral edema. In patients with mild to moderate CHF, symptoms of volume overload respond best acutely to diuretic therapy compared with ACE inhibition. However, diuretic therapy alone is usually insufficient for chronic treatment of CHF, in part because it stimulates the renin-angiotensin system and raises serum catecholamines, leading to increased afterload, reduced cardiac output, and further sodium retention. Although diuretics may be effective in controlling peripheral edema and pulmonary congestion, they do little to prevent the progression of heart failure or improve prognosis. Consequently, diuretics emerge as important treatment for relief of congestive symptoms, but they are insufficient for altering prognosis, especially

in patients with a failing left ventricle.

Overzealous use of diuretics may acutely worsen the situation by producing prerenal azotemia or a dangerous fall in filling pressure (as in critical aortic stenosis). Moreover, escalating diuretic therapy in mitral or aortic valve disease may inappropriately delay the timing of surgical therapy (see Chapter 33).

Selection of Agent and Initiation of Therapy. When symptoms are slight (mild exertional dyspnea, minor ankle edema) or when the patient is asymptomatic but showing weight gain or x-ray findings indicative of early CHF, then diuretic therapy can be initiated with a *thiazide* (e.g., 50 mg/d hydrochlorothiazide). The degree of dyspnea on exertion and weight change are the simplest clinical parameters to follow for gauging response to therapy in mild cases.

Increasing severity of symptoms is an indication for switching to a *loop diuretic* (e.g., *furosemide or ethacrynic acid*). Small doses of loop diuretics may also benefit patients with mild to moderate failure that cannot be adequately controlled by thiazides. Caution is warranted when treating a patient for the first time with a loop diuretic, because a marked diuresis may be evoked, particularly with use of a parenteral dose but sometimes with an oral dose. If a thiazide had been used previously, it should be stopped rather than continued in conjunction with the loop diuretic, because the two agents are very potent when used together (see below). The mercurials have dropped from use because of the need to administer them parentally.

The *potassium-sparing diuretics* (amiloride, triamterene) are relatively weak agents used mainly in conjunction with thiazides and loop diuretics to prevent potassium depletion. Their onset of action is slow; full effect may take up to a week to become evident and they should be used with caution if at all in persons taking ACE inhibitors, because of the risk of hyperkalemia. *Spironolactone* is also a weak diuretic with potassium-sparing effects and of little use for acute reduction in volume; however, small doses may be useful in patients with severe CHF (see below).

Use in Later Stages of Congestive Heart Failure. In severe CHF, absorption of oral loop diuretics declines, which accounts for the oft-noted reduction in efficacy during an exacerbation of heart failure. The maximal effect of a loop diuretic can be achieved by using a *large, single, daily dose* rather than divided doses. Parenteral administration of the drug or high-dose oral therapy is required to achieve diuresis. At times, supplementing oral therapy with an occasional *parenteral dose* in the office will suffice to counter worsening failure refractory to oral therapy. *Adding a thiazide* to the diuretic program may be useful in failure refractory to large doses of the loop diuretic alone. For patients with renal impairment, *metolazone* can be useful as the adjunct. It is similar in potency to the thiazides but more effective in the setting of azotemia.

Spironolactone, the aldosterone-receptor antagonist, can reduce cardiac morbidity and mortality when added to standard maximal medical therapy in persons with severe CHF. The purported mechanism entails inhibition of excessive aldosterone stimulation, a pathophysiologic feature of advanced CHF. Small doses (25 to 50 mg/d) added to a program of ACE inhibitor, loop diuretic, and digoxin improve survival by nearly 30%. If spironolactone is added to the standard maximal program, monitoring for hyperkalemia is essential and potassium supplementation should be limited to persons who manifest a serum potassium of less than 3.5 mg/dL.

Monitoring Diuretic Therapy. Monitoring *postural signs*, *BUN*, and *creatinine* are essential to avoid excess volume depletion and severe prerenal azotemia. When a potassium-wasting diuretic is being used in conjunction with digitalis therapy, it is critical to carefully monitor the *serum potassium* (see Appendix). The incidence of digitalis toxicity rises appreciably in the setting of hypokalemia. *Magnesium depletion* may also be triggered by diuretic therapy and contribute to digitalis sensitivity and refractory hypokalemia. Use of a potassium-sparing drug necessitates watching for hyperkalemia and discontinuing chronic potassium supplementation once hypokalemia is corrected.

Diuretic Preparations

Thiazides. *Thiazides* are sulfonamide derivatives, believed to inhibit sodium reabsorption in the cortical tubule. Although the number of thiazide preparations is large, they differ only in cost and duration of action. *Hydrochlorothiazide* is the least expensive and is available generically. Thiazides cause modest potassium depletion, which can be clinically important if there is underlying heart disease, especially in the setting of ventricular irritability, ischemia, or use of digitalis. Under such circumstances, careful monitoring for hypokalemia and assiduous potassium supplementation or use of a potassium-sparing diuretic may be needed. Mild hyperglycemia and hyperuricemia may result but are usually of little clinical significance (see Chapter 102 and Chapter 155). During the first 7 to 10 days of therapy, the serum calcium may rise, but it will stay elevated indefinitely only in patients with underlying hyperparathyroidism. Absorption from the gastrointestinal tract is rapid; onset of action is 1 hour, and half-life 12 to 24 hours.

Metolazone. *Metolazone*, another sulfonamide diuretic similar to the thiazides in site of action, possesses a longer half-life and is more effective in patients with impaired renal function. The effective half-life is 24 to 48 hours, compared with 12 to 24 hours for the thiazides. Being a sulfonamide, it shares many of the same side effects, such as hypokalemia, hyperglycemia, and hyperuricemia. The maximum daily dose is 10 to 20 mg. Metolazone can be combined with a loop diuretic for use in very refractory cases in which volume overload is a major problem.

Loop Diuretics. *Loop diuretics* are potent agents that act at the loop of Henle. Examples include *furosemide, ethacrynic acid*, and *bumetanide*. Absorption is rapid, as is onset of diuretic action (30 to 60 minutes); effects last 4 to 8 hours. Caution must be exercised with their use, because serious volume depletion may occur. Frequent urination is a common complaint; evening doses should be avoided if possible. Starting dose of furosemide is 20 to 40 mg/d. Prerenal azotemia (manifested by a BUN–creatinine ratio of more than 20:1), postural hypotension, lightheadedness, and fatigue are clues to marked hypovolemia. Hypokalemia is the most serious metabolic consequence, necessitating careful monitoring of the serum potassium and supplementation should it fall to less than 3.5 mg/dL. Mild hyperglycemia and hyperuricemia may also occur. Ethacrynic acid is potentially ototoxic, especially when used in combination with an aminoglycoside antibiotic such as kanamycin. Audiograms should be obtained if ethacrynic acid is to be given for a prolonged period.

The Potassium-Sparing Diuretics. *The potassium-sparing diuretics* (e.g., *triamterene, ameloride*) are weak diuretics used predominantly to help preserve potassium. *Spironolactone*, the aldosterone-receptor antagonist, is also potassium sparing but has a unique role in severe CHF by helping to counter aldosterone excess. Serious hyperkalemia may occur with the use of these agents, particularly in treatment programs that include ACE inhibition or potassium supplementation. Frequent serum potassium determinations and discontinuation of potassium supplementation with onset of their use is essential. These drugs should not be used in renal failure, because life-threatening hyperkalemia may ensue. Spironolactone can cause gynecomastia and breast pain in chronic users; there is also a question of increased risk of carcinogenesis with long-term use based only on animal data.

Fixed Combinations. *Fixed combinations* containing a potassium-sparing diuretic and a thiazide are heavily promoted and expensive (see Chapter 21), although they are convenient and facilitate compliance. Before prescribing such a preparation, the proper dose of each agent should be determined separately. The combination preparation is reasonable to use only if it can provide the exact dosages desired. Many combinations contain subtherapeutic thiazide doses.

Angiotensin-Converting Enzyme Inhibitors

Rationale. Advances in understanding the effects of preload and afterload on cardiac output in the failing heart have added a new dimension to the treatment of CHF. Agents have been sought that would act safely both on the arterial bed (to reduce impedance to the ejection of blood from the left ventricle) and on the venous bed (to decrease preload and reduce pulmonary and systemic venous congestion). The goal was to address both systolic and diastolic dysfunction. Initially, no single agent sufficed, but the combined use of hydralazine for arterial dilation and isosorbide for venodilation achieved significant afterload and preload reductions, symptomatic improvement, and a 20% to 30% reduction in mortality in patients with mild to moderate heart failure.

With the advent of ACE inhibitors (e.g., captopril, enalapril, lisinopril) came the opportunity to achieve both goals with a single agent and in a more physiologically advantageous manner than previously achievable. These agents act on both the arterial and venous sides of the circulation, decreasing left ventricular filling pressure and increasing cardiac output. They bind to a receptor on the ACE, preventing the formation of angiotensin II—a potent vasoconstrictor and stimulant of renin and aldosterone secretion. Conventional vasodilator therapy triggers neurohumoral counterregulatory mechanisms that result in reflex vasoconstriction, adrenergic stimulation of the heart, and sodium retention; the ACE inhibitors do not set off such counterregulatory forces. In addition, their suppression of the renin-angiotensin-aldosterone axis helps prevent the harmful myocardial and vascular fibrosis and remodeling that result from long-term activation of this system.

Unlike digitalis (whose efficacy is confined to patients with significant systolic dysfunction), ACE inhibitors have been found effective in most CHF patients, whether they are suffering from mild, moderate, or severe disease. Several landmark studies (e.g., CONSENSUS, SOLVD) have documented this broad spectrum of efficacy, demonstrating significant reductions in cardiac *mortality* and *morbidity* from progressive heart failure compared with therapy that included use of other vasodilators

and diuretics and digoxin. Reductions in heart size, symptoms, and need for other medications were also found.

Randomized controlled trials (e.g., the Vasodilator–Heart Failure Trial) have established that ACE inhibitor therapy is superior to combination use of nonspecific vasodilators such as hydralazine-isosorbide in patients with chronic CHF, probably in part by not triggering potentially harmful neurohumoral counterregulatory mechanisms.

Choice of Agent. Debate continues as to optimal choice of ACE inhibitor. Cost and convenience are two major determinants. Generic captopril is probably the least expensive at present but has the disadvantage of requiring administration three times daily compared with the once daily proprietary preparations (e.g., lisinopril). In the few randomized controlled studies directly comparing ACE inhibitors for treatment of chronic CHF, both longer and shorter-acting preparations proved similarly effective, although the long-acting agents tended to have a greater propensity to cause prolonged hypotension, especially when used in high doses. Quality-of-life study comparing captopril with enalapril in hypertensive patients suggested that captopril may be the better tolerated, causing less sexual dysfunction. The patents on many of the proprietary ACE inhibitors are soon to expire, which should lead to reductions in cost and make less necessary a choice between cost and convenience/compliance.

Initiating Therapy and Minimizing Adverse Effects. ACE inhibitor therapy should be considered if diuretics alone fail to control congestive symptoms. It is important to inquire into exercise tolerance; patients may note improvement at rest with use of diuretics but still have exercise intolerance. To achieve maximum long-term benefit, treatment should not be delayed until the later stages of CHF. Persons with mild to moderate CHF (NYHA class II disease) experience significant reductions in morbidity and mortality with addition of ACE inhibitor treatment.

Because *hypotension* is common at the onset of therapy (especially in the elderly), it is recommended to start with *small doses* (e.g., as little as 6.25 mg of captopril, 2.5 to 5.0 mg of lisinopril) and *reduce concurrent diuretic therapy*. The dose is then increased gradually to the doses associated with a survival benefit (e.g., captopril 50 mg three times a day, lisinopril 20 mg/d). Monitoring *blood pressure* is important not only to ensure adequate renal perfusion but also to minimize dizziness and falls. Most CHF patients are elderly and can be very susceptible to even mild degrees of cerebral hypoperfusion. Continuous blood pressure monitoring is needed, because onset of hypotension may be delayed a few weeks yet persist.

Renal Dysfunction. Patients with preexisting bilateral renal artery stenosis and those receiving very large ACE inhibitor doses are at greatest risk for renal impairment, limiting use under such circumstances. Monitoring of renal function (BUN, creatinine, urinalysis) is indicated. Any otherwise inexplicable deterioration in renal function should result in considering a reduction in dose, which may suffice. Rarely is discontinuation of therapy necessary, although there have been case reports of proteinuria and membranous glomerulopathy linked to ACE inhibitor therapy that resolved only with cessation of therapy. Early reports of frequent renal dysfunction with use of these agents were due to the very high doses given.

Because ACE inhibitors reduce aldosterone levels, the *serum potassium* may rise and should be monitored, particularly in patients receiving potassium supplementation or a potassium-sparing agent as part of their diuretic therapy. In many instances, such supplementation or use of a potassium-sparing agent can be discontinued or at least reduced.

Other adverse effects are mostly idiosyncratic and include a dry irritant cough (affecting as many as 10%), *neutropenia* (usually within the first 3 months and only with captopril, due to its sulfhydryl group), loss of taste, and rash (including necrotizing vasculitis). *Angioedema* has also been reported. The cough is believed due to the agent's effect on kinins and can be very irritating, interfering with sleep and causing the patient to stop taking the drug.

Alternatives in Patients Intolerant to Angiotensin-Converting Enzyme Inhibitor Therapy. Patients who cannot tolerate ACE inhibitor therapy because of incapacitating cough or worsening of renal function clearly attributable to the drug can be switched to an *angiotensin II receptor blocker* (e.g., *losartan*) or to combination vasodilator therapy consisting of *hydralazine* and *isosorbide*. Although expensive and not yet proven to have the same morbidity and mortality benefits as ACE inhibitors, the angiotensin II receptor blocker agents also target the angiotensin system and appear to have similar hemodynamic effects without inducing cough. They are well tolerated and a reasonable alternative, especially in elderly patients.

Although ACE inhibitors replaced the combination vasodilator program of *hydralazine* and *isosorbide*, this program still has sufficient survival and hemodynamic benefits to warrant its consideration as an alternative in patients who cannot tolerate ACE inhibition.

Digitalis

Rationale. Digitalis remains a cornerstone of treatment for CHF in persons with systolic dysfunction (ejection fraction less than 40%) by virtue of its ability to increase contractility in the failing heart (mediated through an increase in intracellular calcium by inhibiting the myocyte sodium pump). Other beneficial effects include reduction in neurohumoral responses, vasodilation, increased baroreceptor responsiveness, and increased vagal tone. Although symptomatic and physiologic improvements have been found across the spectrum of patients with systolic dysfunction, the best results have been demonstrated in those with *severe systolic dysfunction* (NYHA class III and IV disease, ejection fraction less than 0.25, audible third heart sound S_3, marked left ventricular dilation). In fact, the presence of an S_3 is a strong predictor of marked response to cardiac glycoside therapy. When added to a program of diuretics and ACE inhibitors in appropriately selected patients, digoxin significantly reduces the rate of hospitalization due to worsening heart failure and shows a strong trend toward reducing cardiac mortality (as in the DIG study). However, patients with CHF in the presence of preserved systolic function and sinus rhythm do not appear to benefit.

Patient Selection. In patients with significant systolic dysfunction (ejection fraction less than 0.40) who remain unacceptably symptomatic despite a program of loop diuretic and ACE inhibitor therapy, digitalis treatment should be seriously considered. Highest priority should be given to those with severe systolic dysfunction (NYHA class III and IV disease, ejection fraction less than 0.25, audible third heart sound S_3, marked left ventricular dilation), but even those with less degrees of pump failure may benefit. The drug can be safely used for systolic dysfunction in patients who have suffered recent myocardial infarction; there is no excess mortality.

Digitalis also remains the drug of choice for heart failure induced by *rapid atrial fibrillation* and some other supraventricular tachycardias (see Chapter 28). The drug is also of use acutely in patients with CHF resulting from *uncontrolled hypertension* or *severe aortic stenosis* but is no substitute for blood pressure reduction (see Chapter 26) or for valve surgery when the aortic stenosis is critical (see Chapter 33). Digitalis is of little use in heart failure resulting from hypertrophic cardiomyopathies, be they idiopathic or due to long-standing hypertension (a common etiology among outpatients, especially women). Patients with idiopathic hypertrophic subaortic stenosis may develop worsening outflow tract obstruction with use of digitalis.

Digitalis is also of no proven benefit in cases of mitral stenosis, as long as the patient is in sinus rhythm, and is of no use in patients with episodes of CHF due to recurrent transient ischemia. The efficacy of digitalis in *cor pulmonale* is in question; the drug is occasionally beneficial, but the results are not impressive and the risks of toxicity are increased in the setting of hypoxia.

Choice of Preparation and Initiation of Therapy. *Digoxin* is the preparation of choice in most patients (see below). Those who are stable can be started on an oral *maintenance dose* without resorting to a loading dose. Using a daily digoxin maintenance dose of 0.25 mg, one can achieve therapeutic serum levels in 5 to 7 days. If the patient is less stable, but not so compromised as to require hospitalization, then an oral *loading dose* of 1.0 to 1.25 mg can be prescribed in divided doses over 24 hours.

The decision to initiate digitalis therapy should not be made casually. Digitalis toxicity is common and can be deadly. Digitalis therapy should be instituted only *after* before a program of loop diuretic therapy and ACE inhibition has been fully instituted and proven insufficient. Use of serum concentration measurements helps limit the incidence of digitalis toxicity as does careful monitoring and maintenance of serum potassium. However, one cannot depend on serum levels alone for the diagnosis of digitalis toxicity, because there is considerable overlap in serum concentrations among those with and without evidence of toxicity.

Digitalis Preparations. Numerous digitalis preparations are available; the physician should become familiar with one or two, learn their pharmacokinetics, and use them predominantly. *Digoxin* is the most widely used. In the past, some variations in bioavailability had been noted among different brands; this has been corrected. Half-life of digoxin is 36 hours; onset of action is 1 to 2 hours when taken orally; absorption from the gastrointestinal tract ranges from 50% to 75% complete. Excretion is renal and decreases significantly with reduction in creatinine clearance. Higher doses are not needed in obese patients; their nonlipid extracellular fluid volume is normal.

If a patient presents taking a digitalis preparation other than digoxin, it is best to leave them on the drug they are used to. The exception to this generalization concerns patients taking *digitalis leaf*. Because of its variable and unpredictable composition of digoxin and digitoxin, digitalis leaf should be discontinued, and one of the preparations containing only a single active ingredient should be used instead. *Digitoxin* may be beneficial when digitalis must be given to a patient with renal failure, because elimination of digitoxin is not dependent on renal function. However, a major disadvantage with digitoxin is its long half-life of 4 to 6 days, making for serious problems if toxic levels occur. Digoxin can be used safely in renal failure as long as renal function and serum levels are frequently checked and necessary dosage adjustments made.

Monitoring Therapy. Digitalis therapy requires careful monitoring. *Serum levels* should be measured at least three or four times per year, more frequently if there are changes in the patient's renal or volume status. Monitoring should help reduce the incidence of digitalis toxicity. A sample should be drawn at least 6 hours after the last dose, because there is a 4- to 6-hour rise in serum level after an oral dose. In most instances, it is best to have the patient omit the day's dose when coming to the office for a serum determination.

A number of factors can affect serum concentration, including renal function when digoxin is being used and hepatic function in digitoxin therapy.

Absorption of digitalis from the gut remains adequate in CHF but may fall in severe cases of malabsorption. Thyroid status can affect digitalis metabolism; hypothyroidism prolongs the half-life, and hyperthyroidism shortens it. Treatment of thyroid disease needs to be accompanied by an adjustment of dose.

The serum level of digitalis is not in itself diagnostic of *toxicity*, because there is considerable overlap in serum concentrations among those with and without evidence of toxicity, but if the *digoxin level* is *greater than 2.0 ng/mL*, the probability of encountering toxicity increases considerably. In one series, 80% of patients without evidence of toxicity had a digoxin level below 2.0 ng/mL; in 87% of those with toxicity, the level was above 2.0 ng/mL.

To avoid *digitalis toxicity*, even when the dose is closely followed, the physician needs to monitor factors that increase the "sensitivity" of the myocardium to the toxic effects of the drug. Such factors include *hypokalemia*, abnormalities in serum *calcium* and *magnesium*, organic heart disease, and pulmonary disease with acute *hypoxia*.

Digitalis Toxicity. Symptoms of digitalis toxicity can be divided into noncardiac and cardiac manifestations. Anorexia, nausea, vomiting, diarrhea, visual disturbances including yellow halos around lights, and in rare instances delirium have been described since Withering's time. Arrhythmias are the predominant cardiac manifestation of toxicity. Digitalis can cause any type of rhythm and/or conduction disturbance because it affects automaticity of myocardial tissues and the conduction system. *Ventricular irritability* (especially bigeminy), *paroxysmal atrial tachycardia* with block, and *junctional tachycardia* are particularly characteristic of digitalis excess.

The unexplained onset of an arrhythmia in a patient on digitalis raises the possibility of drug-related toxicity. The drug should be withheld; a serum level obtained; potassium, calcium, and magnesium levels checked; and serious consideration given to immediate hospitalization for monitoring and parenteral antiarrhythmic therapy. The high incidence and mortality rate of this preventable and often treatable condition call for vigilance.

Pitfalls in Digitalis Use. A few pitfalls in the use of digitalis are worth repeating. Digitalis should not be used unless there is genuine evidence of severe chronic systolic dysfunction or atrial fibrillation. An all-too-common error is to assume that ankle edema in the elderly patient is a sign of CHF and an indication for starting digitalis. The ankle edema may be due to venous insufficiency; even if due to congestive heart failure, it may be a manifestation of diastolic dysfunction and respond better to diuretics or ACE inhibitors. Digitalis should not be discontinued unless a reversible cause of pump failure has been fully corrected or there is no basis for using the drug in the first place. Patients who respond to digitalis need the drug chronically; they have been shown to deteriorate clinically and hemodynamically when the drug is withdrawn in experimental circumstances, even in the context of ACE inhibitor use. Digitalis-induced ST-T wave changes on the electrocardiogram have no correlation with optimal or toxic dose levels and cannot be used for such determinations. Serum drug levels are necessary.

Alternatives to Digitalis to Enhance Contractility: Phosphodiesterase Inhibitors. These agents are potent enhancers of contractility, but experimental results have been marred by increased rates of cardiac death. Early reports noted impressive clinical improvement with such agents as *milrinone*, *flosequinan*, and *vesnarinone*, but follow-up revealed unacceptable rates of cardiac morbidity and mortality—flosequinan had to be recalled after receiving U.S. Food and Drug Administration (FDA) approval. Vesnarinone improves survival and functional status when used in doses too small to affect phosphodiesterase, but in larger doses, cardiac mortality rises markedly. Such results underscore the importance of factors other than contractility in determining the outcome of CHF. Demonstrating improved contractility does necessarily predict improved outcome. Neurohumoral activation is believed to be a causative factor affecting CHF mortality.

Beta-Blockers

Although the traditional view has been that beta-blockade will worsen outcomes in CHF, there is emerging evidence that it may be helpful as an adjunct to standard therapy, possibly slowing disease progression. Sympathetic stimulation is one of the major neurohumoral responses to heart failure, increasing with severity of disease and serving as an independent predictor of mortality. Some believe that it may play a role in disease progression. A few large-scale, randomized, placebo-controlled trials of both cardioselective and nonselective beta-blockers (e.g., metoprolol-XL, bisoprolol, and carvedilol) in CHF have shown improvements in symptoms, ejection fraction, rates of hospitalization for heart failure, and, in some instances, survival. *Carvedilol* (a nonspecific beta-blocker that also blocks a receptors, prevents upregulation of cardiac beta receptors, reduces cardiac norepinephrine, and demonstrates strong antioxidant effects) has received FDA approval for use in CHF, showing benefit when added to standard therapy in persons with moderately severe CHF (NYHA class II and III). Definitive evidence for a long-term mortality benefit and safety in persons with severe CHF (NYHA class IV) remains to be demonstrated. Moreover, there is concern about a short-term increase in risk with use of such agents.

Until more data are forthcoming, beta-blockers should be considered only as a possible adjunct to standard therapy, not as a replacement. Cardiac consultation is recommended, both to facilitate case selection and initiation of therapy. Patients may worsen clinically during the first weeks of beta-blocker treatment. Doses at first should be small (e.g., metoprolol-XL 25 mg/d, carvedilol 3.25 mg/d) and titrated upward slowly. The immediate goal is a resting heart rate of 50 to 60 beats/min. An increase in diuretic dose may be necessary due to fluid retention, which is common in the early phases of beta-blocker therapy.

Oral Anticoagulation

Although the presence of CHF is not, per se, an indication for warfarin anticoagulant therapy, it does increase the risk of thromboembolic disease in a patient with an underlying predisposition for an embolic event. For example, the CHF patient who is put to bed rest is at increased risk of deep vein thrombophlebitis and deserves consideration for anticoagulation (see Chapter 35). The same holds true for the patient in atrial fibrillation who develops CHF (see Chapter 28). The initiation and monitoring of oral anticoagulant therapy require considerable attention to detail (see Chapter 83).

Concurrent Drug Use

Use of medications that might depress left ventricular function or alter neurohumoral regulatory mechanisms should be undertaken with extreme care and only after the potential risk is weighed. For example, *beta-blocking agents* (see above), *disopyramide*, and such calcium channel blockers as *verapamil* are myocardial suppressants; they are relatively contraindicated for use in CHF. In a study of the role of prostaglandins in CHF, it was discovered that use of prostaglandin inhibitors, such as the *nonsteroidal antiinflammatory agent* indomethacin, caused a worsening of CHF in patients with advanced disease complicated by hyponatremia; patients without hyponatremia were unaffected.

Fortunately, some important medications are not contraindicated in CHF. For example, the *tricyclic antidepressants* do not cause a reduction in left ventricular performance; they are relatively well tolerated, although they occasionally cause postural hypotension in CHF patients. A study of the effects of *acute intake of alcohol* on patients with functional class III or IV CHF found no deleterious effect on cardiac function; in fact, a modest reduction in afterload was noted, although the authors hastened to add that they were not recommending alcohol as a vasodilator.

Calcium Channel Blocker Use in Congestive Heart Failure. Many patients with heart failure have underlying ischemic heart disease or hypertension and may already be taking a calcium channel blocker for control of anginal symptoms or blood pressure. One needs to be aware that randomized, prospective, controlled studies have documented a significant increase in the risks of worsening heart failure, life-threatening arrhythmias, myocardial infarction, and death with the use of

calcium channel blocker therapy when calcium channel blockers are used in persons with heart failure. These risks have prompted many authorities to advise against prescribing calcium channel blocker therapy for patients with coronary disease complicated by severe chronic heart failure.

The mechanisms responsible for these cardiac complications remain poorly understood. It was thought that the reflex tachycardia and negative inotropic effects of many of these agents were responsible, but even the use of sustained-release preparations and agents with little effect on the left ventricle have not lowered the risk. Of the calcium channel blockers, only *amlodipine* has proven safe for use in anginal patients with severe chronic left ventricular dysfunction (ejection fraction less than 30%). Of the drugs in its class, it appears to have the least effect on contractility, conductivity, and neurohumoral reflexes. Why it should be the best tolerated of the calcium channel blockers remains unclear, although it appears to be among the least negatively inotropic. However, amlodipine does not improve survival and carries a 5% risk of inducing pulmonary edema, probably because of pulmonary vasodilation. Moreover, its cost is high. All drugs in this class should be used with caution, if at all, in patients with clinical evidence of chronic CHF. Cardiac consultation is indicated.

Nonpharmacologic Measures

Salt Restriction. Salt restriction has traditionally occupied an important place in supportive therapy. It is probably most helpful in preventing unnecessary exacerbations of failure. Patients are placed on a *no-added-salt diet*, which provides about *4 g sodium/d.* The patient and family are instructed to prepare and serve meals without addition of salt and to avoid foods with large salt content, including canned ham (which is packed in salt water), bacon, catsup, canned soups, and other processed foods. Rarely is extreme salt restriction (e.g., 1 to 2 g sodium diet) urged on the patient, because it is often unrealistic and unpalatable, leading to poor caloric intake and depression. Fluid restriction is reserved for severe cases that are complicated by hyponatremia.

The Activity Prescription. The activity prescription has an important function in minimizing myocardial work demands while maintaining the patient's ability to live as fully as possible. The level of allowable activity needs to be tailored to the patient's medical status, life-style, and responsibilities. Patients with symptoms of failure on moderate exertion (NYHA class II disease) can continue to work as long as reasonable limits are placed on emotional and physical demands. It may be more stressful psychologically (and consequently physically) to have to quit one's job than to continue working in a somewhat more limited capacity. In most instances, the amount of allowable activity can be determined from an office visit by a careful history that elicits the degree of exertion that precipitates symptoms. At times, symptoms may be out of proportion to physical findings; taking a walk up a flight of stairs with the patient can provide helpful data regarding exercise tolerance. Treadmill testing is sometimes necessary to gauge exercise capacity, especially if the patient has coronary disease and it is unclear whether it is failure or ischemia that is limiting the patient. Regardless of etiology, a daily rest period and reduction of psychological stress are key means of lessening myocardial work in the patient with failure.

If weight is increasing, orthopnea worsening, and dyspnea on exertion more severe and brought on by less exertion, activity should be further restricted. A few days of bedrest are often beneficial and may obviate the need for hospitalization. The patient with failure who is put to bed should use a footboard or get out of bed periodically to avoid prolonged venous stasis and thrombus formation.

Atriobiventricular Pacemakers and Implantable Defibrillators. Atriobiventricular pacemakers and implantable defibrillators are under study for use in advanced heart failure. Initial investigations suggest that atriobiventricular pacemakers can improve functional status and quality of life in patients with severe heart failure and intraventricular conduction delay, and that prophylactic defibrillator implantation improves survival in advanced heart failure patients (EF <0.35) having inducible sustained ventricular tachycardia (see Chapter 29). The literature should be followed closely for emerging data on patient selection, cost-effectiveness, and long-term risks and benefits.

Updated: 3/27/02

PATIENT EDUCATION

Because the medical program is often complex and the need for compliance is great, the physician must take the time to discuss with patient and family the rationale behind therapy and to set with them the guidelines for activity, diet, and use of medication. In this way they can become valuable partners in the treatment effort.

Patients should be instructed to weigh themselves each morning before breakfast and to keep a *weight record.* If their clinical status, weight, and medication program are stable, less frequent recordings are necessary. Patients are advised to call their physician if weight increases suddenly by more than 2 or 3 pounds, because this may be the earliest sign of increasing CHF and a forerunner of more severe symptoms. Reliable intelligent patients may be instructed to adjust their diuretic doses according to weight. Debilitated or uncooperative individuals should have a family member or visiting nurse obtain weight recordings. Weight is among the most helpful parameters to follow in outpatient management of failure.

Patients and their families must know the identity of the medication being used. It is easy for the patient to become confused, because multiple-drug regimens are common and many of the pills are similar in appearance. Medication booklets are invaluable. Each tablet is taped to the page alongside its generic and brand names, dose schedule, indication for use, and warning signs of toxicity. For patients with poor eyesight, a family member or visiting nurse should set aside the pills to be taken each day.

INDICATIONS FOR REFERRAL AND ADMISSION

Patients with markedly worsening or refractory failure should be considered for hospital admission and cardiac consultation. For the patient with seemingly refractory disease, hospitalization provides the opportunity to observe response to treatment under controlled conditions that ensure compliance with the medical regimen. Moreover, hospitalization helps to ensure safe initiation of additional therapy and a search for a treatable underlying etiology that may have initially eluded detection. Cardiac consultation can be helpful when considering adjunctive pharmacologic therapy (e.g., beta-blockade, aldosterone inhibition) and is essential to exploring indications for pacemaker or defibrillator implantation. Relatively young patients failing maximal medical therapy may be appropriate for consideration of transplantation, provided renal, pulmonary, hepatic, and central nervous system functions are preserved. Other indications for admission include evidence of digitalis toxicity, renal failure, hypotension, and inadequate support and supervision at home.

THERAPEUTIC RECOMMENDATIONS

- Identify the etiology of the CHF (e.g., dysrhythmia, hypertension, valvular disease, ischemia, cardiomyopathy) and any precipitating factors (e.g., fever, anemia, atrial fibrillation, infection, salt excess); treat these specifically if they are amenable to therapy rather than relying solely on symptomatic measures to ameliorate the CHF.
- Identify the underlying pathophysiology, particularly the degree to which there is systolic and/or diastolic dysfunction, and tailor the treatment program to the patient's pathophysiology.

Mild Disease (NYHA Class I)

- Initiate a no-added-salt diet (4 g sodium) but do not restrict water intake unless dilutional hyponatremia ensues.
- Begin diuretic therapy if there is evidence of volume overload or pulmonary venous congestion. If symptoms are mild, begin with a thiazide (e.g., hydrochlorothiazide 50 to 100 mg/d).
- If thiazides do not suffice, switch to a loop diuretic (e.g., furosemide 20 to 40 mg once or twice daily). Be alert for a very brisk diuresis in patients who have never before received a loop diuretic. Exercise particular caution with use of potent diuretics in situations that require a high filling pressure (e.g., critical aortic stenosis).
- In initial stages of loop diuretic use, divide daily dose to minimize the inconvenience of a large diuresis in the morning or evening that might interfere with activity. Avoid giving an evening dose if sleep is being interrupted by nocturia.
- If patient does not respond adequately to a loop diuretic dose that is being given in divided fashion, try combining the entire daily dose into one administration of the drug, before increasing total daily dose.

Mild to Moderate Disease (NYHA Class II to III)

- If moderate doses of diuretic therapy do not suffice to relieve congestive symptoms, then add an ACE inhibitor, starting at a low dose to minimize the risks of hypotension and hypoperfusion (e.g., 6.25 mg captopril three times a day or 5.0 mg lisinopril/d). Monitor blood pressure, potassium, BUN, and creatinine, and decrease diuretic dose if blood pressure falls or prerenal azotemia develops.

- Gradually advance ACE inhibitor therapy to improve exercise tolerance and relieve congestive symptoms while continuing to monitor blood pressure, potassium, and renal function. If tolerated, advance to doses associated with best outcomes (e.g., captopril 50 mg three times a day; lisinopril, 10 to 20 mg/d).

Moderate to Severe Disease (NYHA Class III to IV)

- In patients with moderate to severe heart failure due to worsening systolic dysfunction (low ejection fraction, S $_3$, left ventricular dilation), add a digitalis preparation to the program of a loop diuretic and an ACE inhibitor.
- Use digoxin as the digitalis preparation of choice, except in the setting of severe renal failure, where digitoxin or markedly reduced doses of digoxin are indicated.
- If the candidate for digitalis is relatively stable, begin therapy with an oral maintenance dose (e.g., digoxin 0.25 mg/d), checking the serum level in 1 week and making any needed dose adjustments on the basis of clinical response and serum level.
- If the digitalis candidate has worsening heart failure but does not require immediate hospitalization, then start digitalis therapy with a loading dose of 1.0 to 1.25 mg of digoxin orally, given in four divided doses over 24 hours. Dose is then adjusted as above.
- If volume overload persists, advance loop diuretic therapy to full doses (e.g., 80 to 120 mg/d of furosemide), given once daily to achieve maximum effect; add a thiazide or metolazone (if there is azotemia) if additional diuresis is desired. Monitor for prerenal azotemia and halt advancement of diuretic program if it becomes marked.
- Be sure full doses of an ACE inhibitor are being prescribed and taken (e.g., captopril 50 mg three times a day; lisinopril, 10 to 20 mg/d). For patients unable to tolerate an ACE inhibitor because of development of an irritant dry cough, consider switching to an angiotensin II antagonist (e.g., losartan 50 mg/d).

Refractory Disease: Adjunctive Programs, Hospitalization, and Transplantation

- Consider addition of low-dose spironolactone (25 mg/d) in persons with severe disease who are still unacceptably symptomatic. Cease any potassium supplementation and monitor potassium levels closely; use with extreme caution, if at all, in the setting of worsening renal function (creatinine more than 2.5 mg/dL).
- Consider adding a low dose of beta-blocker therapy (e.g., carvedilol 3.25 mg/d or metoprolol-XL 12.5 to 25 mg/d) for patients with moderate disease and suboptimal response to standard therapy. Obtain cardiac consultation to facilitate case selection and initiation of therapy. In most instances, resting heart rate should be in excess of 70 to 80 beats/min and systolic blood pressure more than 100 to 110 mm Hg. Titrate dose slowly upward to achieve a resting heart rate of 50 to 60 beats/min. Monitor patient closely for fluid retention and clinical worsening, especially in the first 2 months of treatment; adjust diuretic dose upward if necessary.
- Consider hospitalization for patients with severe refractory disease for full review of disease status, precipitants, aggravating factors, compliance, and initiation of any adjunctive therapies. Also admit for markedly worsening CHF, suspected digitalis toxicity, or inadequate support and supervision at home.
- If there is refractory failure and intraventricular conduction delay, refer for consideration of atriobiventricular pacing. If there is advanced heart failure (EF <0.30) and concern about ventricular dysrhythmias, refer for consideration of electrophysiologic study and candidacy for prophylactic defibrillator implantation. Transplantation is a consideration if the patient is relatively young and has end-stage myocardial disease but preserved renal, hepatic, pulmonary, and neurologic function. **Updated: 3/27/02**

Monitoring and Adjusting Therapy

- Advise patient and family to check weight regularly, measuring it before breakfast and calling if there is an unexplained weight gain of more than 2 to 3 pounds since the last reading.
- Monitor potassium, BUN, and creatinine regularly and, in persons taking digitalis therapy, follow the serum digoxin level. Avoid having the serum digoxin level drawn sooner than 6 hours after the last dose, because there is a transient increase in serum level after an oral dose.
- Monitor serum potassium particularly closely in those taking digitalis plus potent diuretics or an ACE inhibitor plus a potassium-sparing diuretic or potassium supplementation. Correct any potassium abnormality promptly to minimize risk of a serious dysrhythmia.
- If prerenal azotemia develops or worsens, adjust the diuretic program; for those taking digoxin, obtain a serum digoxin level and reduce the dose until a serum digoxin level is available to guide further administration or estimate the required dose from available nomograms.
- Monitor heart rate and rhythm; if a cardiac dysrhythmia is noted, investigate and treat promptly, especially in persons taking a digitalis preparation who manifest paroxysmal atrial tachycardia with block, ventricular irritability (especially bigeminy), junctional tachycardia, or severe bradycardia.
- Use oral potassium supplements and potassium-sparing diuretics with extreme caution, if at all, in patients taking ACE inhibitors and only if the serum potassium falls to less than 3.5 mg/dL. If a potassium-sparing diuretic is used, chronic oral potassium supplementation should be stopped.
- Monitor serum magnesium in patients taking digitalis and those with refractory hypokalemia. Diuretic-induced hypomagnesemia is common and may impair potassium repletion; it also enhances sensitivity to the toxic effects of digitalis.

Additional Measures and Precautions

- Initiate oral anticoagulant therapy for CHF patients if prolonged bedrest, atrial fibrillation, or severe congestive cardiomyopathy ensue (see Chapter 83).
- Avoid, if possible, large doses and combinations of cardiac drugs with negative inotropic effects such as verapamil, disopyramide, and beta-blockers. If beneficial, use smallest dose possible and prescribe in conjunction with cardiac consultation (see above). Consider discontinuation of calcium channel blockers in patients with chronic CHF, especially those with ejection fractions less than 0.3. Of available calcium channel blockers, only amlodipine is not associated with increased risk of worsening failure, life-threatening dysrhythmias, and sudden death. Obtain cardiac consultation if continued use is believed essential.
- Provide patient and family with thorough instruction on the purpose and proper use of medications prescribed for CHF.
- Advise bedrest for exacerbations of CHF, but discourage major reorganization of a patient's life-style unless symptoms are severe and refractory. A gentle exercise program may actually improve exercise tolerance once the exacerbation has cleared.

CHAPTER 33 MANAGEMENT OF VALVULAR HEART DISEASE

RICHARD R. LIBERTHSON

As a result of increased physician awareness and improvements in noninvasive diagnostic techniques, the diagnosis of valvular heart disease is being made earlier in the course of illness. Such techniques also reveal cardiomyopathies that may contribute to valvular dysfunction or simulate it by causing outflow-tract obstruction (see Chapter 21). Outpatient management of valvular heart disease has become commonplace because symptoms are frequently absent or mild at the time the condition is discovered. Although consultation with a cardiologist is often obtained, the responsibility for long-term care usually falls on the primary physician. Proper management requires that the primary physician is familiar with the natural history of valvular disease, the early warning signs of hemodynamic deterioration, and the indications for medical and surgical therapies. Skill in application of anticoagulation (see Chapter 83) and antibiotic prophylaxis (see Chapter 16) is essential as is ability to manage the early phases of heart failure (see Chapter 32) and atrial fibrillation (see Chapter 28). Of major importance is the proper timing of referral for consideration of valve repair. Also important is the early recognition and proper management of the common cardiomyopathies that cause left ventricular outflow tract obstruction (see Appendix).

NATURAL HISTORY

Mitral Stenosis

Most cases of mitral stenosis are *rheumatic* in origin, even though as many as 50% of patients cannot give a history of rheumatic fever. The symptom-free interval averages about 10 years (range, 3 to 25 years). In most instances, symptoms develop gradually over a decade, roughly paralleling the progression of stenosis; however, some people remain relatively free of complaints until stenosis becomes severe. Left atrial and pulmonary venous pressures increase substantially as valve area falls below 1.5 cm^2, and at this point patients typically experience *dyspnea on exertion.* Any stimulus that rapidly increases blood flow or decreases the time available for diastolic filling can precipitate a sudden increase in pulmonary congestion and result in acute shortness of breath. Strenuous activity, fever, emotion, and onset of atrial fibrillation are often responsible for acute dyspnea.

Progressive narrowing of the valve orifice is accompanied by worsening exercise tolerance and increasing dyspnea. In patients with tight stenosis (valve area less than 1.0 cm^2), the period from onset of symptoms to incapacity averages 7 years, but the decline can be precipitous with the onset of atrial fibrillation or pneumonia. Chronic marked increase in pulmonary venous pressure often leads to fixed *pulmonary hypertension.* Cardiac output usually falls with onset of severe pulmonary hypertension, and fatigue may become a prominent symptom. The right ventricle hypertrophies in response to the rise in pulmonary artery pressure, and *right-sided heart failure* and death ensue unless intervention occurs; deterioration may be rapid at this stage.

Atrial fibrillation complicates 40% to 50% of cases of symptomatic mitral stenosis. The correlation between development of atrial fibrillation and the severity of stenosis is slight and not due solely to the degree of left atrial enlargement. The loss of atrial systole and the increase in heart rate that characterize atrial fibrillation markedly reduce flow across the mitral valve and boost left atrial pressure. Premature atrial contractions and paroxysmal atrial fibrillation often precede sustained atrial fibrillation due to mitral stenosis.

Systemic embolization occurs in 10% to 20% of patients with mitral stenosis. Age and presence of atrial fibrillation are the major determinants of risk; severity of stenosis is not a determinant, and in fact, embolization may be a presenting symptom of mitral stenosis.

In sum, there is typically a symptom-free period of about 10 years. Patients then begin to note dyspnea on exertion over the next 10 years, which progresses in many instances in the following decade. Once symptoms are present on minimal exertion, survival becomes markedly reduced. Patients with New York Heart Association class IV disease (symptoms at rest) have been found to have a 5-year mortality rate of 85%. Some patients have disease that may remain stable for many years. In another subset of patients, symptoms do not develop until late in the illness.

Mitral Regurgitation

Rheumatic mitral regurgitation can remain asymptomatic for many years, because the left ventricle dilates and adjusts well to the increase in volume load. Onset of dyspnea and fatigue may not occur for decades. Symptoms take an average of 10 years to progress to the point of disability and need for surgery. It is not until very *late* in the course of the disease that myocardial reserve falters. Once the left ventricle fails, patients note *progressive dyspnea* and *fatigue*; symptoms become present at rest (functional class IV disease). If pulmonary hypertension develops, signs of right-sided heart failure will ensue. Prognosis is poor at this stage.

Atrial fibrillation is found in more than 75% of cases, but the abrupt episodes of pulmonary congestion that typify mitral stenosis complicated by atrial fibrillation are less frequent in mitral regurgitation, although rupture of one of the chordae tendineae can result in sudden deterioration.

Nonrheumatic forms of chronic mitral regurgitation are commonly encountered in the outpatient setting. Etiologies include mitral valve prolapse, papillary muscle dysfunction, and calcified mitral valve annulus. The widespread use of the diet-pill combination *phentermine/fenfluramine* in the mid-late 1990s (see Chapter 234) was associated with reports of new onset of clinically significant incompetence of mitral, tricuspid, and aortic valves. The valves of persons who came to surgery were characterized by striking fibrosis of the endocardial surface identical to that seen in carcinoid syndrome, leading some to speculate that this might be the consequence of excessive seratonergic effects on valve endocardial metabolism. Patients at greatest risk appeared to be those taking the combination program at maximal doses for prolonged periods (more than 4 months), but the true magnitude of the risk has been hard to determine. Because of concern over valve injury, both drugs have been withdrawn from the market.

Mitral valve prolapse (MVP) is one of the most common valvular disorders, with a community prevalence of 2.5%, which is less than the previous estimate of 5% that resulted from data skewed by referral bias. Only patients with truly redundant and thickened mitral leaflets on B-mode (two-dimensional) cardiac ultrasound should be considered to have MVP. These patients have myxomatous proliferation of the spongiosa and elongation of the chordae. Many patients with normal mitral valve leaflets appearing bowed or saddle-shaped on certain echocardiographic views have been mistakenly labeled as having MVP and approached as if they have its attendant risks.

Although patients with true MVP are at increased risk for valvular incompetence, endocarditis, systemic embolization, and dysrhythmias, the prognosis for most is excellent, and most are entirely asymptomatic and at only minimal risk. Many MVP patients do not experience hemodynamically significant regurgitation or an increase in regurgitant flow with time, but there is a subset that do, particularly those with an initial left ventricular diastolic dimension in excess of 60 mm. The associated valvular insufficiency can cause *chronic volume overload*, leading to *left-ventricular dysfunction* and sometimes necessitating mitral valve replacement. Because the initial phases of decline may not be accompanied by symptoms or major fall in ejection fraction, serial echocardiographic examination is required for timely detection of left ventricular dysfunction.

There is a slight increase in risk of *bacterial endocarditis*, especially in those with clinically evident valvular incompetence (regurgitant murmur evident on examination) or a markedly redundant and thickened valve on echocardiogram. The American Heart Association suggests endocarditis prophylaxis for those with MVP who have evidence of mitral insufficiency. Patients with normal variants have little or no increase in risk of endocarditis and do not require antibiotic prophylaxis (see Chapter 16).

Stroke risk is also much less than previously estimated, due to stricter criteria and better precision in diagnosis of MVP. Among younger persons with embolic stroke,

there is no increase in prevalence of MVP, suggesting that risk is minimal in the absence of other embolic risk factors. A very small group of MVP patients have *malignant ventricular arrhythmias*; overall risk of sudden death is extremely low in most patients with MVP but heightened in those with a history of syncope, prior ventricular tachyarrhythmias, or a family history of sudden death. Risk appears related to degree of myxomatous changes but not to degree of valve incompetence or left ventricular dysfunction.

Some have raised the question of a relation between *panic disorder* and MVP, because of paniclike symptoms occurring in a small percentage of patients with MVP. Indeed, a small percentage of MVP patients do suffer from *autonomic dysfunction* and complain of palpitations, atypical chest pain, orthostatic dizziness, near-syncope, cold extremities, throbbing headaches, and neurasthenia and manifest tachyarrhythmias, orthostatic hypotension, and peripheral vasoconstriction. However, careful studies have found no causal link between MVP and autonomic dysfunction or panic disorder.

Papillary muscle dysfunction is responsible for as many as 10% of mitral regurgitation cases found clinically. Causes include ischemic injury, left ventricular dilatation, and cardiomyopathy. Ischemic heart disease is the most frequent etiology, with 40% of posterior infarcts and 20% of anterior infarcts accompanied by the development of papillary muscle dysfunction. The amount of regurgitant flow is highly variable. Severe mitral regurgitation and marked pulmonary congestion can occur, even in the context of only a minimal reduction in left ventricular ejection fraction. However, prognosis does depend on left ventricular systolic performance.

Calcification of the mitral annulus occurs in older people, often in conjunction with calcification of the aortic valve. The mitral lesion is usually not of hemodynamic significance, but heart block can develop if calcification extends into the ventricular septum.

Mixed Mitral Disease

Mortality is increased when significant stenosis and regurgitation occur simultaneously. In one large series of patients managed medically, the 10-year survival rate from the time of diagnosis was 33%.

Aortic Stenosis

Because of the marked ability of the left ventricle to hypertrophy and compensate for the pressure load, patients with aortic stenosis can remain symptom-free for many years, even with tight stenosis (valve area less than 0.7 cm^2). This is especially true in young patients. However, it must be remembered that sudden death can occur in previously asymptomatic individuals with critical aortic stenosis. Onset of *angina* and *effort syncope* suggest a hemodynamically critical lesion that is limiting cardiac output, although in as many as 30% to 60% of aortic stenosis patients with angina, there coexists significant occlusion of a coronary vessel. Survival averages 3 years from the onset of angina or effort syncope. The development of *congestive failure* is an ominous sign, for it signals the inability of the myocardium to continue tolerating the severe pressure load; survival averages 2 years from the time failure is first noted. More than half of patients with aortic stenosis die of congestive failure. Sudden death accounts for another 20%. The mean age of death for patients dying suddenly is 60 years; the mechanism of death in these cases is believed to be a dysrhythmia triggered by myocardial ischemia, although debate continues. The rate of stenosis is unpredictable and can progress rapidly over a few years, especially as the patient enters their sixties. Figures for survival are only averages; the range is wide, and many patients die soon after the onset of symptoms.

Age at clinical onset of aortic stenosis is dependent in part on the underlying etiology. Significant aortic stenosis appearing in a patient younger than 30 years of age is congenital in origin, due most often to a *bicuspid* valve. In approximately 15% of such patients, obstruction is caused by a discrete *subaortic membrane*. Patients presenting between ages 30 and 70 have either a bicuspid valve or a valve damaged by *rheumatic fever*. Those who present with significant aortic stenosis caused by rheumatic fever average 10 to 15 years older than patients who present with rheumatic mitral stenosis, due to the more gradual progression of the illness when it involves the aortic valve. Nevertheless, the course can be one of rapid deterioration.

Aortic stenosis developing in the *elderly* is usually due to *primary degenerative calcification* of a normal aortic valve. Unlike aortic stenosis caused by rheumatic disease with its fusion of valve commissures, *calcific aortic stenosis* results from calcific thickening of the valve leaflets and their loss of mobility. Patients with calcification of a bicuspid valve may present as early as the sixth decade; those with senile calcification of a tricuspid aortic valve present with stenosis in the eighth and ninth decades. By 80 years of age, half of the population has a systolic ejection murmur; in a small percentage, hemodynamically significant stenosis ensues.

Calcific aortic stenosis of the elderly now accounts for most new aortic stenosis cases. Unlike rheumatic aortic stenosis with its fixed valve orifice, the degree of stenosis in calcific aortic stenosis varies with the strength of the left ventricle. The weaker its contraction, the less the valve will open and the greater the outflow obstruction. A failing left ventricle may cause a rapid downhill course. Thus, the contractile state of the left ventricle is a critical determinant of the clinical course of calcific aortic stenosis. Also, the degree of calcification may progress.

Aortic sclerosis in the elderly, even in the absence of hemodynamically significant stenosis, is associated with a 50% increase in morbidity and mortality from coronary artery disease. As such, it serves as a marker for atherosclerotic disease but is not necessarily a pathologic lesion of significance to valvular function.

Aortic Regurgitation

Rheumatic fever accounts for the largest number of aortic regurgitation cases. Most patients live for decades with little incapacity, as the left ventricle dilates to accommodate the extra volume load. The latent period from occurrence of rheumatic fever to onset of clinical manifestations is about 10 years. During the next decade, symptoms appear and progress. The onset of symptoms is typically gradual, with *palpitations* being among the earliest changes noted by the patient, followed by *dyspnea on exertion* and *fatigability*. Appearance of *left ventricular hypertrophy* with strain and progressive *left ventricular dilation* are associated with a markedly increased risk of heart failure and death within 5 years. If exertional dyspnea worsens, other manifestations of congestive failure are likely to follow and signal the beginning of a rapidly declining phase of the disease due to left ventricular decompensation. At this stage, deterioration is rapid, with death occurring within 1 to 2 years of the onset of congestive failure. *Angina* is common, reported by almost 30% of patients; unlike the angina of aortic stenosis, it typically takes place *at rest* rather than on exertion. Angina becomes more frequent when there is worsening heart failure. *Sudden death* may also occur in patients with severe aortic regurgitation.

Nonrheumatic Causes. About 5% of persons with a *bicuspid aortic* valve also have aortic regurgitation as may those with other less common anomalies (e.g., supracrystal ventricular septal defect and discrete subaortic membranes). Other causes of aortic regurgitation include *syphilis*, myxomatous degeneration, bacterial endocarditis, and connective tissue disease. Aortic regurgitation secondary to untreated syphilis appears about 15 to 25 years after the initial infection and often has a more rapid downhill course than aortic regurgitation caused by rheumatic fever. *Myxomatous degeneration* has been found in 10% to 15% of cases of aortic regurgitation studied pathologically. The process is progressive and becomes clinically evident between the ages of 30 and 60. Although *bacterial endocarditis* can damage a tricuspid aortic valve, particularly one that is fibrotic or calcific, it is far more likely to occur with a biscuspid valve.

Ankylosing spondylitis is complicated by aortic regurgitation in about 3% of cases. The severity of the lesion is highly variable, and conduction defects are frequent. Aortic regurgitation may appear before the onset of other symptoms, but in most instances it follows the appearance of arthritic symptoms by 10 to 20 years. The presence of severe aortic regurgitation shortens the otherwise normal life expectancy of patients with ankylosing spondylitis. *Reiter's syndrome* is associated with the development of aortic regurgitation in 5% of cases, typically in those with florid manifestations of the disease such as iritis, mucocutaneous changes, and extensive sacroiliac inflammation. Onset of aortic regurgitation occurs an average of 15 years after the disease is first noted, often preceded by conduction disturbances. The severity and course of the aortic regurgitation are highly variable.

Use of the appetite-suppressant combination *phentermine/ fenfluramine* in the mid-late 1990s (see) was also associated with reports of new onset of aortic insufficiency. Risk appeared greatest for those using the combination rather than a single agent and for use in excess of 4 months. The precise magnitudes of the relative and absolute risks remain controversial, and the natural history of the lesion is unknown.

Mixed Aortic Valve Disease. Many patients with aortic stenosis have some degree of aortic regurgitation, and vice versa. Whenever the gradient across the aortic valve is greater than 25 mm Hg in the context of significant regurgitation, there begins to develop a substantial pressure load and an increased volume load on the left ventricle. The clinical course is similar to that for isolated aortic stenosis of the same degree, although some clinicians believe there is an earlier onset of symptoms.

Combined Aortic and Mitral Disease. The etiology is mostly rheumatic; in fact, most cases of rheumatic fever produce some degree of multiple valve damage, though disease of one valve often dominates the clinical picture. Mitral stenosis may be overlooked in the setting of concurrent heart failure, pneumonia, or aortic valvular disease. In a study of 152 patients with echocardiographically significant mitral stenosis, 15% of mitral stenosis cases were unrecognized before ultrasound

examination, yet most had an audible murmur on reexamination. The most common combination is aortic regurgitation in conjunction with mitral disease. Atrial fibrillation and systemic embolization are more frequent than in isolated aortic regurgitation, as is the severity of pulmonary symptoms. Less common is the coexistence of aortic stenosis and mitral stenosis. Symptoms and signs of aortic stenosis are blunted by significant mitral stenosis, such that pulmonary symptoms, atrial fibrillation, and systemic embolization may dominate the presentation, but there may be more angina and syncope than expected from isolated mitral stenosis. Course is dictated by the severity of the individual lesions, but mitral stenosis can delay the appearance of some of the manifestations of advanced aortic stenosis.

ESTIMATING SEVERITY OF DISEASE

Mitral Stenosis

Symptoms provide crude indications of the severity of stenosis. *Dyspnea* correlates with increase in left atrial pressure and development of *pulmonary venous congestion*, but the relationship between degree of stenosis and elevation of left atrial pressure is variable. *Fatigue* occurs most often in the context of *pulmonary hypertension*, but the nonspecific nature of the symptom lessens its utility in estimating severity. *Hemoptysis* is related to pulmonary *venous hypertension* but does not necessarily imply severe stenosis. Thus, history alone may fail to detect severe stenosis that is unaccompanied by marked pulmonary congestion; however, a worsening of dyspnea and a decline in exercise tolerance suggest hemodynamic deterioration and require further investigation.

On *physical examination*, the interval between the second heart sound and the opening snap, referred to as the S_2-OS *interval*, and the duration and timing of the diastolic murmur provide additional clues of severity. The S_2-OS interval is a function of the elevation in left atrial pressure. The greater the pressure, the shorter the interval. Unfortunately, the degree of mitral stenosis is not the only determinant of left atrial pressure; the interval can be affected by factors other than valve area, such as heart rate and left ventricular pressure. Moreover, the valve must be mobile to snap; in advanced disease, the valve may calcify and the snap becomes inaudible. Nevertheless, the S_2-OS interval is useful because it can be determined at the bedside and does provide data that may help in judging severity when considered in the context of other findings. Perhaps the most precise use of the interval is in separating hemodynamically insignificant disease from moderate and severe mitral stenosis. An interval of greater than 0.11 seconds at rest with a heart rate of 70 to 80 beats/min argues against a significant lesion (although there are exceptions). Patients with moderate to tight stenosis usually demonstrate intervals less than 0.08 seconds, which shorten with exercise. Proper estimation of the S_2-OS interval takes considerable practice.

The intensity of the *diastolic murmur* does not correlate with severity of stenosis, but its duration through diastole does. However, development of pulmonary hypertension may decrease cardiac output from the right side of the heart, result in a diminution of flow across the mitral valve, and consequently shorten the duration of the murmur.

Chest x-ray provides important evidence of severity. The earliest radiologic sign of mitral stenosis is dilation of the left atrium, which is best seen on a lateral view in conjunction with a barium swallow to outline the esophagus. The finding is not a very reliable manifestation of severity. A better sign is redistribution of pulmonary venous blood flow, producing dilation of the upper zone pulmonary veins. Upper zone redistribution becomes prominent at a left atrial pressure of 25 mm Hg and parallels severity of stenosis. This change in pulmonary venous flow is very sensitive to changes in left atrial pressure, but it is not unique to mitral stenosis. Radiologic evidence of pulmonary hypertension (dilation of the right pulmonary artery to 15 to 18 mm, rapid tapering of vessels, and right ventricular enlargement) strongly suggests advanced mitral stenosis, although again the findings are not specific for mitral stenosis. Presence of Kerley B lines, perihilar haze, and other manifestations of interstitial edema are seen in patients with severe dyspnea due to mitral stenosis; the absence of interstitial edema on chest film does not rule out tight mitral stenosis, but a patient with dyspnea at rest should always show these changes on chest x-ray; otherwise, one must question the etiology of the shortness of breath. In sum, no single radiologic finding is specific for severe mitral stenosis, but x-ray data can provide important supporting evidence.

The *electrocardiogram* (ECG) is of limited utility for estimation of severity. The best ECG sign appears to be the QRS axis; a rightward shift to greater than +60 is associated with a valve area of less than 1.3 cm^2 in more than 85% of cases. The absence of the rightward shift in axis means little. The greater the pulmonary artery pressure, the more likely right ventricular hypertrophy will appear on ECG.

Cardiac ultrasound (echocardiography) is the most sensitive noninvasive method for evaluating mitral stenosis. *One-dimensional (M-mode)* echocardiography readily identifies mitral valve thickening, calcification (when present), and the degree of limitation of valvular movement or excursion. *Two-dimensional (B-mode)* echocardiography provides definitive assessment by allowing direct visualization of the entire valve and its supporting apparatus, measurement of the valve orifice, left atrial and left ventricular chamber dimensions, and assessment of abnormality of other cardiac valves. The addition of *Doppler ultrasound* techniques—including *continuous-wave* Doppler and *color-flow* study—to the ultrasound examination provides detailed delineation of valve anatomy, blood flow, and magnitude of obstruction. A scoring system based on ultrasound data helps to stratify risk and identify candidates for transcatheter balloon dilation of the stenotic valve.

Transesophageal ultrasound is useful when there is concern about intracavity thrombosis (as in atrial fibrillation; see [Chapter 28](#)) or valvular vegetations (as in endocarditis). *Cardiac catheterization* is indicated when symptoms are progressive and cardiac surgery or balloon valvuloplasty is being considered (see below).

Mitral Regurgitation

A reasonable estimate of the severity of mitral insufficiency can be obtained by history and physical examination. *Dyspnea on exertion* and *fatigability* are early symptoms of hemodynamically significant regurgitation, although the absence of such symptoms does not rule out severe disease. On physical examination, severe mitral regurgitation produces *left ventricular enlargement* with a hyperdynamic, slightly diffuse, apical impulse displaced to the left but of normal timing and duration. In addition, there is a pansystolic murmur (its loudness does not correlate directly with severity), a loud *third heart sound* (S$_3$), often a mid-diastolic rumble from increased flow across the mitral valve, and at times wide splitting of the second sound due to shortening of left ventricular systole and early aortic valve closure. In contrast to other forms of valvular disease, a third heart sound may sometimes be audible in a mitral regurgitation patient in the absence of other signs of severe mitral regurgitation and need not represent a failing left ventricle.

In patients with advanced disease, cardiomegaly and left atrial enlargement are pronounced on *chest film*. A normal heart on chest x-ray and absence of an apical pansystolic murmur rule out significant mitral regurgitation. The *ECG* reflects both left atrial and left ventricular enlargement but is hardly specific for mitral regurgitation. *B-mode cardiac ultrasound* is useful for identifying the specific process causing the mitral regurgitation, be it rheumatic fever, prolapse, a ruptured chordae tendineae, or endocarditis. Also readily ascertained are such important items as left atrial and left ventricular size and ejection fraction. In addition, the severity of disease can be ascertained by *Doppler study* that includes color-flow mapping.

Cardiac catheterization is indicated in patients with progressive symptoms and rapidly increasing heart size who are being considered for surgery. One needs to estimate degree of regurgitation, assess ventricular function, and check for the presence and severity of associated valvular and coronary disease.

Mitral Valve Prolapse. In patients with mitral regurgitation due to MVP, severity of regurgitation increases with *age, male gender, duration* of the murmur, degree of valve leaflet thickening, and degree of *posterior leaflet prolapse*. Only patients with truly redundant and thickened mitral leaflets are at risk for complications from MVP (e.g., valvular incompetence, endocarditis, systemic embolization, and dysrhythmias). Those with mild bowing and normal leaflets should be considered to have a variant of the normal mitral valve and not true MVP. Those with true MVP and associated valvular insufficiency are at risk for chronic volume overload leading to left ventricular dysfunction; there may be no premonitory symptoms or fall in the ejection fraction.

Aortic Stenosis

There are numerous pitfalls in the clinical estimation of severity of aortic stenosis, especially in the elderly. Nevertheless, careful history and physical examination can provide important clues. Effort *syncope, angina*, and symptoms of congestive *heart failure* point to advanced disease with markedly reduced chances of 5-year survival. At times, it is impossible to tell clinically if these worrisome symptoms are due to aortic stenosis, because of the high prevalence of coexisting coronary disease. The presence of angina must be interpreted cautiously; cardiac catheterization and coronary angiography are generally necessary.

Delay in carotid artery upstroke is one of the most helpful physical signs of significant aortic stenosis, especially in the young. A normal upstroke in a patient younger than 60 years of age is strong evidence against important stenosis; however, upstroke may appear normal in the elderly patient with severe stenosis because of a stiff noncompliant carotid artery. Particularly when there are prominent transmitted carotid thrills, the *brachial arteries* may better reflect the severity of aortic stenosis and should also be assessed by palpation. When coincidental aortic regurgitation is present, the upstroke may also appear normal in the presence of marked stenosis. A

misleading delay in carotid upstroke can occur from the combination of systemic hypertension and congestive heart failure. Elevation of systolic blood pressure does not rule out hemodynamically significant aortic stenosis, though a pressure greater than 200 mm Hg and a pulse pressure in excess of 80 mm Hg are unusual when stenosis is marked.

In young patients, the *intensity* of the *murmur* often correlates with severity; however, although it is generally true that critical aortic stenosis is unlikely in a young ambulating person who has less than a 3/6 systolic ejection murmur, rare exceptions do occur. In patients with far advanced disease and a failing left ventricle, the murmur may decrease in intensity and appear insignificant as flow across the valve diminishes. In general, the longer the murmur takes to reach peak intensity, the greater the stenosis. Unfortunately, the *timing of maximal intensity* may not be delayed in some cases of severe stenosis, but if the murmur does peak after mid-systole, the stenosis is usually significant. Because the murmur of aortic stenosis in the elderly may lose its characteristic qualities, it is best to judge severity on the basis of symptoms and other findings. Aortic stenosis in the elderly in the absence of evidence of significant outflow tract obstruction suggests *aortic sclerosis.*

A delay in the aortic component of the *second heart sound (S_2)* is another sign of significant aortic stenosis. S_2 may be single or paradoxically split. Calcification and increased rigidity of the valve will often diminish the intensity of the aortic closing sound; it may become inaudible. A forceful *left ventricular impulse* noted on palpation of the precordium is a reliable indication of secondary left ventricular hypertrophy due to significant outflow obstruction.

The *ECG* can contribute to the evaluation by showing signs of left ventricular *hypertrophy* (increased voltage and a strain pattern in the precordial leads V_5 and V_6). The likelihood of finding a strain pattern (i.e., ST and T wave depression in the apical and lateral leads) increases with the increase in gradient across the aortic valve. These ECG changes also identify patients at increased risk of sudden death, as fewer than 10% of patients succumbing to sudden death demonstrate a normal ECG. In children, the ECG is less helpful; even severe aortic stenosis may not produce left ventricular hypertrophy and a strain pattern.

Cardiac ultrasound has become essential for assessment of aortic stenosis, capable of determining degree of calcification, valve anatomy, chamber size, and left ventricular contractility. In the elderly, the *degree of valvular calcification* correlates with severity of stenosis. The absence of significant calcification in a patient older than 60 years of age greatly reduces the probability of important valvular stenosis. Poststenotic dilation of the aorta suggests aortic valvular stenosis but does not have quantitative meaning. The findings of thickening and decreased mobility of the aortic valve leaflets suggest advancing disease. Echocardiography can help distinguish valvular from subvalvular stenosis and, if subvalvular, whether the stenosis is secondary to a discrete membrane, a fibromuscular bar, or a hypertrophic myocardium as in *hypertrophic cardiomyopathy*. In the young patient with normal left ventricular function, the echocardiogram can provide an indirect estimate of the magnitude of the obstructive gradient. The echocardiogram also delineates the magnitude of left ventricular wall thickening and any associated valvular abnormality, particularly rheumatic valve disease. The addition of Doppler techniques to the echocardiographic evaluation provides an accurate determination of valve area and helps detect any accompanying aortic regurgitation. The finding of mitral regurgitation, especially if progressive on serial studies, correlates with severity and progression of aortic stenosis.

Cardiac catheterization is indicated in the young asymptomatic patient with evidence of severe stenosis, as well as in any patient with known aortic stenosis who begins to develop symptoms of angina, heart failure, or syncope. Elderly patients who are deemed healthy enough to be candidates for surgery should also have *coronary angiography* performed to identify significant occlusive disease that may be the source of symptoms or may limit chances of surviving surgery without correction at the time of valve replacement.

Aortic Regurgitation

Severity of aortic regurgitation can usually be well assessed clinically in cases of isolated valvular insufficiency. Marked regurgitation that is long-standing produces dyspnea, a loud diastolic murmur that extends beyond mid-diastole, an S3, a bounding pulse, and a widened pulse pressure. The absence of a wide pulse pressure does not rule out hemodynamically significant aortic regurgitation nor does the degree of widening necessarily correlate quantitatively with severity. Changes in peripheral resistance alone can cause large variations in pulse pressure. ECG and x-ray evidence of left ventricular hypertrophy and enlargement are indicative of long-standing significant regurgitation and suggest worsening left ventricular function if they progress.

The *echocardiogram* with *Doppler* enhancement can determine left ventricular size and contractility and delineate the specific disease process in aortic regurgitation—be it rheumatic, annular dilation, or advanced luetic destruction. Signs of left ventricular dysfunction by ultrasound study often precede symptoms and help determine the optimal time for consideration of surgery (see below). Doppler has a sensitivity approaching 100% for diagnosis of aortic regurgitation, especially when *color-flow* techniques are used, far superior to physical examination or B-mode echocardiography. Color-flow techniques can provide an excellent noninvasive estimate of regurgitant severity that is within 10% of that found at cardiac catheterization. *Transesophageal echocardiography* is worth considering when endocarditis is a concern.

When aortic regurgitation occurs in the presence of coexisting aortic stenosis, mitral stenosis, or heart failure, the estimation of severity can be very difficult to judge on clinical grounds alone. Consultation with a cardiologist and *catheterization* are often needed.

PRINCIPLES OF MANAGEMENT

Therapeutic Objectives and Timing of Interventions. The principal objectives are to preserve exercise capacity, life-style, and life expectancy and to minimize the chances of endocarditis and systemic embolization. Proper timing of intervention is essential to successful treatment. A common management error is to inappropriately delay surgery or valvuloplasty, allowing irreversible myocardial decompensation to develop; this increases the risk of operation and reduces the postoperative benefit. A physician can be lulled into a false sense of security by continuing to control symptoms through repetitive escalations of medical therapy. The need for progressive increases in medication suggests worsening ventricular function and the need for interventional therapy. By ignoring the significance of such developments, the physician may miss the optimal opportunity for the best possible surgical outcome, long-term improvement, and survival.

Roles of Medical and Surgical Interventions. Early in the course of illness, therapy is predominantly medical, directed at minimizing pulmonary venous congestion (see Chapter 32) and preventing potentially dangerous complications, such as arrhythmias (see Chapter 28 and Chapter 29), bacterial endocarditis (see Chapter 16), and systemic embolization (see Chapter 83). Most people can be well managed on an outpatient basis for many years with a mild diuretic regimen supplemented by an angiotensin-converting enzyme inhibitor or digitalis (see Chapter 32) before the need for interventional therapy. However, inappropriately escalating and prolonging medical therapy beyond the optimal time for surgery is a common mistake that must be avoided if the best surgical outcome is to be obtained.

More advanced stages of disease may require invasive intervention. Life expectancy and quality of life are clearly improved by properly timed intervention. Advances in valvuloplasty technique, prosthetic valve design, and operative technique have produced substantial reductions in interventional mortality. At present, mortality rates for patients undergoing valve surgery in major centers average less than 1% for mitral valvulotomy and less than 5% for mitral or aortic valve replacement. Operative mortality increases sharply when patients with advanced disease (e.g., functional class IV) undergo surgery. However, patients with severe disease should not be denied an operation if they have sufficient myocardial reserve and thus a chance for meaningful survival.

The 5-year life expectancy rate for patients with class IV disease who live through valve replacement is usually less than 50%, but this figure is much better than the less than 5% rate for similar patients managed medically. Thus, even when surgery is inordinately delayed, it may still offer the patient some opportunity for prolonging survival. Contraindications to valve surgery include serious coexisting noncardiac illness that would compromise survival and the existence of end-stage myocardial decompensation that would make surgery for naught.

Percutaneous balloon angioplasty is being used effectively and safely for relief of severe mitral valvular stenosis in carefully selected patients. For young patients with valvular aortic stenosis, it has also proved to be efficacious, but in the elderly with severe aortic stenosis, results have been disappointing (high short-term rates of stroke, aortic insufficiency, and mortality). Balloon angioplasty has proven most useful as a palliative short-term measure for patients who are too ill to tolerate the risk of open heart surgery; long-term efficacy is limited.

Postsurgical Management. It is important to emphasize that patients who undergo valve surgery still have a "cardiac problem" after surgical correction, be it a prosthetic valve with a variable and still unknown late course, a need for anticoagulation and endocarditis prophylaxis, or an associated cardiac abnormality such as coronary, myocardial, or conduction system disease. All too often this is forgotten after the patient undergoes valve repair. Such patients need continued close follow-up and will always remain "cardiac patients."

THERAPEUTIC RECOMMENDATIONS AND INDICATIONS FOR REFERRAL AND ADMISSION

- Monitor all patients by periodic assessment of exercise tolerance, cardiopulmonary examination, chest x-ray, and cardiac ultrasound examination (including Doppler study).
- All patients with any form of valvular heart disease should receive prophylaxis for bacterial endocarditis (see Chapter 16).
- Patients younger than 35 years of age with previous rheumatic fever should be considered for rheumatic fever prophylaxis (see Chapter 17), particularly if they have frequent b-streptococcal infections or exposure to young children.
- Onset of atrial fibrillation with a rapid ventricular response rate accompanied by acute hemodynamic deterioration is an indication for immediate hospital admission and treatment. Patients with slower rates who tolerate the atrial fibrillation can be digitalized on an outpatient basis (see Chapter 28).
- Occurrence of systemic embolization is an indication for urgent admission and intravenous anticoagulant therapy followed by long-term oral anticoagulant treatment (see Chapter 83). Some clinicians argue that valve surgery should be considered if embolization occurs; most concur that surgery is indicated if embolization happens repeatedly.

Mitral Stenosis

- Asymptomatic patients with mild to moderate stenosis need no restriction of activity. Those with evidence of tight stenosis and relatively few symptoms should be advised of the risk of precipitating symptoms by extreme exertion or pregnancy.
- Patients with mild dyspnea that occurs only on exertion can be started on a mild diuretic program (e.g., hydrochlorothiazide 50 to 100 mg/d) and advised to follow a no-added-salt diet. Digitalis is of no benefit in isolated mitral stenosis unless there is atrial fibrillation. Extremely vigorous exertion and emotional upset should be avoided to prevent precipitating symptoms.
- Chronic warfarin oral anticoagulation is indicated for the patient with mitral stenosis, particularly when there is atrial fibrillation (see Chapter 28).
- The development of tight mitral stenosis (as evidenced by a short S_2-OS interval, prolonged diastolic murmur, left atrial enlargement and upper zone redistribution on chest x-ray, and narrowed valve orifice and reduced flow on ultrasound) necessitates referral to a cardiologist for consideration of invasive intervention, be it surgery or balloon angioplasty, even if few symptoms are reported. Consultation is also needed for worsening dyspnea that is inadequately controlled by a mild diuretic program and salt restriction.
- Young patients with evidence of isolated tight mitral stenosis with a pliable noncalcified valve should be considered for interventional therapy early in the course of their illness, even before symptoms are disabling, because transcatheter or surgical valvulotomy can be performed. Both procedures provide long-lasting hemodynamic improvement.
- Early referral for cardiologic assessment is advisable, because percutaneous balloon mitral valvulotomy is an increasingly attractive alternative to surgical mitral commissurotomy in appropriately selected patients.
- Older patients with fibrotic valves (absent opening snap, heavy valve calcification, and limited motion) must undergo valve replacement if surgery is needed. Because surgical mortality and complications are greater for valve replacement than for valvulotomy, surgery need not be advised until symptoms are more disabling. However, surgery should not be delayed until symptoms occur at rest or on minimal exertion, because operative risk and long-term mortality increase substantially. A walk with your patient down a corridor or up a flight of stairs may be of great help in convincing both you and the patient that the time for surgery has arrived.
- Cardiac consultation for consideration of catheterization is indicated in the patient being considered for surgery when there is a question of mixed mitral disease or involvement of multiple valves or when symptoms are out of proportion to objective evidence of disease.

Mitral Regurgitation

- Asymptomatic young patients need no restriction of activity.
- Onset of fatigue and dyspnea can be treated with initiation of a gentle diuretic program (e.g., 50 to 100 mg/d hydrochlorothiazide) in conjunction with a no-added-salt diet. A modest diuretic program that adequately controls symptoms may suffice for years in patients with mild to moderate mitral regurgitation and is not an indication for surgery.
- The development of any increase in dyspnea that requires escalation of diuretic therapy is an indication for cardiac consultation concerning valve replacement. Progressive deterioration in clinical status and increasing heart size suggest presence of myocardial decompensation; prompt referral is indicated; medical therapy is no substitute for valve surgery.
- Refractory congestive failure due to mitral regurgitation is not a contraindication to surgery, though risk is increased. Before surgery, symptoms may be lessened by vasodilator therapy, particularly angiotensin-converting enzyme inhibitors (e.g., captopril 25 to 50 mg three times daily; see Chapter 32), which can diminish the magnitude of regurgitant flow by decreasing afterload. Use of vasodilators can benefit the inoperable patient.
- Patients with incapacitating dyspnea and pulmonary congestion thought to be caused by papillary muscle dysfunction should be referred to the cardiologist for catheterization to determine if valve replacement will be of benefit. In one series, those with ejection fractions above 0.35 had the best surgical survival. If there is coexisting coronary disease, it should be treated (see Chapter 30).
- Valve reconstruction is becoming an increasingly frequent option in mitral regurgitation, obviating the need for an artificial valve and its attendant risks in many cases.
- Patients with a prolapsed mitral valve rarely require treatment other than endocarditis prophylaxis (see Chapter 16). Dyspnea is uncommon and digitalis, diuretics, and salt restriction are unnecessary, because the magnitude of the regurgitation is usually insignificant and rarely progressive. However, those with a dilated left ventricle and marked regurgitation should be followed with serial cardiac ultrasonography for early detection of left ventricular dysfunction, a sign of poor prognosis and an indication for consideration of repair. The rare patient with a history of syncope or ventricular tachycardia or a family history of sudden death requires consideration of treatment for malignant ventricular dysrhythmias (see Chapter 29); those with isolated palpitations do not. There is no evidence that prophylaxis for systemic embolization is needed in the absence of concurrent risk factors.
- Patients with calcification of the mitral valve annulus should be followed for development of heart block. Regurgitant flow is usually small; consequently, dyspnea and pulmonary congestion are not major problems.
- Chronic anticoagulation is indicated in mitral regurgitation patients with atrial fibrillation, especially when accompanied by marked left atrial and left ventricular enlargement.

Aortic Stenosis

- Patients with aortic sclerosis are at no increased risk from their valvular disease, but the sclerosis is a marker of increased atherosclerotic risk, which should be attended to (see Chapter 26, Chapter 27, Chapter 30, and Chapter 31).
- Asymptomatic patients with mild aortic stenosis do not require restriction of activity.
- Young asymptomatic patients with evidence of tight stenosis should be advised against heavy physical exertion (e.g., competitive sports) and referred to a cardiologist for consideration of catheterization and valvuloplasty or valve replacement. Cardiac catheterization is needed.
- Many young patients with tight aortic stenosis may benefit from transcatheter aortic balloon valvuloplasty. Results in appropriately selected young patients are comparable with those achieved with surgical valvuloplasty.
- In elderly patients, especially those with fibrotic, calcified valves, and associated aortic incompetence, balloon valvuloplasty is appropriate only as a palliative measure in those unfit for surgery.
- Onset of angina, effort syncope, or congestive heart failure dictates prompt referral for consideration of valve surgery. These are signs of critical stenosis and predict a poor prognosis unless definitive therapy is undertaken. Such patients are at risk for sudden death. Medical therapy is no substitute.
- Congestive failure can be treated symptomatically on a temporary basis by prescribing digitalis and a moderate diuretic program (e.g., cautious use of furosemide 20 to 40 mg/d; see Chapter 32). Such therapy may help reduce pulmonary congestion and sustain cardiac output temporarily, but the need for a high diastolic filling pressure must be kept in mind; overzealous diuretic therapy can cause a precipitous fall in cardiac output; afterload reduction may also be dangerous in severe aortic stenosis.
- Angina can be treated symptomatically but cautiously with nitrates pending surgery (see Chapter 30); beta-blockers are contraindicated due to their negative inotropic effects. Coronary angiography is required at the time of cardiac catheterization to determine if there is coexisting significant coronary artery disease and the need for a bypass procedure at the time of valve replacement.
- Advanced age is not an absolute contraindication to valve replacement. Survival from surgery is predominantly a function of the patient's myocardial reserve. Consequently, even patients in their eighties need not be denied surgery if they are otherwise reasonable surgical candidates and demonstrate an adequate ejection fraction, even in the setting of severe aortic stenosis.
- Because calcification of the aortic valve can progress rapidly over a few years, patients with aortic stenosis should have careful longitudinal care and regular

follow-up, even when disease appears hemodynamically insignificant and the patient is asymptomatic.

Aortic Regurgitation

- No activity restrictions are necessary in young asymptomatic patients with mild regurgitation.
- Assess severity with an initial cardiac ultrasound examination that includes Doppler study and follow patients having evidence of severe regurgitation with serial ultrasound examinations in addition to regular office assessments.
- Asymptomatic patients with moderately severe disease may be treated with afterload reduction (e.g., lisinopril 10 mg twice daily), which appears capable of reducing left ventricular end-systolic and end-diastolic pressures and perhaps slowing disease progression.
- Patients with evidence of worsening left ventricular function (left ventricular hypertrophy) with a strain pattern on ECG, increasing cardiomegaly on chest film, falling ejection fraction, and increasing left ventricular end-systolic dimension on ultrasound examination) should be referred to a cardiologist for consideration of surgery, even in the absence of symptoms. Patients with a declining left ventricle have an increased risk of ventricular tachycardia and an increased 5-year mortality rate. Early identification of high-risk patients is suggested in the hope of correcting aortic regurgitation before the development of irreversible myocardial decompensation, which may have already started by the time symptoms occur.
- Onset of mild symptoms of pulmonary congestion (dyspnea on climbing more than one flight of stairs) in the absence of evidence of significant left ventricular dysfunction can be treated medically with digitalization, a mild diuretic (50 to 100 mg hydrochlorothiazide), or afterload reduction (e.g., lisinopril 10 mg twice daily), but close clinical follow-up and frequent serial ultrasound examinations are essential to prevent inappropriate delay of surgery. Progression of dyspnea to onset after climbing less than one flight of stairs or worsening of left ventricular function on follow-up ultrasound examination indicates the need for prompt cardiac consultation and consideration of surgery.
- Patients with dyspnea prompted by minimal exertion, orthopnea, or paroxysmal nocturnal dyspnea require prompt referral for surgery, because life expectancy is less than 1 year without surgery. Medical therapy with digitalis and diuretics may provide some symptomatic relief temporarily but must not be used in place of valve surgery at this stage of illness.

PATIENT EDUCATION

By far, the most essential elements of patient education are teaching the importance of endocarditis prophylaxis (see Chapter 16) and self-monitoring for early symptoms of cardiac decompensation. The patient with rheumatic heart disease also requires instruction in prophylaxis against group A b-streptococcal infection (see Chapter 17). The chances of compliance are certain to improve if time is taken to explain the rationale for prophylaxis and self-monitoring. Patients and their families should also be fully briefed on allowable activity, to avoid both unnecessary restriction and the risk of sudden death in the high-risk patient (e.g., the young person with critical aortic stenosis). If the safety of unlimited activity is in doubt, then a cardiac consultation may be helpful.

The patient's functional status and the proper timing of interventional therapy can be optimized by close regularly scheduled follow-up and instructions to promptly report early symptoms of cardiac decompensation (e.g., onset of exertional dyspnea). Patient confidence and a sense of partnership care are fostered by such follow-up. It is helpful to inform the patient of the treatability of this condition and its excellent prognosis when therapy is properly selected and timed. This provides the rationale for careful self-monitoring. If the patient cannot be depended on to relate symptoms accurately, then a family member or friend needs to be recruited to watch for early manifestations of worsening disease and monitor therapy. Detailed review of the medical program with all concerned cannot be overemphasized, given the very serious consequences from misuse of diuretics, digitalis, and anticoagulants in valvular disease. Of particular importance is warning against unauthorized self-escalation of the medical program when symptoms worsen.

CHAPTER 34 MANAGEMENT OF PERIPHERAL ARTERIAL DISEASE

DAVID C. BREWSTER

Treatment of peripheral arterial insufficiency has undergone a quiet revolution. Plaque regression has now been demonstrated with aggressive lipid-lowering therapy (see Chapter 27), and in properly selected patients, percutaneous transluminal angioplasty (PTA) with or without intraluminal stenting produces results that approach those of bypass surgery. In addition, great progress has been made in arterial reconstructive surgery for severe cases, making possible the salvage of limbs that would otherwise require amputation. The wealth of available therapeutic options and a relatively favorable natural history provide the symptomatic patient with substantial opportunity for improvement. The primary physician needs to know the natural history of arterial occlusive disease so as to optimize the timing and intensity of therapy; the techniques, efficacies, and indications for conservative therapy, including risk factor modification, and the indications for angioplasty and bypass surgery. With so many treatment modalities available, the primary physician has to be skilled in the timing, selection, implementation, and coordination of care.

NATURAL HISTORY OF PERIPHERAL ARTERIAL DISEASE

The *prognoses* for the *limb* and for *symptoms* in patients presenting with claudication are quite good. The worst clinical courses occur among patients manifesting ischemic ulcers or rest pain, especially if they suffer from long-standing diabetes mellitus or persist in smoking. Even before the advent of surgical reconstruction, only 3% of patients with peripheral artery disease came to amputation within 5 years if the sole manifestation of their disease was claudication, and none of these persons required amputation if they ceased smoking, but over 10% who continued to smoke lost a limb. In the angiographic era, nearly 80% remain stable or improve, and only about 6% come to amputation. Not surprisingly, prognosis parallels severity of disease as measured by distance walked before onset of claudication. Most amputations occur in the high-risk group, but even in severe cases, nearly 70% stay the same or improve and only 15% come to amputation, underscoring the fact that progression to loss of limb is hardly inevitable. After 5 years from onset of symptoms, about half of patients remain symptomatically stable or improved. In the Framingham Study, only a third of patients presenting with intermittent claudication still had persistent symptoms 4 years later. In essence, prognosis is rather good, especially if major atherosclerotic risk factors can be brought under control.

Although prognosis for the limb is favorable, *mortality* rates—both overall and cardiovascular—are high. The risk of dying from a cardiovascular cause is sixfold greater in those with peripheral arterial disease than in those of similar age, sex, and lipid profile without it. All-cause mortality increases threefold, due almost entirely to the increase in cardiovascular risk. Combined mortality rates are in the range of 30%, 50%, and 70% at 5, 10, and 15 years after onset of symptoms, respectively—a relative risk about three times that for patients of similar age and gender. Concurrent disease of the coronary arteries, cerebrovasculature, or aorta accounts for most of the increased mortality, underscoring the systemic nature of atherosclerosis and its adverse effect on prognosis. The prevalence of systemic atherosclerosis in patients with peripheral arterial insufficiency should not be surprising, given that up to 80% give a history of smoking, 40% have hypertension, 30% have lipid abnormalities, and 20% have diabetes.

PRINCIPLES OF MANAGEMENT

Clinical Assessment (see also Chapter 23)

In the patient with diabetes who presents with an ischemic ankle or foot ulceration, the history and physical examination supplemented by a Doppler flow study have been shown to be predictive of outcome and can help direct management. Physicians encountering a diabetic with a foot ulcer should inquire into previous amputation and painful skin ulceration. If there has been previous amputation, the likelihood ratio for an adverse action is 4.0 and the patient should be considered for aggressive therapy (e.g., revascularization). If there is neither previous amputation nor tender ulceration, risk is reduced (likelihood ratio 0.33) and an initial conservative (medical) approach is reasonable. If the ulcer is painful but there is no history of amputation, then referral for Doppler study would be indicated. An audible Doppler posterior-tibial pulse in a person with a painful ulcer is associated with an excellent outcome (relative risk of adverse outcome 0.4) and candidacy for conservative therapy.

In the patient with atherosclerosis who presents with claudication, a full review of atherosclerotic risk factors is essential, as is a detailed history and physical examination for findings indicative of poor prognosis (e.g., rest pain, dependent rubor, cold extremity, painful ulceration, necrotic tissue). Patients with evidence of worrisome disease should be referred promptly for exercise Doppler study to identify candidates for angiography and surgical intervention (see Chapter 23). Because evidence of peripheral vascular disease is a strong predictor of concurrent cardiovascular disease with its attendant morbidity and mortality, a thorough cardiac assessment is essential, especially if surgical intervention is being contemplated (see below).

Medical Management

The basic objectives of medical management are to control or limit disease progression, increase exercise tolerance, and minimize risk of complications.

Smoking Cessation. The most important methods for achieving these objectives are cessation of cigarette smoking, regular daily exercise, and meticulous foot care. Smoking hastens progression of atherosclerosis and may further impair blood flow by inducing vasoconstriction. *Smoking cessation* ranks as a major priority for the patient with peripheral arterial disease. Cessation can reduce rest pain, claudication, risk of amputation, and need for bypass surgery. The risk of repeat occlusion after angioplasty or bypass falls by over two thirds in those who quit. Moreover, quitting decreases cardiovascular morbidity and mortality. The chances of successfully quitting are greatest when a smoker becomes symptomatic from a complication of smoking; the physician's influence is considerable in this context. Nicotine gum or transdermal patch serves as a useful cessation aid by minimizing nicotine withdrawal, although nicotine may induce vasospasm (see Chapter 54). Because vasospasm usually does not play a major role in claudication, nicotine therapy is probably not contraindicated in these patients, but care is advised if used.

Exercise. Daily exercise remains a cornerstone of the treatment program, even though it now appears unlikely that it increases skeletal muscle blood flow or development of collaterals in the ischemic limb. Suggested mechanisms include improvements in muscle metabolism, peak oxygen consumption, red cell movement, and pain threshold. Whatever the reason, physical training significantly increases the pain-free walking distance, which emphasizes that claudication is not strictly a symptom of abnormal hemodynamics. The programs showing the best results are those that combine supervised *group walking sessions* with additional sessions performed daily at home. The best candidates are those with stable intermittent claudication who are free of rest pain, ulceration, unstable angina, congestive heart failure, and severe lung disease or arthritis. Although group results are excellent, predicting outcome in an individual patient is difficult. Most who achieve benefit report it within 3 months of initiating an exercise program. Regularity of exercise is more important than intensity or duration, although at least 30 min/d of continuous leg exercise appears necessary. Any form of dynamic leg exercise will suffice, including stationary bicycling, stair climbing, and walking. An exercise program can also reduce cardiovascular risk (see Chapter 29).

Foot Care. Careful attention to foot care is vital to prevention of limb loss. It has been estimated that up to 80% of amputations required in diabetics are attributable to poor foot care. Feet need to be inspected daily, especially in diabetics with peripheral neuropathy that limits protective sensation. As little as an hour of patient education has been shown to reduce the amputation and ulceration rate by two thirds.

Atherosclerotic Risk Factors. Aggressive treatment of *hyperlipidemia* can reduce or halt atherosclerotic plaque progression in peripheral vessels; modest plaque regression has also been demonstrated. Some decrease in risk and severity of symptomatic peripheral ischemic disease can be expected, but the most important benefit stems from the marked reductions in cardiovascular morbidity and mortality. Because patients with peripheral arterial disease are at high risk for life-threatening cardiovascular complications, they stand to gain considerably from aggressive lipid-lowering therapy (see Chapter 27).

If *hypertension* is present, it too deserves attention (see Chapter 26). The effect of blood pressure reduction on progression of peripheral vascular disease remains

unknown, but treatment clearly reduces morbidity and mortality from stroke and cardiovascular disease. Choosing an agent on the basis of its effect on peripheral vascular tone does not appear to be critical, although some patients complain of worsening symptoms on beta-blocker therapy. Controlled studies have failed to confirm an adverse effect with beta-blockers. Antihypertensive agents with vasodilating potential (e.g., calcium channel blockers) do not materially improve claudication symptoms. Angiotensin-converting enzyme inhibitors are contraindicated if there is coexisting renal artery stenosis.

Weight reduction can be helpful by lessening work load and reducing metabolic demands of the extremities. In addition, weight reduction may also help lower lipid levels, glucose intolerance, and cardiovascular risk (see Chapter 10).

Control of diabetes (see Chapter 102) is essential to limb preservation, mostly by reducing risk of neuropathy. To date, there is no evidence that "tight" control of diabetes improves the clinical course of large-vessel peripheral arterial disease. Perhaps that is because diabetic peripheral vascular disease begins earlier and progresses more rapidly than that of other patients. Moreover, large vessels can remain relatively patent, whereas small vessels become occluded. Foot care is essential.

Hyperhomocysteinemia may be responsible in patients who present with extensive premature peripheral arterial disease (occurring before age 50). Elevated homocysteine levels respond to use of folate supplements plus vitamins B_6 and B_{12} (see Chapter 31).

Pharmacologic Therapy. *Antiplatelet agents* hold some promise. Although there is no evidence that aspirin improves claudication symptoms per se, many clinicians use the drug in peripheral artery disease patients to reduce their risks of stroke and cardiovascular events (see Chapter 30, Chapter 31, and Chapter 171). Moreover, there is some angiographic evidence of an inhibitory effect on progression of peripheral atherosclerosis. *Dipyridamole* may have similar effects on the peripheral vasculature, but its use is limited by its adverse effects on the ischemic heart (increased risk of cardiac events believed due to a steal phenomenon). *Ticlopidine*, a potent antagonist of platelet adenosine diphosphate, has demonstrated a modest benefit in claudication symptoms, but its use is limited by risks of neutropenia and thrombotic thrombocytopenic purpura. *Clopidogrel*, a similarly potent antiplatelet agent without the associated hematologic risks, has not been evaluated for efficacy in improving claudication symptoms but may be considered as an alternative to aspirin in patients unable to tolerate salicylates. Oral anticoagulants (e.g., warfarin) provide no benefit in chronic management of peripheral arterial disease.

Cilostozo, which possesses antiplatelet, antithrombotic, and vasodilating properties, is approved by the U.S. Food and Drug Administration for symptomatic treatment of intermittent claudication. Although the exact mechanism(s) of action responsible for benefit remains uncertain, the drug does modestly increase walking distances (by 28% to 54%) in comparison with placebo and pentoxyphylline in patients with mild-to-moderate claudication. Onset of action can be slow, ranging from 2 to 12 weeks. Side effects include headache, which can be severe, and tachycardia; ventricular ectopy has been noted. The drug is contraindicated in persons with congestive heart failure. There is concern about long-term use, based on reports of cardiovascular injury in animals exposed to the drug more than 52 weeks. *Pentoxifylline*, an agent that appears to increase erythrocyte deformability and blood viscosity and reduce platelet activity, has been promoted as a potentially useful drug for treatment of symptomatic peripheral arterial disease. In placebo-controlled trials, benefit is nil to modest. High cost, nausea, and dizziness further limit pentoxiphylline's appeal.

Gene therapy and *angiogenesis* are exciting areas of intense investigation. Work is ongoing with growth factors for vascular endothelial cells and fibroblasts in an attempt to stimulate angiogenesis. The hope is to stimulate capillary proliferation and collateral blood vessel formation in ischemic tissues. Such arterial gene therapy holds promise, especially for patients with nonreconstructible disease by conventional angioplasty or surgery. Agents that block specific inducers of atherosclerosis are also under investigation, including *omega-3 fatty acids* and *prostaglandin E analogues.*

Chelation therapy and *vasodilators* are heavily promoted but provide no demonstrable benefit to symptoms or clinical course when tested in placebo-controlled, double-blind, randomized trials. The failure of vasodilator therapy reinforces the view that vasoconstriction plays little role in claudication. Although vasodilators may not be helpful, vasoconstrictors can be harmful and should be used with caution, if at all, in patients with severe disease, especially in those with ulcers or rest pain. *Ergot derivatives* are a classic example; *alpha-blockers* also may aggravate ischemic symptoms and impede healing of skin lesions. *Beta-blockers* do not compromise perfusion or worsened symptoms, despite anecdotal reports.

Interventional Therapies

Candidacy. Patients who continue to have disabling symptoms despite implementation of a full medical regimen (smoking cessation, exercise program, control of cardiovascular risk factors) are potential candidates for interventional therapy. With the advent of angioplasty and improvements in surgical technique, the threshold for invasive therapy has been lowered, but the decision to consider such treatment should not be taken lightly or made prematurely. The relatively favorable natural history of peripheral vascular disease and the excellent responses to medical measures argue for resorting to interventional therapy only after other approaches have failed and the patient is incapacitated or a limb is at risk. Persisting inability to walk two blocks and carry out activities of daily living are typical functional criteria for consideration of interventional therapy. Rest pain and a nonhealing ulcer are even more compelling reasons.

Before referring the patient for interventional therapy, a full set of noninvasive studies (including *Doppler ultrasound* scanning and *segmental blood pressures*) should be ordered to more precisely document the location and severity of disease (see Chapter 23). The best candidates for interventional measures are those with proximal disease and preserved distal runoff. Patients who prove to have predominantly small vessel disease (e.g., diabetics) do not benefit much from interventional therapy unless there is concurrent proximal disease that can be alleviated. *Angiography* will be necessary to make the final determination, but detailed noninvasive study can help screen patients and minimize unnecessary angiography, with its attendant risks of intimal dissection, groin hematoma, and dye-induced renal failure.

Percutaneous Transluminal Angioplasty and Stenting. PTA has emerged as a cost-effective and less invasive alternative to bypass surgery, especially for the patient with segmental stenosis of the aortoiliac or femoral artery. In patients with lesions amenable to angioplasty, PTA produces short- and long-term results similar to those of surgery. The cost of PTA is one fifth that of surgery; however, durability of result is moderately less, reducing but not eliminating the cost differential.

The procedure is typically performed at the time of angiography, using a balloon catheter inserted percutaneously at a remote site, usually the femoral artery, and manipulated fluoroscopically within the diseased segment of artery. With balloon inflation, the obstructing plaque is cracked and vessel lumen enhanced.

Results are best for short segmental stenoses in proximal vessels. Patency rates, both immediate and long-term, are a function of location. Aortoiliac procedures average a 90% immediate success rate, and 80% are patent at 5 years; for a femoral lesion, the rates average 75% and 50%, respectively. Risks include groin hematoma, dissection, renal ischemia, and distal embolization. The overall complication rate averages 10%, with about 2% to 5% being serious enough to warrant surgical intervention. Mortality is less than 0.5%. As expected, experienced teams in centers performing large numbers of PTAs have the best results and the fewest complications.

PTA is suitable for about 30% of patients being considered for interventional therapy. The remainder tend to have more widespread or distal occlusive disease. PTA has a lower morbidity and mortality than standard surgery, making it an especially attractive option in patients who are bad surgical risks because of severe underlying disease. In addition, it may be combined with surgery (e.g., correcting a proximal iliac stenosis by balloon angioplasty and bypassing a more distal lesion with a femoropopliteal graft). Poor candidates for PTA include those with a complete occlusion, a stenotic lesion greater than 10 cm in length, multiple serial stenoses, calcified or eccentric plaque, or poor distal runoff.

Stenting is used to improve results of PTA when there is elastic recoil or localized plaque dissection that compromises the vessel lumen. Whether routine initial use of stents with PTA is a better overall strategy than selective use of stenting remains under study. Available data suggest that selective stenting is more cost effective. Advances in stent technology are encouraging increasingly aggressive use of PTA to treat more extensively diseased arterial segments.

Recanalization Techniques. Because angioplasty cannot be performed on a totally occluded vessel, there has been considerable interest in *recanalization techniques. Laser* methods and *mechanical arthrectomy* devices have been applied to allow percutaneous catheter-based opening of atherosclerotic arteries. The initial enthusiasm and commercial promotion of such devices have proven premature; these techniques are rarely used as sole therapy in current practice. With current technology, these techniques can sometimes serve as an *adjunct* to conventional balloon angioplasty, carving out a small channel in a limited area of total occlusion so that a standard PTA balloon catheter may traverse the lesion. The literature should be followed for well-designed studies of this emerging technology.

Surgical Therapy. In patients with *claudication alone*, surgery should be considered only in those who are so severely disabled that their ability to earn a living is compromised, their desired life-style is intolerably limited, and their vascular lesions are not amenable to PTA. The role of arterial reconstruction for claudication alone

remains controversial. In general, the physician must attempt to determine the significance of ischemic symptoms in each patient. The patient's age, work requirements, social circumstances, and general state of health must all be considered. When doubt exists, referral for a surgical opinion is often useful.

Surgical referral is clearly indicated in patients with *advanced ischemia* resulting in *ischemic rest pain*, nonhealing *ischemic ulcerations*, or *gangrene*. Such limbs are clearly at risk, and arterial reconstruction is indicated, if feasible, to maximize chances of limb salvage. In such circumstances, patients should be referred for surgical investigation as soon as possible, before tissue necrosis or infection become too extensive. The morbidity and mortality of common revascularization procedures is in many instances less than that associated with major amputation. For poor-risk patients, various "extraanatomic" reconstructions are also available, which may be done with even more safety.

Many patients with significant arterial insufficiency that requires surgery also have underlying coronary disease that is hemodynamically critical. The coronary disease may be clinically silent due to the exercise restrictions stemming from severe claudication. Such patients have high rates of perioperative morbidity and mortality. *Stress testing* before surgery helps to identify high-risk patients who would benefit from coronary revascularization before peripheral vascular surgery (see Chapter 36).

Great progress has been made in the surgical management of arterial insufficiency. With an experienced surgeon, careful preoperative cardiac evaluation, and good anesthetic and postoperative management, the patient may anticipate successful correction of aortoiliac occlusive disease, with a mortality risk of only 1% to 2% and excellent long-term patency of approximately 85% to 90% at 5 years. Femoropopliteal or tibial artery bypass may be done with even greater safety, although long-term patency is somewhat less, with approximately 70% to 75% of saphenous vein grafts still patent at 5 years. If the saphenous vein is unavailable for use, a number of suitable alternative prosthetic grafts have been developed within recent years. With improvement of direct reconstructive methods, lumbar sympathectomy is rarely considered a primary mode of treatment.

PATIENT EDUCATION

Patient education is vital, because a favorable outcome requires strong patient participation in the treatment program (cessation of smoking, daily exercise, foot care, risk factor reduction). Compliance is facilitated by the patient's understanding the atherosclerotic basis of the problem, the factors that may aggravate the severity of symptoms, and the rationale behind the measures recommended. Many patients come to the physician with reluctance to walk and fear of limb loss. The benefits of exercise, the likelihood of improvement, and the low risk of limb loss are usually of great comfort and reassurance to the patient and family. The importance for foot care must be repeatedly emphasized, especially in the diabetic. A single hour of detailed foot care instruction can greatly reduce the risk of limb loss. Also important to stress is that even the most trivial foot injury or lesion requires prompt attention. Specific instructions for an appropriate exercise program are essential; recommending such a program can provide a considerable psychological boost.

The psychologic management of the patient is essential in preventing depression and invalidism. Emphasis should be on the generally favorable prognosis and the patient's ability to improve his or her own condition. Frequent follow-up in the early stages of the treatment program is reassuring and helps maximize compliance. The patient with new claudication should be seen at least every 2 to 3 months to assess exercise tolerance and inspect the feet for potential pressure points and ulcers.

INDICATIONS FOR REFERRAL AND ADMISSION

Patients with disabling claudication who fail to respond to conservative therapy and have noninvasive evidence of proximal disease should be referred for consideration of PTA. Patients needing direct referral for consideration of bypass surgery are those with such severe disease (rest pain, nonhealing ulcers, early gangrene) that they are at risk for losing the limb. Urgent hospitalization is indicated for the patient with early gangrenous changes or signs of infection in an ischemic extremity. Those with refractory claudication whose life-style or livelihood are *intolerably* compromised by the inability to walk distances and who appear by noninvasive testing to have disease too distal or too diffuse for PTA are also potential candidates for surgery. The final determination regarding candidacy for angioplasty or surgery requires angiography, but noninvasive screening can maximize the appropriateness of the referral.

THERAPEUTIC RECOMMENDATIONS

- *Cessation of smoking.* Total cessation is essential, both to limit disease progression and to prevent reocclusion after interventional therapy. The patient must be firmly told that he or she must stop smoking completely. Smoking as little as five cigarettes per day can compromise a limb. The physician must be unequivocal about this, because patients often interpret half-hearted advice as only a suggestion (see Chapter 54).
- *Exercise.* In the patient with claudication, the best exercise is daily walking. Patients are advised to walk to the point of discomfort, stop briefly, and then resume walking. At least 30 minutes of relatively continuous walking each day is recommended. A weekly group session can be extremely useful. An exercise bicycle can be used as an alternative mode of exercise. It is important to emphasize to the patient that pain does not indicate harm or damage to the leg and that exercise can help rather than aggravate the condition. Any tendency to restrict activity, sometimes to the point of invalidism or confinement to the home, should be avoided, unless severe ischemia is present. Consideration of the patient's cardiac status is important in the design of the exercise program (see Chapter 18 and Chapter 31).
- *Elevating the head of the bed.* Patients with advanced ischemia and rest pain at night may benefit from raising the head of the bed on 6- to 8-inch blocks so that the feet and legs are made slightly dependent; gravity may aid blood flow enough to allow more comfortable sleep.
- *Foot care.* This aspect of preventive medicine is of extreme importance, particularly in the diabetic patient who often lacks protective sensation due to neuropathy and who may be more susceptible to infection. Because there is often a great deal of confusion about what is meant by "foot care," its components require elaboration:
  1. *Inspection.* The feet should be inspected daily for any scratches, cuts, fissures, blisters, or other lesions, particularly around the nail beds, between the toes, and on the heels.
  2. *Washing.* The feet should be washed daily with mild soap and lukewarm (never hot) water. Rinse thoroughly and dry gently but completely, particularly between the toes. Excessive soaking, leading to maceration, should be avoided.
  3. *Lanolin.* A moisturizing cream such as lanolin or Eucerin should be applied to the skin of the foot and heel but not between the toes. A light film, well rubbed in, will prevent drying and cracking of the skin, which is often the genesis of a lesion, particularly on the heel. The cream should not be applied thickly or allowed to "cake" on the foot.
  4. *Lambswool.* A small amount of lambast or dry cotton or gauze may be placed between the toes to prevent lesions, which may occur if toes are allowed to rub together, particularly if orthopedic deformities of the toes are present.
  5. *Powder.* An antifungal powder, such as nystatin, should be applied between the toes if excessive moisture or maceration is a problem.
  6. *Proper footwear.* Properly fitting shoes with ample space in the forefoot are essential. Special shoes are rarely necessary.
  7. *Podiatry.* Nails should be cut with extreme care, in good light, and only if vision is normal. They should be cut straight across and even with the end of the toe, never close to the skin or into the corner of the nailbed. Any abnormality of the nails and any corns or calluses should be treated by the physician or podiatrist.
  8. *Avoidance of trauma.* Never use adhesive tape on the skin (paper tape is better) or any strong antiseptic solution. Avoid heating pads, hot packs, heat lamps, and scalding hot water. Never walk barefoot.
- *Patient education.* It is the physician's responsibility to educate patients in these points of foot care and to urge them to call at the first sign of difficulty; delay can lead to limb loss if gangrene and/or osteomyelitis ensues.
- *Weight reduction* (see Chapter 233).
- *Aggressive control of major atherosclerotic risk factors* (e.g., hypertension [see Chapter 26], hyperlipidemia [see Chapter 27], and smoking). Aggressive control can halt disease progression and may promote plaque regression. It also lowers the associated cardiovascular morbidity and mortality (see Chapter 30 and Chapter 31). In patients with premature disease, test for homocysteine elevation and treat with folate and vitamins B_6 and B_{12} if positive (see Chapter 31).
- *Medications.* Consider aspirin for its generally beneficial effects on cardiovascular risk. Consider a short course (less than 3 months) of cilostazol if symptoms are interfering with ability to engage in an exercise program; avoid longer term use and use in persons with heart failure or ventricular dysrhythmias.
- *Referral for Consideration of Revascularization.* In patients with claudication alone, PTA is worth considering if the pain is disabling and refractory to a full trial of medical therapy and noninvasive study suggests only focal proximal disease. Referral for consideration of surgery is indicated only in patients who have failed medical therapy, have disease that appears amenable to surgery but not PTA, and are so significantly disabled by claudication that their livelihood or life-style is intolerably compromised by their inability to walk distances. Final decision requires angiography, but noninvasive study to screen for appropriate candidates is essential. In patients with more severe disease, those with rest pain, nonhealing ulcers, or early gangrene who have a limb that is in jeopardy should be considered for operation with some urgency. Conduct preoperative stress testing to identify patients with high cardiac risk who might need further cardiac

evaluation and possibly cardiac revascularization prior to peripheral vascular surgery.

CHAPTER 35 MANAGEMENT OF PERIPHERAL VENOUS DISEASE

DAVID C. BREWSTER

INTRODUCTION

Problems of the peripheral venous system (varicose veins, venous insufficiency, and phlebitis) are extremely prevalent, especially among the elderly. Many physicians do little for the more mundane complaints referable to the venous system because of lack of knowledge and confusion about pathophysiology and proper management. Such attitudes are unfortunate, because neglected venous problems can cause considerable disability and place the patient at serious risk. The primary management of venous diseases is still largely nonoperative, and great benefit is possible with well-conceived office care.

PATHOPHYSIOLOGY AND CLINICAL PRESENTATION

The high frequency of venous disorders of the lower extremities is unique to humans and reflects the consequences of an upright posture and gravity. To return blood from the periphery to the right heart, the venous system in the legs must work against the force of gravity without the aid of organs specifically designed for this purpose. A number of factors work to lessen venous pressure in the leg and propel blood toward the heart. These include the " *muscular pump*" effect of the exercising calf musculature, the negative intrathoracic pressure created by the " *bellows effect*" of the chest wall with respiration, and the presence of multiple valves in both superficial and deep venous systems. The last prevents reflux of blood and serves to reduce pressure in the veins that would otherwise equal the weight of an uninterrupted column of blood from the heart to the foot (approximately 100 mm Hg).

A knowledge of basic anatomy of the venous system is vital to evaluation and management of lower extremity venous problems. The existence of two venous systems, superficial and deep, is well known. A third system linking the superficial and deep systems, the communicating or perforating veins, is less well recognized but of great importance. Valves also exist in the communicating veins, permitting flow from the superficial to the deep system but preventing retrograde flow.

When functioning properly, these three systems work in coordinated fashion. The deep system, composed of paired anterior and posterior tibial and peroneal veins, popliteal veins, and superficial and deep femoral veins, handles approximately 80% to 90% of venous return, whereas the superficial network of greater and lesser saphenous systems is much less important in this respect.

Clinical disorders of the venous system usually stem from obstruction to venous return due to thrombosis of the vein lumen or from incompetent venous valves that allow reflux of blood and persistent elevation of venous pressure in the leg and foot.

Varicose Veins

Pathophysiology. The superficial veins lie in the subcutaneous tissue and lack the support afforded by muscle and fascial compartments, making them most prone to difficulty. Varicose veins are extremely common and probably affect some 10% to 20% of the adult population to some degree. They are more common in women, who also seem more likely to consult a physician for advice. A family history of varicosities is present in most patients and lends support to the concept of a hereditary or congenital etiology. It is unclear whether the primary problem is a congenital *incompetence of valves* or a *weakness* of the venous wall itself, which causes dilation of the vein lumen and subsequent valve inadequacy. In any event, a self-perpetuating cycle ensues of venous reflux leading to further vein dilation and valve failure.

In time, the poorly supported superficial veins widen, elongate, and become tortuous. In a smaller percentage of patients, the initial defect may be in the communicating veins, where poorly functioning valves allow abnormal flow toward the superficial system, causing eventual overdistention. In other patients, acquired factors such as old *trauma* or venous *thrombosis* may play a role. Factors that raise intraluminal vein pressure, such as repeated *pregnancies, obesity*, or wearing of *tight garments* that constrict the thigh, may be of importance. The final common pathway remains valvular incompetence.

Clinical Presentation. Varicosities most commonly involve the veins of the greater saphenous system and its tributaries and therefore occur principally in the medial and anterior thigh, calf, and ankle regions. The lesser saphenous system may also be involved, producing varicosities of the posterior calf and lateral ankle region. The exact distribution of involved branches is of real importance only when considering surgical correction.

The presenting symptoms of varicose veins are extremely variable and often seem to bear little relationship to the apparent severity of the varicosities. Complaints are more frequent in women, particularly young women at the time of the menstrual period. Clearly, hormonal factors that favor fluid retention may aggravate venous distention, but in many such patients the main concern is over the cosmetic appearance of minor varicosities.

Typically, patients complain of local aching or burning pain in the area of the varicosities, particularly at the end of the day after having been on their feet at work. "*Tiredness*," "*heaviness*," or a "*bursting*" sensation are commonly reported. *Itchiness* due to a stasis dermatitis may occur in the region of a severe and chronic varix, especially in the region of an incompetent perforating vein. Mild *swelling* of the ankle region may occur; however, this is relatively unusual with uncomplicated varicose veins. Similarly, ulceration attributable solely to varicose veins is rare. Severe swelling or recurrent ulceration almost always implies problems with the deep venous system (see below).

Large varices may be subject to trauma and bleeding. Much more commonly, however, the distended vein with sluggish blood flow may thrombose, leading to *superficial phlebitis.*

Chronic Venous Insufficiency

Pathophysiology. Chronic venous insufficiency, also called the *postphlebitic syndrome*, is a common chronic disorder that is particularly disabling if stubborn venous ulcers develop. Although the superficial venous system may be secondarily involved with varicose veins, the principal defect lies in the deep venous system. A documented history of *deep venous thrombosis* (DVT) can be obtained in fewer than one half of patients with chronic venous insufficiency, but it is believed to be the underlying etiology in most instances. DVT can often be clinically silent, as documented by prospective $_{125}$I-fibrinogen scanning studies in postoperative patients. Despite subsequent recanalization of deep venous occlusions, the phlebitic inflammatory process deforms or destroys venous valves in the deep system, and their incompetence results in reflux and increased venous pressure. Communicating veins undergo similar changes through valvular damage or simply by exposure to chronically elevated pressure from the deep venous system.

Some authorities believe *congenital valvular incompetence* may also play a role, similar to varicose veins of the superficial system. Regardless of cause, high venous pressure generated by muscular contraction forces blood through damaged valves in communicating veins toward the superficial system, resulting in "ambulatory venous hypertension."

Such venous hypertension results in *edema*, usually most prominent in the calf and ankle region. Indeed, swelling is one of the hallmarks of chronic venous insufficiency and usually differentiates the problem from simple varicose veins. Swelling of the thigh may occur, denoting valvular incompetence at the iliofemoral level as well. Generally, this is less severe and less troublesome than the edema of the lower leg.

Venous hypertension leads not only to interstitial fluid accumulation but also to extravasation of plasma proteins and red blood cells into subcutaneous tissues. In time, this results in *brawny induration* of the skin and *pigmentation* of the thickened but fragile tissue. The presence of edema and continual high venous pressure results in reduced local capillary flow and relative hypoxia, which further increase the likelihood of tissue breakdown and subsequent healing difficulties. Eventually

these processes and accompanying infection lead to damage of the lymphatics, aggravating swelling and local tissue breakdown.

Clinical Presentation. The presenting complaints of patients with chronic venous insufficiency usually center around swelling or ulceration of the lower leg. Chronic recurrent *swelling* causes a sensation of tightness or bursting and heaviness or aching of the limb. This is often worst at the end of the day and may largely disappear overnight. With chronicity, brawny *induration, hyperpigmentation*, and skin *ulceration* may ensue.

Superficial Thrombophlebitis

The cause of acute thrombus formation in the venous system is often unclear, but in most instances factors contributing to *intimal damage, stasis*, and *hypercoagulability* (Virchow's triad) comprise the pathophysiologic determinants of venous thrombophlebitis. The condition almost always arises in varicose veins and is clearly a result of static blood flow in these channels. Trauma may occasionally be implicated. In the upper extremity, the cause is most often iatrogenic after intravenous cannulation, but when it occurs in several locations over a short time span, it suggests *migratory superficial phlebitis*. The latter occurs in the context of occult malignancy, especially carcinoma of the pancreas, presumably due to a hypercoagulable state induced by the tumor. On examination of the patient with superficial thrombophlebitis, there will be pain, tenderness, and erythema along the course of the vein, which may also be palpated as a tender cord or knot.

Deep Vein Thrombophlebitis

Pathophysiology. As in superficial thrombophlebitis, there is usually some combination of *intimal damage, stasis*, and *hypercoagulability*. In about half of instances, the immediate cause is an identifiable self-limited event (e.g., recent surgery, new onset of paralysis, stasis, trauma, pregnancy) or some other acquired factor; in the other half of cases, no clinical precipitant is evident, leading to the designation " *idiopathic*." A host of risk factors have been identified (Table 35-1). The emerging pathophysiologic view of idiopathic DVT is that many cases occur in the context of underlying chronic hypercoagulability (either hereditary or acquired) and that a supervening clinical or subclinical event exacerbates the hypercoagulability or causes venous stasis or endothelial injury, triggering acute thrombophlebitis. This view of idiopathic DVT as a *chronic disease* has important implications for therapy (see below) and is supported by the high frequency of recurrent disease, often occurring in a previously unaffected limb.

RISK FACTOR	RISK*	PERCENT OF CASES OF IDIOPATHIC DISEASE
Hereditary Causes		
Factor V Leiden mutation	+	20% first DVT, up to 50% recurrent
Deficiency in protein S or C or antithrombin III	++	7% first DVT, up to 20% recurrent
Homocysteinemia	++	?
Prothrombin gene mutation	++	6% first DVT, up to 18% recurrent
Acquired Causes		
Adenocarcinoma	+++	6% first DVT, up to 17% recurrent
Antiphospholipid antibodies	+++	5% first DVT

*Risk increased markedly when present in combination with factor V Leiden mutation.

DVT, deep vein thrombophlebitis.

Table 35-1. Causes of "Idiopathic" Deep Vein Thrombosis

Hereditary Factors. A number of hereditary risk factors have been identified in the past few years. Mutation in the gene controlling factor V synthesis leads to production of *factor V Leiden*, which is resistant to inactivation by the endogenous anticoagulant, activated protein C. The factor V variant can be found in 25% to 50% of persons with idiopathic DVT and is particularly prevalent among persons of European decent. Although not an extremely powerful risk factor by itself, factor V Leiden confers an independent degree of risk that may rise substantially in the context of other risk factors, such as estrogen use. The *prothrombin gene mutation* is found in only about 5% to 10% of cases, but its presence increases risk by about two to four times more than does factor V Leiden. Deficiencies in the production of proteins that limit clotting to the site of vascular injury (*proteins S and C and antithrombin III*) are found in about 20% of persons with recurrent DVT. Most patients are heterozygotes for the deficiency, which is a potent risk factor for DVT.

Acquired Factors. Major *trauma, recent surgery* (within 3 months), *pregnancy, estrogen use, immobilization*, and *congestive heart failure* are among the powerful readily apparent precipitants of acquired causes of DVT (Table 35-1). Less evident is the production of antiphospholipid antibodies, which are believed to induce thrombosis by causing vascular injury or by interacting with other abnormal clotting factors to induce a hypercoagulable state. Two classes of antiphospholipid antibodies have been identified: *anticardiolipin* and *lupus anticoagulant*. Both appear to develop in response to prior infection. A *secondary antiphospholipid syndrome* is seen in persons with systemic lupus erythematosus. Low titers of antiphospholipid antibody can be found in a small proportion of normal persons and in up to 25% of pregnant woman by the end of the first trimester. A sevenfold increase in risk is associated with production of antiphospholipid antibodies, especially the lupus anticoagulant variety, making this a potent acquired risk factor for DVT. *Malignancy*, especially adenocarcinoma originating in the lung, gastrointestinal tract, or urogenital system, substantially increases the risk of DVT (presumably by inducing hypercoagulability). Less appreciated is the relationship of *occult malignancy* to DVT. Among patients presenting with a first case of idiopathic DVT, more than 10% have been found to have an underlying occult malignancy. The risk of developing clinically evident cancer within 2 years of an episode of idiopathic DVT is estimated at about 8% for a first attack and 17% for recurrent DVT.

Clinical Presentation. DVT is notoriously variable and often subtle in its clinical presentation. Classically, the patient complains of pain in the limb, worse with motion, walking, or dependency and better with rest or elevation of the extremity. Leg edema below the level of the clot, pain on compression of the knee, a *Homan's sign* (calf pain produced by dorsiflexion of the foot), and a palpable cord are cited as the classic physical findings. With extensive DVT, a dusky cyanosis may appear. Engorged or prominent superficial veins are also suggestive of deep venous obstruction. Unfortunately, most classic findings have proven to be disappointingly low in sensitivity and specificity. A patient reporting little or no pain and showing no calf tenderness may harbor extensive deep venous clots, whereas another with impressive pain, calf tenderness, and an apparently positive Homan's sign may be clot-free. *Unilateral leg edema* may be the only finding; it stands out as the most sensitive indicator of DVT.

EVALUATION

Varicose Veins

On physical examination one should note the extent and location of the varicosities and, more importantly, look for signs suggesting pathology in the deep venous system: thrombophlebitis, stasis changes, ulceration, or swelling. Such findings are unusual in patients with only superficial venous pathology but commonly found in those with involvement of both superficial and deep systems. Complaints of leg pain should be carefully evaluated to rule out other possibilities, such as arterial insufficiency, orthopedic or joint disorders, or neurologic problems. Severe varicosities occurring at a young age suggest a congenital arteriovenous malformation, whereas varicosities appearing after trauma should always raise the question of an arteriovenous fistula, which also may produce a bruit.

Venous Insufficiency

Venous insufficiency needs to be distinguished from other causes of leg edema such as lymphatic obstruction, hypoalbuminemia, and DVT (see Chapter 22). Any accompanying leg ulcers must be differentiated from those due to arterial insufficiency, which tend to be more "punched out" in appearance and localized to the dorsum or lateral aspect of the foot or ankle. A history of claudication, rest pain relieved by dependency, absent pulses, bruits, dependent rubor, and atrophic skin changes also helps distinguish arterial disease from venous insufficiency. Noninvasive studies can be helpful (see Chapter 23).

Superficial Thrombophlebitis

Physical examination should strive to exclude other diagnoses that may be confused with superficial thrombophlebitis, such as cellulitis or lymphangitis. In the latter two, one notes the absence of a palpable thrombosed vein, widespread distribution of erythema and swelling beyond the course of a vein, and identification of a possible focus of infection. Musculoskeletal and neurologic causes of pain and tenderness should be sought, such as a Baker's cyst in the popliteal fossa (see

Chapter 152), or radicular pain (see Chapter 147). Swelling of the extremity should also be carefully noted, as isolated superficial phlebitis should not contribute to generalized edema.

Deep Vein Thrombophlebitis

The initial evaluation of the patient who complains of unilateral leg edema (more than 3 cm difference in calf diameter)—with or without calf pain—must include consideration of DVT (see Chapter 22). Prompt detection of deep vein thrombophlebitis is critical; undetected and untreated, it may lead to pulmonary embolization, with its substantial risk of major cardiopulmonary morbidity and mortality. Identification of DVT in the absence of obvious precipitants raises the question of underlying hypercoagulability and occult malignancy, which needs to be addressed.

History and Physical Examination. Truly unilateral swelling, particularly extending above the knee, makes venous thrombosis more likely, but cellulitis and lymphedema must also be considered. Pain alone is an unreliable symptom. The findings of calf tenderness and a "positive" Homan's sign are by no means conclusive. Numerous studies have demonstrated the relative inaccuracy of diagnosis by history and physical examination alone (which is incorrect in up to 50% of cases) and the importance of laboratory testing. Nonetheless, a careful review of the history and physical examination for *DVT risk factors* (e.g., previous DVT, major trauma, recent surgery or pregnancy, current estrogen use, congestive heart failure, limb paralysis, concurrent adenocarcinoma, nephrotic syndrome, systemic lupus) helps to estimate risk. History should also be reviewed for a *family history of recurrent DVT*, which if present suggests a hereditary hypercoagulable state such as factor V Leiden or deficiency in proteins S and C or antithrombin III.

Laboratory Studies for Deep Vein Thrombosis (See also Chapter 22). Noninvasive studies have made a great contribution to the evaluation of patients with possible DVT. The cost savings alone related to patients found to be free of DVT, in whom venography, anticoagulation, and hospitalization are avoided, are enormous. The necessity of firmly establishing the diagnosis by means other than history or physical examination cannot be overemphasized.

Compression venous ultrasound has emerged as the most sensitive and specific of available noninvasive methods for diagnosis of DVT, especially when standard two-dimensional ultrasound ("*duplex scanning*") is enhanced by color-flow *Doppler* technology (so-called "*triplex scanning*"). Sensitivity and specificity for DVT above the knee—where risk of embolization is greatest—exceed 97%, especially with serial testing. Doppler ultrasound is considerably less sensitive (about 60%) for DVT below the knee, but this lack of sensitivity is not clinically important because risk of embolization associated with clot below the knee is negligible (about 3%). Nonetheless, vigilance is indicated in a patient at risk for DVT, because 20% to 30% of clots below the knee propagate above it. If propagation is suspected (e.g., worsening leg edema that extends above the knee) or the first test result is negative but clinical suspicion remains high, then repeat scanning every 2 to 3 days for 1 to 2 weeks is indicated. In some settings the test performs less well, such as in asymptomatic persons who have recently undergone orthopedic surgery, where test sensitivity can be as low as 62%. Drawbacks of duplex and triplex scanning include high equipment costs and required technician time and expertise. Nonetheless, the technology is widely available and clearly the diagnostic procedure of choice in most instances.

Impedance plethysmography remains in widespread use as a noninvasive alternative to Doppler ultrasound. Sensitivity for detection of DVT above the knee approaches 90% to 95% for the test when serial studies are performed, but specificity can be disappointing, producing a high rate of false positives.

Because sensitivity is very high (in excess of 95%) but specificity is not (48% to 65%), D-*dimer testing* (see Chapter 22) is best applied in conjunction with noninvasive vascular study to rule out DVT. The test contributes to assessment by serving as a means of ruling out DVT at the time of initial presentation in patients with a low or low-to-intermediate pretest probability. Its use can obviate the need for repeated noninvasive vascular study when the initial ultrasound is negative (see Chapter 22). In low-probability patients, a negative D-dimer test provides strong presumptive evidence against the diagnosis of DVT and may suffice for ruling out the condition.

Contrast venography remains the gold standard for diagnosis of DVT, but several disadvantages render it undesirable as an initial test. Not only can venography be quite uncomfortable, but it occasionally induces phlebitis (1% to 3%). Moreover, it is costly and technically unsuccessful in up to 20% of candidates. The study involves considerable expertise for both its performance and interpretation and usually requires hospitalization. Nonetheless, it continues to be an important diagnostic modality for use when the results of noninvasive study are inconclusive and the clinical situation mandates additional testing (e.g., suspected iliac-vein occlusion, worrisome disparity between clinical and laboratory findings, symptomatic postphlebitic patient whose chronic venous disease makes noninvasive study difficult to interpret).

Test Interpretation. Patients with an *intermediate-to-high pretest probability* of DVT and a positive Doppler ultrasound test result can be considered to have DVT above the knee and anticoagulated without venography. If the test is nondiagnostic, then either repeat ultrasound every 2 to 3 days for the next 1 to 2 weeks or immediate venography is indicated, depending on the degree of clinical urgency. Patients with a *low or low-to-intermediate pretest probability* and a negative ultrasound result can be confidently observed without anticoagulation. If symptoms worsen, then repeat testing can be performed. When the initial study is negative and pretest probability is low to intermediate, then anticoagulation can be held, but noninvasive testing should be repeated in 48 to 72 hours.

Assessment for Hypercoagulability. Cases in which there is no apparent acute risk factor for DVT—so-called "*idiopathic*" DVT—manifest a high prevalence (approaching 40%) of underlying hypercoagulability (Table 35-1) and a high rate of recurrence (e.g., up to 27% per patient-year). Such figures argue for careful consideration of *hereditary* and *acquired* causes of hypercoagulability (Table 35-1).

Acquired Conditions. Among the important acquired etiologies of idiopathic disease is the *antiphospholipid antibody syndrome*, characterized by thrombosis and elevated titers of antiphospholipid antibody (i.e., *lupus anticoagulant* or *anticardiolipin antibody*). In less than half of such cases, the patient has clinically active systemic lupus or a lupuslike syndrome (*secondary antiphospholipid syndrome*); in the remainder, there is no evidence of active lupus, although the antinuclear antibody test may be positive (*primary antiphospholipid syndrome*). Some patients report a history of fetal loss. Those at greatest risk of thrombosis manifest high antibody titers, thrombocytopenia, Raynaud's phenomenon, and livido reticularis. The antiphospholipid antibody syndrome confers significant risk of recurrent venous thrombosis and arterial clot formation and should be considered in idiopathic and recurrent cases of DVT, especially if the patient has active lupus (see Chapter 146), a positive antinuclear antibody test, or a history of fetal loss. Identification of antiphospholipid antibodies is achieved by serologic testing that includes activated partial thromboplastin time, Russell viper venom time, and dilutional studies.

Idiopathic cases, especially if recurrent, also raise the specter of *occult malignancy*. The frequency of occult cancer in idiopathic disease is just high enough—about 10% in initial cases and close to 20% in recurrent idiopathic cases—to justify a malignancy workup, focusing on detection of potentially curable cancers (e.g., skin, breast, colon, prostate, bladder, lymph nodes, testes, uterus) and those that at least respond to treatment (e.g., small cell cancer of the lung, ovarian carcinoma). Standard screening procedures for curable malignancies (e.g., stool testing for occult blood, sigmoidoscopy, Papanicolaou smear, mammography) are reasonable, but routine computed tomography of the lung and abdomen is of no proven value. The optimal laboratory investigation for underlying malignancy in patients with idiopathic DVT remains to be determined; available data suggest some utility for basic of studies, such as the complete blood count, urinalysis, serum albumin, and chest x-ray. The approach to additional testing should be based primarily on initial clinical findings. Patients not found to have cancer after a careful initial workup have a very low risk of presenting with cancer at a later date. Although such patients need to be followed closely, they require no special additional testing in the absence of new clinical findings.

Hereditary Conditions. Most hereditary hypercoagulable states (e.g., *factor V Leiden, deficiency in protein S or C, or antithrombin III*) represent gene mutations that by themselves confer only modest increases in hypercoagulability. However, when combined with an acquired risk factor for DVT, they appear to greatly increase the likelihood of thrombus formation. This could explain why some patients develop thrombophlebitis and others do not when exposed to the same external risk factors. Although some hereditary hypercoagulable states are rather common (e.g., factor V Leiden can be found in 20% of whites with idiopathic DVT), it remains to be demonstrated that routine screening for these conditions is cost effective. Testing should be considered when the results would substantively affect treatment decisions (e.g., duration of anticoagulation).

Hyperhomocysteinemia, leading to vessel wall injury and increased risks of venous thrombosis and premature atherosclerosis, may be hereditary (enzyme mutation, homozygous) or acquired (folate deficiency). Plasma homocysteine levels in excess of 18.5 nmol/mL (normal, 4 to 15 nmol/mL) confer a fourfold increase in risk of DVT. Screening for homocysteine elevation is appropriate for those with recurrent idiopathic DVT.

MANAGEMENT

Varicose Veins

Conservative Measures. Management of varicose veins can very often be satisfactorily accomplished by nonoperative means, based on appreciation of the principal problem of valve incompetence and poor soft tissue support. Untreated, most varicose veins will slowly worsen and may lead to increasing difficulty and disability. All patients will benefit from proper *elastic support* of medium weight, together with periodic *elevation* of the extremity at intervals during the day. Elastic support is best achieved by a properly fitted surgical stocking obtained from a hospital or commercial surgical company. The various stockings sold in department or drug stores are usually of too lightweight and improper fit. Ace wraps are cumbersome and often applied improperly, creating a "tourniquet" effect at the knee level. A below-knee stocking is preferred, because proper compression is difficult to achieve in the thigh, above-the-knee stockings are difficult to keep up, and patient compliance is considerably less. Fortunately, varicosities in the thigh are much less often associated with symptoms or complications.

In addition, obese patients are urged to *lose weight*, and women are reminded to *avoid* the use of *tight garters* or panty girdles, which will constrict superficial venous return at the thigh level. *Prolonged standing* should be avoided as much as feasible.

Sclerotherapy. Sclerotherapy has some enthusiasts but is not generally recommended. The technique involves injection of a sclerosing agent into the vein lumen followed by application of a pressure dressing maintained for several weeks. An inflammatory reaction causing eventual fibrosis and obliteration of the vein lumen is hoped for. Although occasionally used for small isolated varices or so-called spider veins, sclerotherapy is rarely beneficial for the primary treatment of significant varicose veins.

Surgery. Indications for surgical referral include persistently symptomatic varicose veins (particularly if a conservative approach has been tried), cosmetic dissatisfaction, or recurrent episodes of superficial thrombophlebitis. The option of surgical therapy should probably be discussed initially, because some patients, particularly young women, will prefer this to chronic use of elastic support. In most instances of primary varicose veins, an excellent result can be expected from surgery with extremely low morbidity and a hospitalization of only 2 to 3 days. In experienced hands, the "recurrence" rate of varicose veins should be less than 10%. Often, successful treatment can be achieved with small incisions and so-called "stab-avulsion" techniques; formal stripping of the saphenous vein may not be necessary.

Venous Insufficiency

Management before Ulceration. Treatment of venous insufficiency is best initiated before the occurrence of venous ulceration, which will follow in many untreated cases. An understanding of the pathophysiology again emphasizes the importance of elastic support and periodic elevation of the extremity. *Patient education* is essential, because compliance is poor otherwise. A *knee-length heavyweight elastic stocking* is prescribed and must be worn religiously from the moment the patient gets out of bed until retiring at night. The leg is best elevated on a pillow or by raising the entire foot of the bed at night. *Periodic elevation* during the day is essential in most patients; it must be emphasized to the patient that the leg should be above the level of the heart for this to be effective. This must be done as often as necessary to prevent formation of edema. *Mild diuretic therapy* (e.g., hydrochlorothiazide 50 mg/d) may be of some help in stubborn edema. The chronic and incurable nature of the problem must be made clear to the patient, with reassurance given that symptoms and problems are controllable and preventable by strict adherence to the above program.

Management after Ulceration. Progression to the point of ulceration creates a much more troublesome problem. The ulcers may occur with even minor and unrecalled trauma because of atrophic vulnerable skin and subcutaneous tissues. Most ulcers develop just above the medial malleolus, usually overlying an incompetent communicating vein. These lesions will be refractory to all methods of care as long as venous hypertension from the incompetent deep system continues to be transmitted to the superficial tissues. Secondary infection is common, further impairing any chance for local tissue repair.

Management at this stage is much more difficult, time consuming, and often expensive. Preferred treatment is an extended period of *bedrest* with *elevation* of the involved extremity well above heart level at all times, combined with *wet to dry saline dressings* to the ulceration, applied three times daily (see also Chapter 197). Hopefully such a program can be carried out at home by the family, perhaps with the help of a visiting nurse. Healing may be anticipated over a 2- to 4-week period. Hospitalization is generally not necessary unless dictated by social circumstances. Any infection should be cultured and treated appropriately with oral antibiotics; staphylococci and gram-negative rods are common. The patient should be urged to exercise the calf muscles repeatedly while in bed, ideally against a footboard, to minimize the occurrence of acute deep venous thrombosis.

Alternatively, particularly for patients who cannot afford extensive time off their feet, an *Unna paste venous boot* may be used. Properly applied, this medicated bandage can supply good compression, does not require much patient cooperation, and allows the patient to remain ambulatory. Such boot dressings are best changed every 7 to 10 days. With some experience, many venous ulcers may be successfully handled in this manner. Once healed, chronic use of a heavyweight elastic stocking is resumed.

Surgical referral is advisable for recurrent or nonhealing ulcerations, because surgical interruption of incompetent communicating veins underlying these areas, together with stripping and ligation of associated superficial varicosities, may be indicated. In recent years, some surgeons have reported good results with direct repair of incompetent venous valves or interposition of a competent valve from an arm vein into the deep venous system of the leg. Insufficient long-term experience exists, however, to ascertain the usefulness of such surgical therapy at this time.

Superficial Thrombophlebitis

Superficial thrombophlebitis in the lower leg is best managed by a combination of *local heat* and *compression* with a good elastic stocking. Antiinflammatory agents such as *aspirin* or one of the other nonsteroidal drugs may be useful. Antibiotics have no role. Women taking birth control pills should probably discontinue their use. The patient should avoid sitting or standing but remain ambulatory to minimize the chance of developing any associated clot in the deep venous system. Pain and inflammation usually resolve within 1 to 2 weeks.

If superficial phlebitis extends above the knee, consideration of anticoagulation or ligation of the saphenous vein at the level of the saphenofemoral junction in the groin may be indicated, and surgical consultation should be considered. This is particularly true if the process has ascended while under treatment and observation. The rationale is the increased risk of extension of thrombus into the deep system.

Deep Vein Thrombophlebitis/Venous Thromboembolism|Updated: 09/10/03

Initial Therapy: Heparinization (Unfractionated versus Low-Molecular-Weight). Deep Vein Thrombophlebitis/Venous Thromboembolism (DVT/VTE) above the knee is associated with a high risk of thromboembolization. Standard therapy of acute DVT involves prompt *hospitalization* for immediate intravenous treatment with *unfractionated heparin* and initiation of *oral anticoagulation* with *warfarin*. Heparin and warfarin are continued until the prothrombin time (as measured by INR) has been in therapeutic range for 3 to 4 days (see Chapter 83), at which time heparin is stopped, warfarin is continued, and the patient is discharged. |**Updated: 09/11/03**

The advent of *low-molecular-weight heparin* provides the opportunity for outpatient treatment of acute DVT. Its principal mechanism of action (accelerating formation of irreversible complexes between antithrombin III and activated factor X) is the same as for unfractionated heparin, but there is reduced interaction with platelets and thrombin, making possible equivalent efficacy with less risk for bleeding. Bioavailability is enhanced and half-life is longer because there is little binding to plasma proteins, red cells, or vascular endothelium. Prospective randomized studies show low-molecular-weight heparin to be at least as effective as unfractionated heparin in preventing thromboembolic events, as safe or safer with regards to major bleeding complications, and superior with respect to survival (reduced all-cause mortality at 6 months). The efficacy, safety, and ease of use (standardized dose, twice-daily dosing, no need for partial thromboplastin time monitoring or intravenous access) enable anticoagulation to proceed much earlier on an outpatient basis. For patients with uncomplicated acute DVT, the length of hospital stay needed to initiate anticoagulation has been reduced from nearly a week to 3 days or less. In selected low-risk cases with a good home environment, hospitalization can be reduced to less than 24 hours or even obviated. These features make low-molecular-weight heparin the emerging treatment of choice for initial management of acute DVT uncomplicated by pulmonary embolization. Although low-molecular-weight heparin costs much more per dose than conventional heparin therapy, it is more cost effective by virtue its ability to markedly reduce length of hospital stay without increasing risk of bleeding or thromboembolization.

Low-molecular-weight heparin preparations include dalteparin, enoxaparin, nadroprin, reviparin, and tinzaprin. Although they differ with respect to protein binding and other qualities, none stands out as clearly superior with regards to safety or efficacy. Dalteparin and enoxaparin are the most commonly prescribed preparations in the

United States for outpatient use. They are administered twice daily by subcutaneous injection of a fixed weight-adjusted dose (e.g., dalteparin 100 units/kg twice daily or enoxaparin 1 mg/kg twice daily). The two drugs appear to be clinically equivalent, but dalteparin is about one third lower in cost. Treatment is continued for approximately a week until oral anticoagulation with warfarin (usually started on day 2) is in therapeutic range (INR 2.0) for at least 2 days—same as with unfractionated heparin. The patient must be medically stable, reliable, and have a supportive home environment and available visiting nurse services. The major clinical contraindications to outpatient heparinization are preexisting bleeding difficulties and marked hypercoagulability (e.g., recent surgery, trauma, cancer). The patient should be medically and hemodynamically stable. Monitoring requirements are minimal, but platelet counts and prothrombin times on days 3 and 7 are suggested to check for heparin-induced thrombocytopenia and to assess oral anticoagulation (see Chapter 83).

Oral Anticoagulation. Heparinization is continued while oral anticoagulation with *warfarin* is initiated (see Chapter 83). Heparin is stopped after the prothrombin time reaches an INR more than 2.0 for at least 24 to 48 hours (the time needed for previously synthesized prothrombin to clear the serum).

Duration of warfarin therapy for prophylaxis of recurrent DVT/VTE is a function of underlying etiology and number of episodes. A *3-month course* usually suffices for a first episode of DVT occurring in the setting of a clear-cut *self-limited* precipitant, such as surgery or trauma. For pulmonary embolization in the setting of a clear-cut precipitant, therapy is usually continued for 6 months. A first episode of idiopathic VTE is treated for a minimum of 6 to 12 months due to an increased risk of recurrence. Chronic therapy is a consideration for those at highest risk. Priority candidates include individuals with idiopathic VTE who have had multiple recurrences (risk for recurrence can exceed 5% per year), those who manifested a severe degree of thrombosis or had their DVT complicated by pulmonary embolization, and those subsequently found to have a circulating lupus anticoagulant (risk approaches 25% per year). Other hypercoagulability risk factors do not appear to confer nearly as much risk, but even persons with uncomplicated idiopathic disease and no identifiable determinants of hypercoagulability manifest increased risk of recurrent thrombosis and should be considered for chronic anticoagulation (see below). Chronic anticoagulation is also indicated in other persons with a history of recurrent DVT or DVT in the context of concurrent cancer. | **Updated: 09/10/03**

The intensity of chronic oral anticoagulation that optimizes DVT/VTE prophylaxis while minimizing bleeding complications is an area of active study. A major randomized trial (ELITE) comparing long-term full-intensity warfarin therapy (INR 2 to 3) with low-intensity therapy (INR 1.5 to 2.0) in persons with idiopathic VTE found full-intensity therapy superior with regard to death and recurrent VTE without any increase in risk of clinically important bleeding. While these findings need confirmation, they suggest that full-intensity therapy is preferable for chronic prophylaxis in appropriately selected candidates (see below). It must be kept in mind that under study conditions, maintaining an INR between 2.0 and 3.0 dramatically reduces risk of VTE recurrence while increasing risk of major bleeding by only 3% per patient-year. Observational studies conducted in the community setting put the risk of major bleeding a bit higher, at 5% to 7% per patient-year. | **Updated: 09/10/03**

Optimizing selection of patients for long-term warfarin prophylaxis requires a personalized approach that weighs individual risks and benefits and considers the patient's preferences and willingness to comply with the demands of treatment. A few recommendations can be offered based on available evidence: | **Updated: 09/10/03**

- Attempt a best possible estimate of individual risk for recurrence, taking into account etiology, severity of episode(s), and number of recurrences. Give highest priority to persons with recurrent idiopathic disease, severe episodes of VTE, or presence of lupus anticoagulant or other major risk factor (e.g., malignancy). | **Updated: 09/10/03**
- Take into account age, risk of complications, patient acceptance, and availability of monitoring services. | **Updated: 09/10/03**
- For patients with no contraindications to prolonged warfarin therapy and a willingness to take the drug and have regular monitoring of the prothrombin time INR, prescribe long-term therapy at full intensity (INR 2 to 3). | **Updated: 09/10/03**
- For patients who are unwilling to take the medication or be monitored long-term or who could not tolerate a clinically significant bleeding complication, discontinue therapy after completing the initial 3- to 12-month course of anticoagulation. Monitor such persons closely for recurrence. | **Updated: 09/10/03**

Thrombolytic Therapy (Streptokinase, Tissue Plasminogen Activator) Thrombolytic therapy deserves consideration in patients with *proximal DVT*, especially of the *iliofemoral* system. The objective is to minimize the chances of developing postphlebitic syndrome by instituting clot-lysis therapy. The best results have been achieved in patients with proximal vein DVT of the femoral or iliac system treated within 3 days of onset of symptoms; most studies have used streptokinase. Clot lysis occurs in about 50% of instances. Because there is an increased risk of major bleeding, particularly cerebral hemorrhage, prompt referral to a vascular specialist is indicated to facilitate case selection. Contraindications include recent surgery, trauma, recent or active hemorrhage, any bleeding diathesis, pregnancy, and intracranial disease. | **Updated: 09/10/03**

DVT below the Knee. DVT below the knee poses little risk of embolization so long as the clot does not propagate up into the thigh. Risk of propagation ranges from 10% to 30%. Risk of embolization from a clot that stays below the knee is small (short-term risk, 0.3% to 1.0%). Outpatients suspected of having DVT, but without evidence of extension above the knee, do not require immediate anticoagulation; however, they should be followed closely with serial evaluation for evidence of propagation. Those who require the closest monitoring are patients with multiple risk factors for DVT. Repeat noninvasive study, using Doppler ultrasound or plethysmography, is indicated (see above).

INDICATIONS FOR ADMISSION AND REFERRAL

Admission. Among patients with peripheral venous disease, those with DVT are at greatest risk acutely and most in need of consideration for immediate hospitalization. Although urgent evaluation is definitely in order, hospitalization is no longer inevitable for patients with DVT above the knee. As long as there is no evidence suggesting pulmonary embolization, iliofemoral extension, or hemodynamic instability and as long as the patient is reliable and the home situation is supportive, heparinization can proceed safely and effectively at home with administration of low-molecular-weight heparin.

Referral. Surgical consultation is indicated for the patient with superficial phlebitis that extends above the knee, because saphenous vein ligation at the level of the saphenofemoral junction in the groin may be indicated if the process has ascended while under treatment and observation. Surgical referral is also advisable for recurrent or nonhealing ulcerations due to chronic severe venous insufficiency. Consideration of surgery is reasonable for the patient with persistently symptomatic varicose veins (particularly if a conservative approach has failed), cosmetic dissatisfaction, or recurrent episodes of superficial thrombophlebitis.

CHAPTER 36 STRESS TESTING

The cardiac stress test plays a central role in the evaluation of suspected and known coronary heart disease (CHD) by providing a noninvasive means of detecting ischemia and determining prognosis. Electrocardiographic (ECG), radionuclide, and echocardiographic approaches present the clinician with an array of study options, which include pharmacologic stressing for patients who cannot exercise. The choices can be daunting. Design of a cost-effective workup for CHD (see Chapter 20, Chapter 30, and Chapter 31) benefits from attention to the performance characteristics, costs, advantages, and disadvantages of available stress-testing modalities.

PHYSIOLOGIC BASIS OF THE TEST

Stress testing assesses the ability of the coronary circulation to meet the enhanced myocardial oxygen requirements of exercise- or drug-induced stress. Because the rate of oxygen extraction by the heart is relatively fixed, increased oxygen demand must be met by an increase in coronary blood flow. When coronary artery stenosis critically limits blood supply, oxygen demand may so exceed supply that myocardial ischemia ensues, manifested by transient changes in ECG ST segments, ventricular wall motion, and radionuclide distribution. In addition, the patient may experience abnormal blood pressure and heart rate responses, angina, or an anginal equivalent such as severe dyspnea.

The demand placed on the coronary circulation can be quantified: The product of heart rate times systolic blood pressure closely parallels the measured myocardial oxygen consumption during isotonic exercise and is designated in " *metabolic equivalents*" (METS), where 1 MET = 3.5 mL O_2 consumed/kg/min. Heart rate alone provides a good approximation of oxygen consumption. Because known quantities of work are being performed, the exercise stress test can also provide a measure of exercise capacity and aid in the detection, quantification, and localization of coronary disease.

APPROACHES TO STRESS TESTING

The stress test may use exercise or pharmacologic measures to challenge the capacity of the coronary circulation. Exercise remains the simplest means, usually achieved by treadmill or stationary bicycle activity. Pharmacologic approaches stress the coronary circulation by inducing either reflex tachycardia or intracardiac vasodilation.

Exercise-based Testing. Exercise testing for the detection of coronary disease uses dynamic (isotonic) rather than sustained-contraction (isometric) exercise. Isotonic exercise permits smooth increases in the rate-pressure product to be accomplished, allowing the patient's ischemic threshold to be approached gradually. Nevertheless, isometric exercise testing (e.g., by sustained handgrip) can be of use in special situations, such as in assessing the safety of isometric activities in patients with known coronary disease.

Testing protocols for isotonic exercise testing are divided into maximal and submaximal types, depending on the level of exercise achieved during the test.

A maximal test is defined as one in which systemic oxygen consumption reaches a plateau before exercise is terminated. Maximal effort is usually approximated by exercising the individual to an age-adjusted predicted maximal heart rate. Values for maximal predicted heart rate can be obtained from standardized tables or regression formulas, but the value *220 minus age in years for men or 210 minus age for women* provides a reasonable approximation of the true maximal heart rate. Tests terminated before maximum predicted heart rate has been achieved are less sensitive for diagnosis of CHD. In general, it is best to continue the test to the predicted maximum heart rate or to maximum perceived effort or until angina, ischemia, arrhythmia, or hypotension occurs. If a patient is receiving a b-adrenergic blocking agent, the end point of heart rate is supplanted by having the patient exercise to exhaustion. If perceived effort is "very hard" (19 or 20 on the Borg scale) at the termination of the test, it can be reasonably assumed that maximal exertion has been closely approximated.

A submaximal exercise test is by definition one in which maximal systemic oxygen consumption is not achieved. The test may be terminated prematurely by design (at a certain percentage of predicted maximal heart rate or at a given level of systemic oxygen consumption) or it may be terminated because of the appearance of angina, marked ischemic ECG changes, cardiac arrhythmias, severe hypertension, or hypotension. Submaximal testing has proved useful and safe for early determination of prognosis shortly *after myocardial infarction*. When conducted within 2 weeks of infarction, a submaximal exercise test to a 5-MET level identifies patients at increased risk for subsequent coronary events and death. Many cardiologists prefer to perform a symptom-limited exercise test 1 month after myocardial infarction in lieu of an earlier submaximal test.

Most exercise tests are "*staged*," meaning graded amounts of work are performed in a progressively increasing manner. The rationale for graded exercise is to obtain the greatest increase in heart rate before musculoskeletal fatigue limits the amount of exercise that the patient can performed. Onset of muscle fatigue before achievement of maximum heart rate reduces test sensitivity. Currently, the *treadmill* and *bicycle ergometer* are the most popular devices used for exercise testing. Slightly higher values for maximal oxygen consumption can usually be obtained on the treadmill than on the bicycle ergometer, because a somewhat larger muscle mass is called on during treadmill exercise.

Many different exercise protocols are available for the treadmill and bicycle. Although the staged *Bruce protocol* is very popular and widely used, it has the disadvantages of unequal changes in work load between stages and a very abrupt increase in work load at stage IV, which is too vigorous for many cardiac patients. Walking protocols are generally preferred over protocols that require running for diagnostic purposes in unfit populations. Bicycle ergometer protocols usually consist of 2- to 3-minute stages in which workload is increased by 10 to 30 watts per stage, depending on the level of physical conditioning of the subject. For both treadmill and bicycle tests, it is best to select a protocol that will allow the patient to reach maximal exertion within a 10- to 12-minute period. A longer test may be limited by the subject's endurance, and a shorter test usually increases the workload too rapidly.

Electrocardiographic Monitoring. Continuous *ECG monitoring* is used during exercise testing, as is periodic determination of blood pressure and symptoms. Multilead systems have replaced the traditional single modified V_5 ECG lead (CM_5). Sensitivity is greatly enhanced by use of multiple leads, especially for detection of inferior ischemia. At present, 12-lead monitoring is commonly performed multiple times during the test and three to six leads are monitored continuously; adding another three leads over the right-precordium appears to enhance detection of ischemia due to right coronary or left circumflex disease (see below). The ST segments are assessed for change with exercise. The depth, configuration, and extent of any ST-segment depressions correlate with presence and severity of coronary disease (see below and Fig. 36.1), as do blood pressure responses and time to development of symptoms. Because ischemic changes may not occur on the ECG until after exercise, monitoring is continued for at least 5 to 7 minutes into the recovery phase.

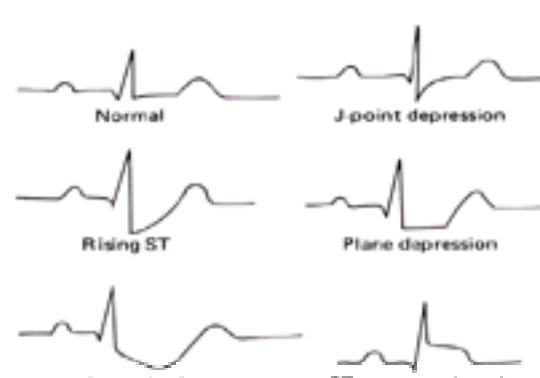
Normal | J-point depression
Rising ST | Plane depression
Downsloping | ST segment elevation


FIG. 36.1. Exercise-induced ST segment changes.

Radionuclide Imaging. Radioisotopes can be administered as part of exercise testing to help image myocardial perfusion. *Technesium sestamibi* and *thallium-201* are the two radionuclides in most widespread use. Their regional distribution in the myocardium is proportional to regional coronary blood flow; underperfused areas will take up less of the isotope and will appear as "cold" spots on the perfusion scan. Areas of viable but ischemic myocardium will appear underperfused during exercise but will "fill in" at rest. Therefore, sequential scanning during exercise and at rest are required to diagnose hemodynamically significant coronary stenoses and distinguish them from areas of previous infarction.

Sestamibi testing requires a 2-day protocol, with a 1-hour resting scan on day 1 and a 2-hour exercise and imaging session on day 2. Thallium study is done all in one day but requires 2 hours for exercise imaging and a 3-hour wait before a 1-hour imaging session at rest. Sestamibi administration allows for determination of ejection fraction. Thallium provides images of pulmonary uptake, which parallel pulmonary capillary wedge pressure and correlate with prognosis. *Single-photon emission computed tomography* (SPECT) is replacing *planar scanning* technology for image production because it provides better sensitivity.

Echocardiographic Imaging. Stress echocardiographic study provides information on global ventricular function in response to exercise (by measuring change in ejection fraction and end-systolic volume) and on segmental myocardial perfusion (by comparing regional ventricular wall motion at rest and during or just after maximal exercise). Ischemic manifestations include failure to increase ejection fraction with exercise and new regional wall-motion abnormalities. Compared with radionuclide testing, there is less time required, no radiation exposure, and lower cost; in addition, results are immediately available. Test sensitivity for ischemia is reduced by presence of resting wall-motion abnormalities.

Pharmacologic Stress Testing. Patients who cannot exercise are potential candidates for pharmacologic approaches to testing the adequacy of the coronary circulation, be it by inducing reflex tachycardia or coronary vasodilation. Because the sensitivity of ST-segment changes associated with pharmacologic stress testing is low, cardiac imaging (either radionuclide or echocardiographic) is required.

Adenosine or Dipyrimadole with Radionuclide Scanning. These agents rapidly induce coronary vasodilation when given by intravenous infusion, usually over 4 to 6 minutes. Normal coronary arteries respond by dilating and markedly increasing regional myocardial blood flow. Diseased vessels are unable to respond in such fashion. The net result is a steal phenomenon, in which blood flow is diverted away from the areas of myocardium supplied by the stenosed vessels, exacerbating the differences in regional perfusion. Radionuclide (thallium or technesium sestamibi) is administered in conjunction with the vasodilator infusion to provide images of regional myocardial perfusion and detect any significant differences suggestive of clinically important coronary disease. Adenosine is the shorter acting of the two vasodilators (half-life 10 seconds vs. 20 minutes) and preferred by many because adverse effects (e.g., flushing, nausea, headache, chest tightness, hypotension) are shorter lived, though more common, than with dipyrimadole. Methylxanthines (e.g., theophylline, caffeine) block the actions of these agents and should be withheld for up to 3 days before testing.

Dobutamine with Echocardiography. Dobutamine is a relatively selective b-agonist that is used to stress coronary circulatory capacity by inducing an increase in myocardial oxygen demand through simulative effects on heart rate and myocardial contractility. Underperfused areas show up on ultrasound as thickened hypokinetic myocardium. Sometimes, the muscarinic blocking agent atropine is infused in addition to dobutamine if at least 85% of the maximum predicted heart rate is not achieved by dobutamine alone. Side effects of dobutamine include chest pain, palpitations, dysrhythmias, and blood pressure changes. They usually resolve quickly with cessation of the infusion. Test safety is similar to that for exercise.

Dipyridamole with Positron Emission Tomography. Positron emission tomography (PET) involves administration of the vasodilator dipyrimadole along with rubidium-82. The isotope's myocardial uptake is measured by PET, providing a very sensitive and specific, albeit expensive, means of imaging ischemia.

TEST SENSITIVITY, SPECIFICITY, AND PREDICTIVE VALUE FOR CORONARY DISEASE

Gold Standard, Workup Bias, and Test Limitations. The gold standard for the diagnosis of CHD remains the *coronary angiogram*. A significant stenosis is defined as an angiographic narrowing of the vessel lumen by 50% or greater. Stress-test performance characteristics (sensitivity and specificity) are determined by comparing test results against angiographic findings. However, the figures cited in the literature for sensitivity and specificity may be subject to " *workup bias*" that derives from preferential enrollment of study patients likely to have coronary disease and therefore willing to undergo angiography. The consequence of such bias is an exaggeration of test sensitivity and underestimation of test specificity. Workup bias always needs to be considered when interpreting published studies of sensitivity and specificity (see Chapter 2).

Another limitation of stress testing is that it does not identify lesions that may become the cause of sudden death; it only detects impaired blood flow. Most patients who die suddenly from coronary disease do not succumb from a chronic flow-limiting atherosclerotic plaque. Rather, they may die from the acute rupturing and thrombosis of a nonoccluding plaque. Exercise testing does not help to identify such non–flow-limiting lesions, although it can provide an estimate of prognosis by determining extent and severity of disease, which correlates with overall risk (see below). Direct identification of dangerous plaques remains an area of active investigation.

Predictive Value for Coronary Heart Disease and the Importance of Pretest Probability in Test Performance. With an emphasis in the stress-test literature on test performance characteristics (i.e., sensitivity and specificity), it is easy to confuse them with predictive value (the probability of CHD, given a "positive" stress test). The latter is the relevant probability for the clinician caring for the patient with suspected coronary disease and necessitates considering not only test sensitivity and specificity but also the patient's pretest probability for CHD. Figures for the predictive accuracy of the exercise stress test have varied greatly from series to series and between men and women, often because of wide differences in the prevalence of underlying coronary disease in the populations studied. The predictive accuracy of any diagnostic test is directly related to the *prevalence* of the disease in the population examined (see Chapter 2).

A stress test will have a low predictive accuracy when disease prevalence is low, regardless of how sensitive and specific the test is. Proper test interpretation necessitates knowing not only the sensitivity and specificity of the test but also the patient's pretest likelihood of CHD. A positive test in a person with a low pretest probability is far more likely to be a false-positive than a true-positive. Careful estimation of the patient's pretest probability of CHD (see Chapter 20) is essential to proper stress-test interpretation. Prevalence of coronary disease has been found to be 16% in patients with nonanginal chest pain, 50% in those with atypical pain, and 89% when typical angina is present.

High Pretest Probability. The predictive value of a positive stress test for diagnosis of CHD is mathematically greatest in patients with *typical angina* and *multiple coronary risk factors*; however, in such instances the history of classic angina (pretest probability for CHD, about 90%) is about as good for diagnosis as the test's predictive value (about 90%). Thus, performing a stress test adds little to diagnosis beyond that which is already known from the history. In such patients, the value of stress testing is confined to estimating prognosis and assessing need for revascularization (see below and Chapter 30).

Intermediate Pretest Probability. Stress testing may be of considerable diagnostic help in patients with *atypical chest pain*, as long as the criteria for atypical pain are rather rigid (e.g., at least two characteristics of classic angina [see Chapter 20] must be present along with a risk factor or two). In this context, a positive exercise test would substantially increase the posttest likelihood of underlying coronary disease and a negative test would substantially reduce it. In general, exercise testing makes its greatest diagnostic contribution to those whose pretest likelihood of having coronary disease is intermediate.

Low Pretest Probability. In the setting of *noncardiac chest pain* and *no risk factors*, the stress test is not likely to perform well. Although a negative test can be very reassuring to the patient, the specificity of stress testing is not high enough to eliminate the risk of a false-positive result. The ratio of false-positives to true-positives in the setting of a low pretest probability is likely to be high, making it necessary to warn the patient that a positive test result in this setting is not tantamount to a diagnosis of coronary disease. In trying to reassure a nervous patient who does not have coronary disease by performing a stress test, one might actually make matters worse. Careful thought and patient preparation are needed before going ahead with stress testing such patients. The same considerations and high risk of false-positives also limit the usefulness of stress testing as a screening procedure for detection of CHD in *asymptomatic patients.*

Electrocardiographic Testing. Although not very sensitive for detection of single-vessel coronary disease (sensitivity, 35% to 61%), the standard ECG study

approaches other forms of stress testing for detection of more serious anatomy such as left-main or three-vessel disease (sensitivity, 75% to 93%; see below). Overall, the mean sensitivity for detection of coronary disease is about 68% and specificity, 77%. When adjusted for workup bias, the figures are 45% and 85%, respectively. The wide ranges cited for ECG sensitivity and specificity have to do with differences in diagnostic criteria and approaches to testing and monitoring.

Diagnostic Criteria and Other Factors Affecting Test Sensitivity and Specificity. A major factor affecting sensitivity and specificity is the magnitude of ST *segment depression* used as a diagnostic criterion for ischemia. Lowering the ST-segment criterion from at least 2.0 mm of ST depression to 1.0 mm increases sensitivity by nearly threefold but reduces specificity by 10 percentage points. The *configuration of the ST segment* (Fig. 36.1) is also important to specificity. A downsloping ST-segment criterion produces a specificity of 99%; horizontal or plane depression is associated with a specificity of 85%; and a slowly upsloping ST segment (at least 1.5 mm ST depression at 0.08 seconds after the J point) produces a specificity of 68%. Taking into account not only *ST-segment* changes but also any abnormal *blood pressure* or *heart rate* responses and any *angina* or severe *dyspnea* can raise relative sensitivity by over 20%. The occurrence of typical angina during exercise confers, by itself, a sensitivity of 51% and specificity of 90%, about the same diagnostic significance as ST-segment changes.

The *type of exercise protocol* and the *number and location of ECG leads* affect sensitivity. Submaximal protocols are much less sensitive than maximal ones. A 12-lead study is more sensitive than one using fewer leads. The addition of 3 right-precordial leads to a standard 12-lead study markedly improves test sensitivity for single-vessel disease, particularly that involving either the right coronary artery or the left circumflex. With such multilead testing, sensitivity and specificity approach that of radionuclide scanning.

False-Positives. The specificity of ST segment changes is limited by the fact that ST segment depression is not unique to coronary disease. Patients with *valvular* or *hypertensive* disease, nonischemic myocardial disease, and *preexcitation* syndromes may demonstrate ST segment depression during exercise in the absence of ischemia. In addition, left ventricular *hypertrophy*, recent *glucose* ingestion, *hypokalemia*, and *sedatives* may produce false-positive results. *Digitalis* glycosides are notorious for their ability to cause deviations in ST segments. If possible, it is best to discontinue digitalis for at least 48 hours before testing. If this is not feasible, then exercise-associated ischemia should not be diagnosed until at least 2 minutes of ST segment depression is observed. Studies have also suggested that false-positive responses may be more common in middle-aged *women* than in men by a factor as high as 3, but this may be more a reflection of the low pretest probability of CHD in this population than of a problem with the test. Simple *J-point depression* with a rapidly upsloping ST segment is a nonspecific finding and not diagnostic of ischemia.

Asymptomatic patients with few or *no CHD risk factors* who are subjected to exercise testing and demonstrate "ischemic" changes are, as noted earlier, less likely to have underlying coronary disease and more likely to have a false-positive test. Therefore, asymptomatic subjects with an abnormal stress test should be screened carefully for possible causes of a false-positive response. In asymptomatic populations, abnormal ST segment responses should be viewed as a "risk factor" for coronary disease rather than as definite evidence of the disease. In these individuals, the incidence of coronary disease is modest (about 6%) but doubles by the sixth decade.

Radionuclide Scanning. Stress-test sensitivity is enhanced by radionuclide scanning. With use of planar scanning, overall test sensitivity for detection of coronary disease rises from 68% for ECG to 79% when planar scanning is used and to 88% with SPECT. Specificity is about the same as for ECG testing. Sensitivity for three-vessel and left-main disease rises from 86% for ECG to 93% and 98% for planar scanning and SPECT, respectively. Use of radionuclide scanning has proved especially valuable in patients who have resting repolarization abnormalities on the ECG or left bundle branch block, both of which render interpretation of the standard exercise test difficult. Scanning is also useful in patients whose ECG stress-test results are suspected to be false-positive or false-negative. Test performance characteristics are about the same for exercise and pharmacologic methods of radionuclide stress testing. Test sensitivity is reduced by image attenuation due to obesity or large breasts.

Echocardiography. Echocardiographic assessment has a reported mean sensitivity of 76% for detection of coronary disease and a specificity of 88% (Table 36.1). Mean sensitivity for three-vessel or left-main disease is 94%. Results are similar for exercise and dobutamine-stimulated testing, provided the same increase in heart rate is achieved. Reported figures are from centers where there is major expertise in the performance of the study. Test performance is very operator dependent, and local results may be quite different from those reported in the literature if the operator is inexperienced. Obesity and emphysema may impair performance of the test.

TEST TYPE	SENSITIVITY	SPECIFICITY	SENSITIVITY FOR THREE-VESSEL/LEFT-MAIN DISEASE	RELATIVE COST
Electrocardiographic	0.68	0.77	0.86	1.0
Echocardiographic	0.76	0.88	0.94	2.5
Thallium imaging, planar only	0.79	0.73	0.93	2.0
SPECT	0.88	0.77	0.98	4.0
PET	0.91	0.92	1	14.0

SPECT, single-photon emission computed tomography; PET, positron emission tomography.
a Sensitivity and specificity as reported from renowned center settings.

Table 36.1. Sensitivity, Specificity, and Costs of Stress Tests for the Detection of Coronary Disease

Positron Emission Tomography. Test sensitivity and specificity in research settings often exceed 95%, but when the test is applied in community settings, test performance drops into the 85% range.

STRESS TESTING FOR ASSESSMENT OF CORONARY HEART DISEASE PROGNOSIS

Stress testing represents a useful noninvasive means of screening for predictors of poor CHD prognosis, including left-main, three-vessel, and left-main-equivalent disease and left ventricular dysfunction. Assessment of prognosis of patients in the early postinfarction period also may be aided by exercise testing.

Electrocardiogram. Whereas ECG stress testing is relatively insensitive for detection of single-vessel disease, it compares rather favorably with radionuclide and echocardiographic studies for detection of high-risk anatomy (mean sensitivities 86%, 93% to 98%, and 94% respectively; Table 36.1) and poor prognosis. Stress test findings indicative of worrisome disease include marked ST-segment depression, multilead ST-segment depression, early onset of ST changes, persistence of ST-segment depression past 8 minutes into the recovery period, downward sloping ST configuration, hypotensive response at low workloads, impairment of heart rate response to exercise, and development of angina. The occurrence of both angina and ischemic changes during exercise has been reported to predict an increased likelihood of multivessel disease.

The *Duke exercise treadmill score* is a widely used and well-validated prognostic formula that incorporates easily measured stress-test parameters identified by multivariate analysis as independently predictive of CHD prognosis. It is calculated as follows: exercise time – (5 times the ST deviation in mm) – (4 times the treadmill angina index), where exercise time is in minutes of the Bruce treadmill protocol; ST deviation is the largest ST displacement in mm in any lead; and angina index is scored 0 for no angina, 1 for typical angina during the test, and 2 for angina that halts the test. A score of – 11 or less indicates "high risk" (5-year mortality more than 25%), whereas a score of +5 or more predicts "low risk" (5-year mortality less than 6%). Patients at high and moderate-to-high risk require consideration of coronary angiography for identification of high-risk coronary disease and determination of candidacy for bypass surgery (see Chapter 30). Even in the presence of resting ST-segment abnormalities, the ECG stress test retains its ability to risk-stratify patients with CHD by means of the Duke treadmill score.

Although ECG stress testing can help determine prognosis and guide need for angiography, the study does not localize the site of ischemia. Most patients with a positive ECG stress test have ST-segment changes in the anteroapical leads irrespective of the location of their ischemia. More diffuse involvement only indicates increased probability of high-risk coronary anatomy. Coronary angiography is required when considering revascularization.

Submaximal ECG stress testing is very helpful prognostically in the *postinfarction period*. The greater the workload tolerated, the better the prognosis. Patients who develop angina on a limited exercise test conducted just before hospital discharge have twice the rate of postinfarction angina. Those with no ST-segment changes

have a very low 1-year mortality (about 2%), compared with a 25% mortality for those who develop ST-segment depression during exercise testing.

Radionuclide Scanning. Unlike ECG testing, thallium and technesium images identify the location and extent of underperfused myocardium (sometimes referred to as the "*amount of myocardium at risk*"). Diffuse ischemia suggests high-risk coronary disease (three-vessel or left-main stenosis) and the need to consider coronary revascularization (see Chapter 30). *Pulmonary uptake* of thallium is a sign of left ventricular dysfunction, another independent indicator of poor prognosis. First-pass resting sestamibi images provide an estimate of ejection fraction and aid in assessment of left-ventricular function.

Echocardiography. Stress echocardiography supplies information on extent and location of ischemia by its 16-segment analysis of left ventricular wall motion. The greater the number of segments manifesting wall motion abnormalities, the greater the probability of multivessel or left-main disease. Resting wall-motion abnormalities reduce predictive accuracy. Echocardiography provides an accurate estimate of left ventricular ejection fraction, an important prognostic determinant.

OTHER ROLES FOR STRESS TESTING

Determination of Exercise Capacity. The patient is made to perform known quantities of work under direct observation and continuous ECG monitoring. This determination is essential for designing a safe cardiac rehabilitation program and may help to reassure the patient who is unnecessarily restricting activity out of fear of sudden death or infarction. The work level achieved during the test can be used to define the degree of incapacity (when it is in question) and provide guidelines for establishing safe levels of daily activity for the patient.

Detection of Dysrhythmias. Assessment of atrial and ventricular rhythm disturbances can sometimes be facilitated by exercise testing, especially if the dysrhythmia is believed to be exercise induced. Ambulatory monitoring should be obtained in conjunction with an exercise test if the objective is optimal detection of dysrhythmias; electrophysiologic study may also be indicated (see Chapter 25, Chapter 28, and Chapter 29).

SAFETY AND CONTRAINDICATIONS

Reported mortality in a multicenter study involving 170,000 exercise tests was 0.01%. There was no relationship to the type of test or to exercise intensity. Morbidity requiring hospitalization was 0.2%. Safety is enhanced by a preexamination history, a physical examination, and a resting ECG. Patients with unstable angina, uncompensated congestive failure, severe anemia, high-grade heart block, severe aortic stenosis, cor pulmonale, or severe hypertension should not undergo testing. A physician should be present throughout, and a defibrillator and other resuscitation equipment should be in the room. The test should be terminated if blood pressure or heart rate falls suddenly during exercise or if exhaustion, angina, faintness, marked ST changes, severe hypertension, or serious arrhythmias (ventricular tachycardia, heart block, etc.) occur. When performed by experienced personnel, exercise testing is very safe and is one of the most useful noninvasive tests for evaluating cardiovascular function and disease.

The safety of pharmacologically induced stress testing is similar to that for exercise-induced studies. Contraindications to adenosine or dipyrimadole stress testing include severe COPD, asthma, and significant carotid or aortic stenosis. Contraindications to dobutamine stress testing include cardiac dysrhythmias and uncontrolled hypertension.

TEST SELECTION FOR CORONARY HEART DISEASE DIAGNOSIS AND PROGNOSIS

The *ECG stress test* remains a very cost-effective diagnostic option for the patient with a normal resting ECG. Although the standard test is rather insensitive for identification of single-vessel disease, its sensitivity for high-risk coronary disease and correlation with prognosis are very high, approaching those of the much more expensive radionuclide studies (Table 36.1). Moreover, use of right-precordial leads holds promise for enhancing sensitivity for single-vessel disease. Even in the setting of nonspecific resting ECG abnormalities, the ECG stress test retains its prognostic utility when using the Duke treadmill score.

Echocardiographic stress testing represents another cost-effective option for CHD diagnosis. Sensitivity and specificity when performed by expert operators are similar to that for radionuclide scanning, and like the more expensive scans, information is provided on left ventricular function and regional perfusion.

Radionuclide scanning is very sensitive and specific for diagnosis of coronary disease and extremely useful when resting ECG abnormalities preclude ECG stress testing for identification of CHD. However, isotopic imaging is many times more expensive than ECG testing and only marginally better for detection of high-risk disease and determination of prognosis (Table 36.1). These factors limit its cost effectiveness.

For patients unable to exercise, infusion of a vasodilator (*adenosine* or *dipyrimadole*) in conjunction with radionuclide scanning is a reasonable option; dobutamine echocardiography is another. *PET* cannot be recommending at this time, because its cost is extremely high and test performance in the community setting is no better than that of radionuclide imaging.

PART 4 RESPIRATORY PROBLEMS

CHAPTER 37 SCREENING FOR LUNG CANCER

ALBERT G. MULLEY, JR.

INTRODUCTION

Lung cancer is the most common fatal malignancy in the United States. In recent years, it has claimed the lives of as many men and women as have tumors of the colon and rectum, breast, and prostate combined. The incidence of lung tumors in men has been rising dramatically since 1930. More recently, a dramatic increase among women has occurred. Approximately 10% of American men and 5% of American women alive today will have lung cancer during their lifetime; of these, more than 85% will die of the disease.

Most people are aware of the epidemic proportions of the lung cancer problem. Many have lost friends or relatives and know the grim prognosis of the disease. The screening of asymptomatic persons who are at high risk can offer little reassurance. Efforts to improve the prognosis by early detection have been thwarted by the insensitivity of available tests, poor compliance with screening programs among patients at high risk, and the aggressive natural history of most lung tumors. Although some see promise in the use of low-dose computed tomography adapted to lung cancer screening, we do not yet know whether the benefits of this approach exceed the considerable harms of false-positive results and potential overdiagnosis. Without an understanding of such limitations, the primary care provider may expend resources that produce little more than exaggerated fear in some patients and inappropriate reassurance in others. Knowledge of the risk factors for and natural history of this disease, and of the validity of available diagnostic tests, provides the basis for a reasoned approach to many pulmonary symptoms (see Chapter 40, Chapter 41, Chapter 42, Chapter 43, and Chapter 44).

EPIDEMIOLOGY AND RISK FACTORS

The epidemiology of lung cancer is dominated by its association with smoking. The dramatic increase in cancer death rates among men and the more recent increase among women can be attributed to trends in cigarette consumption. A dose–response relationship between duration and intensity of cigarette smoking and risk for lung cancer has been documented in men and women. In comparison with the risk for lung cancer among nonsmokers, the risk is increased 5, 10, and 20 times for men who smoke less than half a pack, one-half to one pack, and one to two packs per day, respectively. A decrease in risk has been demonstrated in smokers who are able to stop and in those who smoke filter-tipped cigarettes. Cigar and pipe smokers incur much less risk, but again a dose–response relationship has been documented (see Chapter 54).

The association between smoking and cancer is strongest for the epidermoid (squamous cell) and small-cell undifferentiated (oat cell) tumors. The relationship is less certain for adenocarcinoma (alveolar cell) and large-cell undifferentiated (anaplastic) histologic types.

The observation that lung cancer occurs in men far more often than in women can be explained for the most part by differences in historical smoking patterns. In fact, lung cancer without a smoking history is more common among women. A slight apparent excess of lung cancer cases also occurs in urban areas and among low-income groups. The presence of polycyclic organic matter in urban pollution and in some occupational environments (see Chapter 39) may provide a partial explanation. Exposure to asbestos, chromate, nickel, uranium, or radon gas has also been associated with significantly increased rates of lung cancer. The combined effect of such exposures and smoking is generally more than additive. For example, smokers exposed to asbestos have a 90-fold greater risk for lung cancer than do unexposed nonsmokers.

NATURAL HISTORY OF LUNG CANCER AND EFFECTIVENESS OF THERAPY

Lung cancer's rapidly progressive and usually inexorable course has to date frustrated screening efforts. The 5-year survival rate is between 5% and 10%. At the time of symptomatic presentation, 75% of patients have lesions that are clearly unresectable. Of the remainder, 60% prove to be unresectable because of mediastinal involvement, discovered by further evaluation or at thoracotomy. Five-year survival rates after resection in the relatively few remaining patients vary from about 10% for patients with oat cell tumors to 30% for patients with squamous cell tumors.

Reports of 5-year survival rates based on the symptoms present at the time of diagnosis are more relevant to the question of early detection. In a group of patients with an overall 5-year survival of 7%, the 6% with disease discovered before the appearance of symptoms had an 18% survival rate, compared with 10% to 15% for patients with local symptoms and 6% for those with systemic symptoms. Nearly one third of the patients had symptoms of metastatic disease; all died within 5 years.

Higher survival rates have been reported in patients after resection of *in situ* lung cancer diagnosed by means of chest radiography or sputum cytology followed by bronchoscopy, but these may represent little more than selection of slow-growing or otherwise benign lesions. Some highly speculative estimates of growth rate suggest that squamous cell carcinomas and adenocarcinomas take as long as 10 and 25 years, respectively, to reach a size likely to be detected by radiography. If such estimates are accurate and if the natural history is widely variable, overestimation of the benefits of early detection are likely a consequence of the problems of lead time and time-linked bias sampling (see Chapter 3).

SCREENING AND DIAGNOSTIC TESTS

Chest Radiography. In a controlled British study of semiannual chest radiography in more than 29,000 men, 101 lung tumors were detected during a 3-year period. Seventy-six were detected in a control population of 25,000. The overall 5-year survival rates among cancer patients from the screened and control groups were 15% and 6%, respectively. Of the 101 cancers in the screened group, only 65 were detected by routine chest radiography; the remainder presented symptomatically during screening intervals.

The value of chest radiographic screening was also addressed by the Philadelphia Pulmonary Neoplasm Project, which attempted to screen more than 6,000 male volunteers older than 45 years with semiannual radiographic examinations. Lung cancer developed in 121 patients during a 10-year period, with an ultimate mortality rate of 92% at 5 years. The poor results were attributed to poor patient compliance with screening, patient and physician delay, advanced age or concomitant illness contraindicating surgical therapy, and inadequate sensitivity of the screening method.

Three additional randomized trials of lung cancer screening were conducted by members of the Cooperative Early Lung Cancer Group. Separate studies at the Mayo Clinic, Memorial Sloan-Kettering Cancer Center, and Johns Hopkins Hospital each enrolled more than 10,000 male smokers. In the Mayo study, those randomized to close surveillance were screened with both sputum cytology and chest radiographic examination every 4 months, whereas control patients were advised, but not reminded, to have such studies annually. At Memorial Sloan-Kettering and Johns Hopkins, patients were randomized to undergo either annual chest radiography and sputum cytology every 4 months or annual chest radiography alone. The findings of these studies indicate that screening, particularly sputum cytology, may advance the time of diagnosis, with more cancers detected in an earlier stage. However, no difference in survival was found between screening groups at Memorial Sloan-Kettering and at Johns Hopkins, which suggests that no benefit is derived from the addition of cytology to annual radiographic screening. Furthermore, in the Mayo study, no significant difference was noted in lung cancer mortality rates between the screened and control groups despite the fact that more than twice as many postsurgical stage I lung cancers were found in the screened group as among controls.

It should be kept in mind that false-positive chest radiographic findings engender considerable fear in addition to the morbidity associated with confirmatory diagnostic tests. Although the specificity of radiographic screening has been shown to be in the range of 90% to 97%, it is still too low to provide an acceptable predictive value. A Veterans Administration study of lung cancer screens found 438 false-positive radiographic readings, compared with 97 true-positive readings, for suspected neoplasm. In the Memorial Sloan-Kettering study described above, 10,040 persons were screened with both chest radiography and cytology. Approximately 10% had abnormal chest radiographic findings that led to additional studies to rule out cancer. The predictive value of such a positive finding in this and other recent studies has been in the range of 1% to 5%.

Cytologic Screening. The sensitivity of cytologic screening varies with the cell type and location of the tumor and the methods of specimen collection. It used to be thought that a single cytologic specimen would detect about 70% of squamous cell lesions and that three specimens would increase sensitivity to 90%. However, data from recent large, randomized trials indicate that cytologic examination is much less sensitive. Only 10% of cancers in the Memorial Sloan-Kettering study and 13% of those in the Mayo study were detected initially by cytology alone. Presumably, these disappointing findings can be explained by the spectrum problem—that is, decreased sensitivity for early- rather than late-stage tumors (see Chapter 3). The low sensitivity can also be explained by the relatively low proportion of cancers that were of the squamous cell type, which is the histologic type most likely to be detected by cytologic examination. The specificity of sputum cytologic examination is high, in the range of 98% to 99%. In the Memorial Sloan-Kettering prevalence screen of 10,040 men, only seven screenees had cytology findings classified as marked atypia or cancer before they were found not to have cancer. Although rare, such false-positive findings are highly problematic and often require meticulous bronchoscopic examination to sixth- and seventh-generation bronchi.

It should be noted that as *diagnostic* tests, chest radiography and cytologic examination are complementary. In a Veterans Administration study, cytology alone had an overall screening sensitivity of 33% and a specificity of 98%; radiographic screening had a sensitivity of 42% and specificity of 98%; the sensitivity for combined radiographic and cytologic examination was 63%. Radiographic examination, including computed tomography, is more sensitive for peripheral lesions, whereas cytologic examination is more sensitive for central squamous cell tumors.

Low-Dose Computed Tomography. Computed tomography techniques have been adapted in an effort to detect early lung cancer in the general population and among asymptomatic high-risk individuals. Population-based screening in Japan and Germany, as well as the prospective, uncontrolled Early Lung Cancer Action Project (ELCAP) in the United States, have demonstrated much greater sensitivity than chest radiography. Specificity, however, is poor, with more than 20% of prevalence screens positive for lung nodules in the ELCAP study. These same prevalence screens among long-term smokers detected cancers among 2.7%, a rate four times higher than that detected with concurrent chest x-rays. Nearly all of the detected cancers were resectable and most were stage I. However, the impact of computed tomographic screening on mortality awaits further study. Randomized trials are underway, but early answers won't be available for 5 to 10 years. **Updated: 2/7/03**

SUMMARY AND CONCLUSIONS

- Lung cancer is a major cause of morbidity and mortality among men and women.
- Smoking is the overwhelming risk factor for lung cancer. Occupational exposures also are relevant.
- Little is known about the presymptomatic natural history of lung cancer. It is presumed to be highly variable. The 5-year survival despite all forms of therapy is 5% to 10%. Survival is slightly better when an asymptomatic lesion is detected.
- Some see promise in the use of low-dose computed tomography, which has been demonstrated to have high sensitivity and moderate specificity in uncontrolled studies. Randomized trials are underway to determine whether benefits outweigh harms. **Updated: 2/7/03**
- Cytologic examination of the sputum and chest radiography are complementary diagnostic tests. However, neither is sensitive nor specific enough to serve as a screening test.

CHAPTER 38 TUBERCULOSIS SCREENING AND PROPHYLAXIS

BENJAMIN DAVIS AND HARVEY B. SIMON

Active tuberculosis (TB) remains relatively uncommon in ambulatory practice, although its prevalence is beginning to increase again in some populations, especially patients infected with HIV, immigrants from countries where TB is endemic, and the urban poor. Being a contagious yet potentially treatable condition, TB is always an important consideration in patients presenting with hemoptysis (see Chapter 42), chronic cough (see Chapter 41), or fever and weight loss (see Chapter 9 and Chapter 10). Tuberculin reactivity remains prevalent. On a daily basis, the primary physician faces the questions of whether to test for reactivity and how to respond when it is present.

EPIDEMIOLOGY AND RISK FACTORS

Until the mid 1980s, the number of reported TB cases in the United States was declining at an annual rate of about 6%, with most new cases occurring among the institutionalized elderly, who represented a remaining pool of latent endogenous infection. The prevalence of tuberculin skin test positivity in this population has been estimated at 20% and the prevalence of active disease at 2.4%. In 1985, the incidence of active TB began to grow for the first time in half a century, in part because of the HIV epidemic, but also because of cutbacks in funding for the public health clinics responsible for treating and preventing TB. Federal resources were returned to state and local TB-control programs in the early 1990s. Since 1992, the rates of TB have fallen annually, and in 1996, a rate of eight cases per 100,000 represents the lowest seen since national reporting began in 1953. TB remains a problem for patients infected with HIV, the foreign-born, and the urban poor. Compared with persons uninfected with HIV, whose risk for development of active TB after infection is *10% per lifetime*, HIV-infected persons have a risk for development of active disease of *10% per year*. Other population groups with a disproportionately high incidence of TBinclude alcoholics; IV drug users; patients with diabetes, malnutrition, or end-stage renal disease; persons who have undergone gastrectomy; and patients who take immunosuppressive drugs.

NATURAL HISTORY OF TUBERCULOSIS AND EFFECTIVENESS OF THERAPY

Natural History

Mycobacterium tuberculosis is transmitted by way of fresh droplet nuclei expelled by a person with cavitary disease. It cannot be spread by hands, utensils, or other fomites, although organisms can be cultivated from room dust. Although inoculation can occur via the gastrointestinal tract, the vast majority of infections in the United States begin in the lung (see Chapter 49). Until the HIV epidemic, it was rare for primary infection to result in early progressive disease; young children were at greatest risk for this complication. However, among HIV-positive patients, the risk for rapid progression to active disease is substantial, with some studies showing a rate of 30% and a mean incubation period of only 80 days. Based on polymerase chain reaction and molecular epidemiology studies, it is now felt that 40% of all active TB cases in urban centers like New York City represent newly acquired infection rather than reactivation of latent disease.

Approximately 5% to 15% of new tuberculous infections eventually progress to serious disease. Risk is greatest during the years immediately following infection. Late reactivation occurs in only 3% to 5% of patients without clinical disease 5 years after infection.

Effectiveness of Therapy

Three strategies may be used in the prevention of clinical infection: (a) biologic prophylaxis of uninfected persons with bacille Calmette-Guérin (BCG) vaccine; (b) chemoprophylaxis of newly or recently infected persons with isoniazid (INH); and (c) INH chemoprophylaxisof selected persons with latent infection.

Biologic Prophylaxis with BCG vaccine is widely practiced in countries where TB is prevalent. The vaccine is used for prevention in uninfected persons; it is of no value in infected persons. BCG vaccine contains a live, attenuated strain of *Mycobacterium bovis*, which has little virulence in humans. It should not be administered to patients who react positively to the purified protein derivative (PPD) tuberculin skin test. BCG itself may cause a positive PPD test result in the first 2 to 3 years following vaccination. After this period, however, a positive PPD test result should not be ascribed to vaccination with BCG, nor should prior BCG vaccination be considered a reason not to perform skin testing, if it is otherwise indicated. The vaccine has been in clinical use since 1922, but its role remains controversial. Early trials demonstrated that BCG could prevent TB in up to 80% of recipients, but subsequent trials on the Indian subcontinent failed to demonstrate efficacy. Even though recent studies in Great Britain and Canada suggest that the vaccine may be up to 60% effective, BCG is not currently recommended for routine use in the United States. The relatively low incidence of new tuberculous infections in the United States still makes case finding and INH prophylaxis a more effective approach (see below).

Chemoprophylaxis appears to reduce significantly the risk for progression from latent infection to active disease. In patients who have not received chemotherapy, a positive skin test result implies the presence of a few dormant but viable tubercle bacilli, which have the potential for reactivation. It has been demonstrated that the administration of *INH* daily for 6 to 12 months reduces the risk for reactivation by up to 80%. Because the risk for progressive disease is greatest soon after infection, recent converters to tuberculin reactivity are most likely to benefit from such therapy.

Current guidelines for INH chemoprophylaxis depend on the patient's *age*, the *strength of the tuberculin reaction*, and the presence of *other risk factors*. The following groups should be considered candidates regardless of age:

- Patients with known or suspected HIV infection (5 mm).
- Close (especially household) contacts of patients with known active pulmonary TB (5 mm). *Children and adolescent contacts of a person with TB should be offered INH regardless of PPD status until a PPD test can be repeated at 12 weeks*.
- Patients with fibronodular disease on chest radiography compatible with old, healed TB (5 mm).
- Patients with documented PPD conversion within the preceding 2 years (10 mm).
- IV drug users uninfected with HIV (10 mm).
- Patients with medical conditions predisposing to active TB, such as malnutrition, diabetes, end-stage renal disease, silicosis, gastrectomy, or use of immunosuppressive drugs (10 mm).

The following groups should be considered candidates for INH chemoprophylaxis if less than 35 years old:

- Foreign-born patients from countries where TB is endemic (10 mm).
- Native-born patients from medically underserved low-income areas, especially if homeless (10 mm).
- Patients residing in long-term care facilities such as nursing homes, correctional facilities, and mental institutions (10 mm).

Persons without risk factors for acquiring TB and without medical conditions predisposing to active TB should be considered candidates for INH only *when they are younger than 35 years and when the PPD test shows at least 15 mm of induration*.

When INH is used for prophylaxis, it should be administered daily for *6 months*, except in the case of *HIV-positive* persons and those with *old TB* according to radiographic criteria; the latter require *12 months* of INH. INH may also be given twice weekly via directly observed therapy (DOT). Enthusiasm for INH prophylaxis must be tempered by the significant side effects of the drug, particularly hepatotoxicity. Liver injury is quite rare in patients younger than 20 years and occurs in no more than 0.2% of those between ages 20 and 34. On the other hand, INH-induced liver disease may develop in more than 2% of patients older than 50 (see Chapter 49). *INH alone should never be given to a patient with active TB*. A chest radiograph and a clinical encounter designed to uncover subtle signs and symptoms of active TB are mandatory before INH chemoprophylaxis is initiated. *If any doubt exists*, INH should be deferred pending the results of sputum cultures or the resolution of

ambiguous symptoms.

The Centers for Disease Control and Prevention (CDC) has recommended that a *2-month regimen of rifampin (RIF) and pyrazinamide (PZA)* be used as an alternative to 12 months of INH in *HIV-infected persons*. It is anticipated that this recommendation will be extended to HIV-negative patients in the near future. Although its shorter duration will increase adherence, the two-drug regimen is more likely to cause side effects.

SCREENING AND DIAGNOSTIC TESTS

The tuberculin skin test is the most useful test for the diagnosis of past or present tuberculous infection. The Mantoux test with use of an intradermal injection of Tween 80–stabilized *PPD* is more reliable than multiple-puncture tests, such as the Tine Test. PPD is available in three strengths: the *"first strength"* contains *1 tuberculin unit (TU)*; the *"intermediate strength," 5 TU*; and the *"second strength," 250 TU. Only the 5-TU strength should be used for screening*.

The tuberculin skin test result should be interpreted 48 to 72 hours after injection; the diameter of *induration* (not erythema) determines the interpretation. Until recently, a single standard was used to interpret the tuberculin skin test in all people: 0 to 4 mm was "negative," 5 to 9 mm was "doubtful," and 10 mm or more was "positive." As noted above, authorities such as the CDC now recommend that different skin test criteria be applied to different population groups, to provide a more accurate assessment of risk.

The current CDC *criteria for skin test positivity* include the following:

- Induration of *5 mm* for patients who are HIV-positive and for patients who are very likely to have TB, such as close contacts of documented cases and patients with chest x-ray films that strongly suggest TB (see Chapter 49)
- Induration of *10 mm* for members of high-incidence populations or for patients with medical conditions predisposing to active TB
- Induration of *15 mm* for persons with no identifiable risk factors

Repeated tuberculin skin tests can produce a *booster effect*, but only among patients already infected with TB. Among hospital employees or other populations who may undergo repeated skin testing, a booster effect can be mistaken for tuberculin conversion. Confusion can be avoided by repeated testing of persons with negative or doubtful skin test results 1 week later; any increase in the diameter of induration can be attributed to the booster effect. In contrast, increased reactivity that occurs at 1 year, but not at 1 week, should be attributed to newly acquired infection.

False-negative reactions (anergy) have been documented in up to 20% of patients with TB, particularly those who are immunocompromised by HIV infection, overwhelming or advanced disease, malnutrition, or debility. Approximately 50% of patients with clinical AIDS may have false-negative PPD test results in the setting of active TB. The lowering of the criterion for a positive skin test result in HIV-positive patients to a 5-mm induration is an attempt to improve test sensitivity. The CDC no longer recommends the use of *Candida*, mumps, or tetanus toxoid antigens as "controls" for anergy because anergic HIV-positive patients do not benefit from INH chemoprophylaxis.

In addition to immunologic incompetence of the host, other causes of false-negative skin test results are mishandling of the antigen and faulty injection technique. Tuberculin should never be transferred from one container to another, and skin tests should be administered as soon as possible after the syringe is filled. Subcutaneous rather than intradermal injection may result in false-negative reactions. Because tuberculin sensitivity develops 2 to 10 weeks after initial infection, results of early skin tests may be negative in newly infected persons.

Although tuberculin skin testing is highly specific, false-positive reactions may also occur, usually because of cross-reactivity with atypical mycobacterial antigens acquired environmentally. This may cause intermediate skin test reactions in people who have not been exposed to *M. tuberculosis*—hence the requirement for larger areas of induration when a low-risk population is screened.

RECOMMENDATIONS AND CONCLUSIONS

- As long as the tuberculin skin test and INH remain useful for case finding and prophylaxis, respectively, biologic prophylaxis with BCG for PPD-negative patients is not recommended.
- PPD testing should be performed *annually in all HIV-infected patients*. Other high-risk persons should also be tested, including IV drug abusers, homeless persons, immigrants from countries with a high incidence of TB, prisoners, residents of long-term care facilities, and persons who are immunosuppressed or have chronic illnesses known to increase the risk for active TB.
- Healthy persons with a high risk for exposure to TB, such as those in the health care professions, should undergo tuberculin testing on an annual basis so long as they remain PPD-negative.
- INH prophylaxis should be considered for tuberculin-positive persons based on the strength of the PPD reaction, the presence of risk factors, and age. Positive reactors require 6 months of daily INH prophylaxis (300 mg/d); those at highest risk (HIV-positive, old TB on chest x-ray films) require 12 months of daily prophylactic treatment. Care must be taken to ensure compliance to prevent the emergence of drug-resistant strains, and twice-weekly DOT may be appropriate.
- Treatment with RIF and PZA for 2 months is as effective as treatment with INH alone for 12 months in HIV-infected patients, although side effects are more common.
- Active TB must be excluded before INH chemoprophylaxis is begun.

CHAPTER 39 EVALUATION AND PREVENTION OF OCCUPATIONAL AND ENVIRONMENTAL RESPIRATORY DISEASE

L. CHRISTINE OLIVER AND JOHN D. STOECKLE

Occupational lung disease, one of the 10 leading causes of work-related health problems in the United States, results from the inhalation of organic and inorganic dusts, irritant vapors and gases, and toxic fumes, which adversely affect both the upper and lower respiratory tracts. Although the true scope of occupational respiratory illness and disease is unknown, some estimates can be given. In the United States, about 15% of newly diagnosed cases of asthma in adults are the consequence of occupational exposures. It has been estimated that approximately 65,000 men in the United States have clinically identifiable asbestosis; moreover, it is predicted that 19,000 cases of malignant mesothelioma and 55,000 cases of lung cancer will occurby the year 2009 in men with a history of occupational exposure to asbestos. Persons permanently disabled by respiratory disease resulting from previous exposure to cotton dust number about 30,000; active cotton mill workers who are partially disabled number about 85,000. Ten percent of active coal miners and 20% of retired miners have coal worker's pneumoconiosis (CWP). The U.S. Department of Labor has estimated that more than 1 million workers are exposed to silica and that approximately 60,000 have silicosis.

Nevertheless, these figures underestimate the extent of occupational pulmonary disease. The reasons are several. First, because the clinical findings in patients with work-related respiratory disease resemble those in persons with respiratory disease that is not occupationally related, the diagnosis is often missed. Second, the latency period between exposure and the subsequent development of disease may be long, which obscures the causal relationship. Third, physicians often underdiagnose because they have inadequate training in occupational medicine. Fourth, occupational disease is underreported by health care personnel. Further, the estimates do not include the "paraoccupational" lung disease that results from bystander exposure, household contact with toxins carried home on work clothes, and neighborhood exposure. Asbestos-related disease has been reported in family members of asbestos workers and in persons living in close proximity to shipyards and asbestos manufacturing plants. Chronic beryllium disease has resulted from residence in the neighborhood of beryllium plants, and asthma from residence near grain elevators.

It is critical that the primary care physician be familiar with occupational lung diseases and their diagnosis if unnecessary morbidity is to be avoided. Because respiratory symptoms caused by toxic exposures are nonspecific, recognizing their relationship to the toxic agent or agents is essential to proper diagnosis and treatment. Continued exposure may result in needless, irreversible functional abnormalities and the development of chronic and even fatal respiratory disease.

PATHOPHYSIOLOGY AND CLINICAL PRESENTATION

Inhaled dusts, gases, and fumes exert their effects on the respiratory tract in several ways. The first is *direct irritation* and *inflammatory response*. Symptoms include excessive mucous secretion, cough, airways hyperreactivity, chest tightness or pain, wheeze, and dyspnea. Asthma, chemical pneumonitis, or pulmonary edema may develop. Irritation is associated with an inflammatory response involving chemosensitive neurons and the release of vasoactive and chemotactic mediators. Clinical manifestations may be delayed, as after exposure to the irritant gases nitrogen dioxide and phosgene, when a delay of 12 to 24 hours may precede the onset of pulmonary edema.

Second, dusts such as silica and asbestos may be retained in the lungs and provoke a *fibrotic* or *granulomatous response*. To reach the lower respiratory tract, substances must have a particle size of 5 μm or less. The latency between onset of exposure and the clinical manifestation of disease may be as long as 20 to 25 years and is often related to the intensity of exposure.

Third, an *immunologic response* with *development of hypersensitivity* may play a role in occupational lung disease. Hypersensitivity is important etiologically in hypersensitivity pneumonitis, certain types of occupational asthma, and pulmonary beryllium disease. Increased circulating levels of immunoglobulins, rheumatoid factor, antinuclear antibody, and a_1-antitrypsin have been observed in persons with asbestosis. Peripheral blood T-lymphocyte abnormalities appear to be related to the duration of asbestos exposure and radiographic outcome. Elevated titers of circulating antinuclear antibody and rheumatoid factor are seen in association with silicosis. Persons with beryllium disease are reported to have alterations in circulating T lymphocytes and a high rate of blast transformation of lymphocytes in peripheral blood and bronchoalveolar lavage specimens.

Fourth, *other host factors* are important. Asbestos acts synergistically with cigarette smoke to increase the risk for lung cancer. The prevalence of bronchitis and airways obstruction is increased in welders and coal miners who smoke in comparison with their nonsmoking co-workers.

Finally, *social* and *economic factors* often determine the geographic proximity of home to industrial sources of air pollution, and *work practices* affect the likelihood that family members will bring workplace toxins home on work clothes.

Occupational respiratory disease can be classified clinically as airways disease, interstitial disease, or cancer (Table 39.1).

Table 39.1. Classification of Occupational Respiratory Disease

Airways Disease

Work-related airways disease may be acute or chronic and reversible or irreversible. Airways obstruction may or may not be present. The nature of the exposure and duration of exposure after development of symptoms are important variables in determining outcome.

Occupational Asthma is the most common occupational lung disease in developed countries. Of cases of work-related lung disease reported in the United Kingdom and BritishColumbia, 26% and 52%, respectively, were occupational asthma. Inhalation of substances in the workplace can cause or exacerbate reversible airways hyperreactivity, with or without airways obstruction. Preexisting asthma that is exacerbated by occupational exposures is diagnosed as occupationally aggravated asthma.

At least 250 agents have been reported to cause occupational asthma. These substances have most recently been classified on the basis of their association with latency, and those with similar latency are further subdivided on the basis of molecular weight. Asthma that is associated with exposure to high-molecular-weight

substances is mediated by immunoglobulin E and is similar etiologically to "allergic" asthma that is not related to work. The mechanism in the case of low-molecular-weight (<1,000 D) substances is less clear. An example of such substances is the class of chemicals known as isocyanates, which are in widespread use in the manufacture of rigid and flexible foams, products used in floor refinishing, sealant materials, wood varnishes, and packaging and thermal insulation materials. They cause asthma through either or both of two mechanisms: (a) direct irritation of bronchial mucosa and (b) sensitization through an immunologic mechanism that is not yet clearly defined. Once sensitized, persons are at risk for severe and even fatal attacks of asthma on repeated exposure. Substances that induce asthma without latency include irritant vapors, gases, and fumes.

Occupational asthma occurs in persons both with and without atopy. Symptoms include chest tightness, wheezing, dyspnea, and cough. Lung function tests may reveal small-airways dysfunction and an obstructive defect that is partially reversible following administration of bronchodilators. Temporal associations between work and decline in lung function, measured by peak expiratory flow (PEF) or forced expiratory volume in 1 second (FEV_1), may be observed during the work shift or more gradually during the work week. A fixed level of obstruction may ultimately develop. The longer the duration of exposure after onset of symptoms, the more likely is the development of irreversible changes.

Byssinosis is characterized by respiratory symptoms and obstructive airways disease and follows exposure to cotton, flax, and hemp dust. It is seen most commonly in the United States among cotton textile workers. Symptoms of chest tightness and dyspnea, with reduction in rates of air flow, initially appear on the first day of the work week after a 2-day absence from work. These abnormalities may become persistent and result in chronic, irreversible disease if exposure is continued. The bract of the cotton plants is thought to contain the causal agent.

Airways Disease and Multiple Chemical Sensitivity may occur together following an acute inciting event and subsequent exposure to multiple, often unrelated chemicals. The occurrence of airways disease as one of the manifestations of multiple chemical sensitivity is a logical outcome of a postulated physiologic mechanism for chemical sensitivity—namely, irritation of respiratory tract epithelium followed by an inflammatory response with release of mediators, effects on epithelial chemosensitive neurons, and alteration in the permeability of respiratory tract epithelium. Causal workplace exposures often occur in the service sector and affect white collar professionals.

Industrial Bronchitis is a nonspecific manifestation of airway irritation and inflammation. It is characterized by cough and the production of sputum and results from the inhalation of particulates and irritants. Acute bronchitis is self-limited. Chronic bronchitis is defined as cough and sputum production on most days for 3 months or more per year, in two or more consecutive years. It may be associated with the development of irreversible airways obstruction. Causal agents include coal dust and silica, irritant gases such as sulfur dioxide, diesel exhaust, and welding fumes. Industrial bronchitis is also associated with exposure to high levels of nonspecific dust (e.g., in the construction industry).

Interstitial Lung Disease

Interstitial lung disease associated with exposure to dust (pneumoconiosis) was at one time the most commonly recognized form of occupational lung disease. In 1950, the International Labor Organization developed a system for classifying interstitial fibrosis of the lung resulting from exposure to silica and coal dust; the system was updated in the 1970s to include exposure to asbestos. The most common of the pneumoconioses are described below.

Asbestosis is fibrosis of the lung parenchyma or pleura as a result of asbestos exposure. Fibrosis of the pleura may take one of two forms—circumscribed pleural plaques or diffuse pleural thickening. Pleural plaques may contain calcium. The severity of asbestos-related pulmonary fibrosis is related to both total dose and latency. In epidemiologic studies, parenchymal asbestosis is more closely associated with dose, and pleural asbestosis with latency. Respiratory symptoms are nonspecific and depend on the extent of disease. Physical examination may reveal characteristic dry end-inspiratory crackles at the lung bases. Physiologic abnormalities include restrictive mechanics and impaired gas exchange. Small-airways dysfunction, probably resulting from peribronchiolar fibrosis, may be an early finding.

Radiographic changes on posterior–anterior views of the chest include irregular, small opacities in the lower lung zones and pleural plaques. Lateral views of the chest are useful in detecting *calcified hemidiaphragmatic plaques*, a hallmark of asbestos exposure. The value of oblique views in detecting pleural plaques is inversely related to risk for development of disease. Extensive pleural thickening has been associated with respiratory failure; the presence of pleural plaques has been associated with increased risk for subsequent development of lung cancer and malignant mesothelioma. The full effect of exposure to asbestos in asbestos-containing materials in schools and other public buildings remains to be determined. Asbestosis has been reported in school custodians, and malignant mesothelioma in custodians and building occupants.

Silicosis results from exposure to silicon dioxide (SiO_2) or quartz, which is fibrogenic. Silica exposure occurs in a wide variety of occupational settings. Particularly important is bystander exposure. For example, sand blasters are often provided with respiratory protection while workers around them are not. Silicosis may occur in a simple nodular form or in a "complicated" form with progressive massive fibrosis (PMF). Latency and severity of disease are directly related to level of dust exposure.Fulminant silicosis may develop after 1 to 2 years of high-level exposure. It may be complicated by mycobacterial or fungal infection. Radiographic abnormalities characteristically precede functional abnormalities and initially occur as small, rounded opacities involving the upper lung zones. Hilar lymph nodes may become enlarged with "eggshell" calcifications. Physiologic abnormalities reflect the peribronchiolar location of the silicotic nodules and include small-airways dysfunction and impaired gas exchange in the early stages. With PMF, obstruction, restriction, or a mixed pattern may develop.

Coal Worker's Pneumoconiosis results from the deposition of coal dust in peribronchial tissues, with the formation of dust macules and the distention of terminal bronchioles. The occurrence and extent of disease depend on both the level of dust exposure and the rank of the coal, with anthracite being more fibrogenic than bituminous coal. CWP occurs in two forms: "simple" pneumoconiosis, characterized by the presence of small dust nodules, usually less than 5 μm in diameter, and "complicated" pneumoconiosis, or PMF, characterized by large masses of dust and collagen tissue. The most prevalent respiratory symptom is chronic bronchitis, which is unrelated to the radiographic appearance of the lungs and is more common in miners who smoke. Physiologic abnormalities on lung function testing are variable and, with the exception of the single-breath diffusing capacity for carbon monoxide (D_{LCO}), unrelated to the radiographic appearance in simple CWP. A reduced D_{LCO} is associated with category p opacities (<1.5 mm in diameter) in simple CWP and with advanced PMF. Airway obstruction may be seen in PMF and in association with chronic bronchitis.

Acute and Chronic Beryllium Disease results from the inhalation of beryllium oxide. At risk are workers engaged in the manufacture of beryllium-containing products and in the electronics and aircraft industries. Acute disease follows the inhalation of relatively high concentrations of beryllium. Its irritant effect on the respiratory tract may produce nasopharyngitis, tracheobronchitis, or clinical pneumonitis. Chronic beryllium disease is a systemic granulomatous disorder that is often confused with sarcoidosis. The chest radiograph typically reveals a diffuse reticulonodular infiltrate, with hilar lymphadenopathy in about 40% of patients. Lung function tests may reveal obstruction or restriction and impaired gas exchange. The angiotensin1-converting enzyme level is elevated in about 50% of persons with active sarcoidosis, a finding that may be useful in distinguishing this entity from chronic beryllium disease. Elevated levels of beryllium in urine or tissue suggest the diagnosis and provide definitive evidence of exposure. The blast transformation of pulmonary lymphocytes on *in vitro* exposure to beryllium salts confirms the diagnosis.

Hypersensitivity Pneumonitis (Extrinsic Allergic Alveolitis) occurs following exposure to organic dust. Causal agents include thermophilic actinomycetes, *Aspergillus*, and serum and urine protein from animals and fish. Clinical disorders include farmer's lung, bird fancier's lung, bagassosis, humidifier fever, and animal handler's lung. Both acute and chronic reactions may occur. The chest radiograph may reveal miliary or larger discrete opacities in the middle and lower lung zones. Repeated exposure may result in recurrence of symptoms and ultimately in the development of chronic disease, with interstitial fibrosis on the chest radiograph and impaired lung function on physiologic testing. The acute phase may be mild and pass relatively unnoticed. Antigen-specific precipitins appear in about 90% of cases.

So-called "benign" pneumoconioses occur following exposure to certain inert dusts. The chest radiograph reveals interstitial opacities. Lung function generally remains intact. These pneumoconioses follow exposure to iron oxide (siderosis), tin oxide (stannosis), barium (baritosis), and zirconium.

Cancer

Occupational and environmental exposures causally associated with cancer of the respiratory tract include *asbestos, radon, diesel exhaust*, arsenic, chromium (hexavalent), nickel, vinyl chloride monomer, radiation, and possibly fumes from the welding of stainless steel. Radon daughters of uranium and the chemicals bischloromethyl ether and chloromethylmethyl ether have been shown to cause *small-cell carcinoma*. Of the environmental concerns, asbestos and radon are the two most closely linked to cancer.

Asbestos causes both *bronchogenic carcinoma* and *malignant mesothelioma*, a tumor of the pleura and peritoneum. Asbestos and cigarette smoke act synergistically to increase the risk for lung cancer 50 to 70 times, whereas asbestos alone increases the risk by a factor of three to five. Smoking does not affect the risk for malignant mesothelioma. The risk appears to be greater with exposure to processed asbestos than with exposure to mined asbestos because processing breaks up the bundles into shorter thinner fibers that can reach the lung more readily.

Radon is a naturally occurring gas emanating from uranium-containing rock and soil that is ubiquitous in the United States. Radon itself is harmless, but its daughter products emit a-particles, a potential source of radiation-induced injury to the tracheobronchial tree when attached to dust particles that are inhaled during many years. It is estimated that up to 10% of homes in the United States are built on soils sufficiently radon-rich to produce indoor radon concentrations of concern (>4 pCi/L as established by the Environmental Protection Agency). The actual risk to persons is unknown, but long-term exposure is probably required. The estimated risk derives from experience with uranium miners and is of the magnitude of 5,000 to 50,000 lung cancers per year in the United States. The Environmental Protection Agency recommends that homes in radon-rich areas be tested and remediation efforts undertaken if the level exceeds 4 pCi/L. Remediation, which is not expensive, involves venting the gas in the soil under the home away from the foundation.

NATURAL HISTORY OF DISEASE AND EFFECTIVENESS OF CONTROL

Although much remains to be learned about the natural history of most occupational lung diseases, practical control steps can be taken. It is worthwhile to distinguish agents commonly causing acute symptoms from those producing disease that becomes evident only after an asymptomatic latent period. Continued exposure to a causal agent increases the likelihood of chronic, irreversible, and more severe disease. This is truewhether symptoms are manifested acutely or only after a long latency. The difference is that for those diseases with a short latency or none at all, the cause should be more easily recognized and exposures reduced or eliminated altogether.

Occupational asthma is an example of an acute disease that may be reversible if its association with the causal agent is recognized and addressed. With continued exposure, it can progress to chronic, irreversible disease. Other examples are byssinosis and disorders caused by organic dusts (farmer's lung) and toxic metals (beryllium), in which acute and then chronic symptoms are related to the level and duration of exposure.

Diseases such as CWP and asbestosis become clinically manifest only after a long and asymptomatic latent period. Clinical findings of CWP usually follow 10 years of exposure. Similarly, 10 to 20 years of asbestos exposure is typically required to produce detectable pulmonary asbestosis. Silicosis also has a long latent period unless exposure is intense. Despite improved methods of dust control, elimination of exposure altogether is advised for people with identifiable pneumoconiosis. Disease once manifested continues to progress even after cessation of exposure. Moreover, continued exposure to a substance that is also a carcinogen increases the risk for development of related lung cancer.

DIAGNOSIS

Eliciting the *occupational history* is the most important step in the diagnosis of occupational respiratory disease. Although a chronologic lifetime work history is ideal, it is often unnecessary in the primary care setting. Three questions will usually suffice: (a) What is your current job? (b) What was your previous job? and (c) What is your usual job—that is, the one you have worked at the longest? It is important to obtain not only a job title but also a job description. Specific information about the type, level, and duration of exposure is needed. Material safety data sheets for chemicals in use in the workplace and the results of industrial hygiene surveys of the workplace are often useful sources of exposure information. It is important to characterize the temporal relationship of symptoms and disease to work, and to inquire about similar illness in co-workers and family members. A screening environmental history is also important, including exposure to possible air pollutants and radon.

Lung function tests and other laboratory tests provide valuable diagnostic information. A reduced D LCO may be the only abnormality in developing pulmonary fibrosis. Small-airways dysfunction may be an early sign of interstitial or obstructive lung disease. Preshift and postshift *PEF* or *spirometry* is often useful in the diagnosis of occupational asthma. If the history and clinical findings suggest a diagnosis of pneumoconiosis, then a *chest radiograph* should be interpreted according to the International Labor Organization system of classification, developed for purposes of standardization and more specific radiographic characterization and quantification of pneumoconiosis. *Bronchial provocation* by inhalation under carefully controlled conditions can be a useful tool in the diagnosis of occupational asthma.

Thorough documentation is essential, not only to design a treatment program but also to determine disability and compensation.

RECOMMENDATIONS FOR PREVENTION

- Include an occupational/environmental history as a routine part of the screening medical examination in all patients.
- Recommend testing when exposure is suggested by the history.
- Consider obtaining a DLCO determination if pulmonary fibrosis is a concern, a chest radiograph if pneumoconiosis is suspected, and prework and postwork spirometry supplemented by bronchial provocation testing if occupational asthma is a possibility.
- If the diagnosis is confirmed, inform the patient and explain its possible relation to any occupational or environmental causes. Ascertaining patient understanding is important because of statutes of limitation associated with legal remedies, such as workers' compensation.
- Work with the patient, employer, and community if possible to develop a reasonable approach to the reduction or elimination of the causal exposure.
- Inform the employee and a regulatory agency, such as the Occupational Safety and Health Administration or Environmental Protection Agency, of any serious or potentially life-threatening hazards to the patient, co-workers, or other citizens to facilitate an evaluation of the workplace and environment and elimination of the toxic exposure.
- Encourage patients to abstain from habits, such as smoking, that are inherently toxic to the lungs and exacerbate respiratory effects of workplace and environmental exposures.
- Institute appropriate medical surveillance for the subsequent development of other exposure-related pulmonary disease, such as lung cancer.
- Elimination of exposure through the use of rigorous engineering and environmental controls is the ultimate goal in prevention. Removal from the job or home should be a last resort.

CHAPTER 40 EVALUATION OF CHRONIC DYSPNEA

Dyspnea is the subjective sensation of difficult or uncomfortable breathing. Patients commonly complain of "shortness of breath" to describe their respiratory difficulty. *Acute dyspnea* is most often a manifestation of sudden left ventricular dysfunction (see Chapter 32), bronchospasm (see Chapter 48), pneumonia (see Chapter 52), pulmonary embolization (see Chapter 20), or anxiety (see Chapter 226). The patient often presents in the urgent care setting. Patients with chronic dyspnea, even when severe, are more likely to come to the office for care. Longstanding dyspnea can be evaluated safely in the outpatient setting.

Heart and lung diseases account for most cases of chronic dyspnea. At times, the differentiation can be difficult; moreover, these causes often coexist. In such instances, diagnosis requires determining which one is predominant. In evaluating the chronically dyspneic patient, one needs to check for precipitants and reversible components, in addition to ascertaining the cause. Also important are an assessment of functional status, severity of deficits, and prognosis.

PATHOPHYSIOLOGY AND CLINICAL PRESENTATION

The pathophysiology of dyspnea is multifactorial and complex. In most instances, dyspnea results from cardiac or pulmonary decompensation and is provoked by the stimulation of receptors responsive to metabolic changes, pulmonary interstitial stretch, respiratory muscle tension, and central respiratory command. Shortness of breath is experienced when ventilatory demand exceeds the actual or perceived capacity of the lungs to respond. The work of breathing may be increased by altered chest wall mechanics, decreased lung compliance, airway obstruction, increased ventilatory requirements, or exogenous factors such as obesity.

Dyspnea occurs in several important clinical settings. *Congestive heart failure* (CHF) can cause dyspnea as pulmonary capillary pressure rises and fluid accumulates in the interstitium, leading to a fall in pulmonary compliance and a sense of difficulty breathing. The earliest symptom is often dyspnea on exertion. More severe failure is manifested by orthopnea and finally paroxysmal nocturnal dyspnea. Basilar crackles (rales) and a third heart sound (S_3) are important signs of left-sided heart failure and pulmonary venous hypertension; the S_3 is one of the most specific signs of CHF. Peripheral edema and jugular venous distention are common manifestations of right-sided heart failure, but these findings, particularly leg edema, are very nonspecific, (see Chapter 22). Contributing and precipitating factors include fever, acute ischemia, excessive dietary sodium intake, dysrhythmias, concurrent use of agents that are negatively inotropic (e.g., b-blockers, disopyramide, verapamil), and poor compliance with medical regimen (see Chapter 32).

Besides CHF, a number of other causes of pulmonary venous hypertension result in increased pulmonary capillary pressure and dyspnea. *Mitral stenosis* is the most important in this class of conditions.

Airway obstruction at any level of the respiratory tract can lead to difficulty breathing. *Tracheal stenosis* resulting from intrinsic disease or extrinsic compression is characterized by dyspnea in conjunction with stridor and inspiratory retraction of the supraclavicular space. *Chronic obstructive pulmonary disease* (COPD) (see Chapter 47) is the leading cause of airway obstruction. *Chronic bronchitis* is a subcategory of COPD that is defined as cough and sputum production persisting for 3 months or more in two consecutive years. Characteristically, these patients have a long history of smoking, productive cough, and a slowly progressive decline in exercise capacity. In advanced stages, they may become plethoric and cyanotic andcough incessantly; the term "blue bloater" has been applied to such patients. Tobacco-stained fingers, wheezes, coarse rales, rhonchi, and a prolonged expiratory phase of respiration are often present on examination. Signs of cor pulmonale (right ventricular heave, jugular venous distention, leg edema) are late findings indicative of severe, advanced disease.

Another group of COPD patients are those with *emphysema*. Sputum production is minimal compared with that in patients with bronchitis, and mismatching of ventilation and perfusion is less pronounced; consequently, hypoxia and cyanosis are less prominent. Gradual deterioration in exercise capacity takes place through many years. Patients with advanced emphysema appear thin and barrel-chested. They may purse their lips during expiration to keep their poorly supported airways from collapsing. The chest is hyperresonant, breath sounds are distant, and a few end-expiratory wheezes may be noted; expiration is prolonged.

Patients with COPD and *bronchiectasis* have a clinical presentation similar to that of patients with chronic bronchitis, except that their physical findings are more localized, the clinical course is punctuated by more frequent episodes of pneumonia, and their sputum tends to be more copious and sometimes bloody.

Asthma is another of the obstructive airway diseases. It usually produces attacks of acute dyspnea, but airway obstruction may persist for a prolonged period after an acute episode and result in more chronic respiratory complaints, including exercise intolerance, cough, and sputum production. At times, sputum production may be the predominant early symptom and mistaken for infection. Diffuse wheezes are commonly noted on examination; severe cases are characterized by use of accessory muscles, retraction, and pulsus paradoxus. Exercise-induced asthma is common in young people and may contribute to recurrent dyspneic episodes (see Chapter 48).

Diffuse *interstitial lung disease* alters pulmonary compliance and may lead to a disturbance in the balance between ventilation and perfusion. The process is usually very gradual, and often patients have few symptoms when pulmonary involvement is mild or even moderate; however, tachypnea and cyanosis ensue in severe cases. Diffuse, "dry" midexpiratory crackles are often heard on auscultation. As the interstitial process progresses, dyspnea and hypoxia worsen and exercise tolerance deteriorates (see Chapter 46).

Kyphoscoliosis is the major chest wall deformity capable of seriously impairing pulmonary musculoskeletal mechanics. Advanced cases can even terminate in cor pulmonale and respiratory failure. Among the extrapulmonary conditions hindering lung mechanics are severe *obesity*, marked *ascites* (see Chapter 71), and large *pleural effusions* (see Chapter 43). Dyspnea is often the chief complaint in such patients.

Pulmonary hypertension represents a serious cause of chronic dyspnea and has a poor prognosis. It may be primary or secondary and is characterized by a fixed elevation in pulmonary artery pressure and resultant strain on the right side of the heart strain. Common physical findings include an accentuated pulmonic component of S_2, a right ventricular S_3, the murmur of tricuspid regurgitation, and peripheral edema.

Secondary pulmonary hypertension occurs with conditions that chronically elevate pulmonary artery pressure, such as *recurrent pulmonary embolization, chronic hypoxemia, pulmonary parenchymal disease*, and *left-sided heart failure*. Some forms of secondary disease have subtle presentations and can easily be mistaken for primary disease. For example, pulmonary hypertension resulting from recurrent pulmonary embolization typically occurs in patients with few symptoms of embolization. Except for recalling perhaps a single episode of pleuritic chest pain and acute dyspnea, most patients report few symptoms before the onset of pulmonary hypertension. In those with symptomatic, recurrent embolization, significant pulmonary hypertension rarely develops. The reason for this paradox remains unclear. The source of emboli is believed to be the proximal deep veins of the legs.

Primary pulmonary hypertension is a diagnosis of exclusion. It occurs most commonly in women between the ages of 20 and 40. The mean age is about 35, and the ratio of women to men is 1.7:1. Dyspnea is the most frequently reported symptom, followed by fatigue, near-syncope, and Raynaud's phenomenon. An immunologic basis for the condition is suspected because of the high frequency of antinuclear antibody seropositivity in many of these patients, especially women. Immunologically mediated endothelial damage is postulated. Hyperventilation may result and be mistakenly attributed to anxiety.

Anxiety attacks are often confused with more serious conditions because the patient may appear to be in severe respiratory distress. Patients often report chest tightness or claim that they cannot take in enough air. The florid, acute case is represented by the hyperventilation syndrome (see Chapter 226), but more common is a less dramatic, chronic feeling of dyspnea and fatigue that is affected little by exertion. Frequent sighing, multiple bodily complaints, nervousness, and normal physical examination findings are typical of such patients.

DIFFERENTIAL DIAGNOSIS

The causes of chronic dyspnea encountered in the office setting are listed in Table 40.1.

Cardiac
Congestive heart failure
Other causes of pulmonary venous congestion (mitral stenosis, mitral regurgitation)
Pulmonary
Chronic obstructive pulmonary disease
Pulmonary parenchymal disease (including interstitial diseases)
Pulmonary hypertension
Severe kyphoscoliosis
Exogenous mechanical factors (ascites, massive obesity, large pleural effusion)
Chronic asthma
Psychological
Anxiety
Hematologic
Severe chronic anemia

Table 40.1. Common Causes of Chronic Dyspnea

WORKUP

History remains the single most useful diagnostic modality. In studies of dyspnea, the diagnosis is established by the history in about 75% of instances. However, differentiating dyspnea caused by cardiac disease from that caused by pulmonary pathology can be a challenge. For example, exertional dyspnea occurs in both cardiac and pulmonary disease. A frequent misconception is that paroxysmal nocturnal dyspnea is unique to heart failure. Excessive airway secretions from chronic obstructive lung disease often pool at night and lead to airway obstruction, causing dyspnea and forcing the patient to sit up to clear the airway. Wheezing is a nonspecific manifestation of large-airway bronchospasm, whether it is caused by heart failure or obstructive lung disease.

In general, a history dominated by chronic cough, sputum production, recurrent respiratory infection, occupational exposure, or heavy smoking suggests lung disease rather than a cardiac origin. However, unless a strong history of previous lung disease or substantial sputum production is present, it may be very hard to distinguish a cardiac from a pulmonary source on the basis of history alone. Moreover, both may coexist concurrently. Physical findings and laboratory studies are often necessary for a better differentiation (see below).

Dyspnea that is a manifestation of a chronic anxiety state may superficially mimic cardiopulmonary disease and cause some confusion. Onset at rest in conjunction with a sense of chest tightness, suffocation, or inability to take in air are characteristic features of the history. Also, little evidence of significant heart or lung disease is present, although the patient may fear it greatly. Multiple bodily complaints, a history of emotional difficulties, an absence of activity limitations, and a lack of exacerbation on exercising argue for a psychogenic cause. Unfortunately, patients with pulmonary hypertension may have episodes that can resemble anxiety-induced bouts of dyspnea; sometimes, a young patient with primary pulmonary hypertension is incorrectly labeled "neurotic."

It is helpful to define as precisely as possible the degree of activity that precipitates the sensation of dyspnea, estimate the severity of disease, determine the extent of disability, and detect changes over time. One means of achieving these objectives is to relate symptoms to the patient's daily activities and interpret the degree of restriction in terms of the expected endurance of a patient of similar age.

Factors that may contribute to the occurrence or worsening of dyspnea should be documented, including cigarette smoking, occupational exposure, excessive salt intake, weight gain, and increasing sputum production. The occupational history is particularly important, as the relationships between exposures and lung disease are becoming increasingly evident (see Chapter 39).

The patient should be asked about hemoptysis; the symptom raises the possibilities of bronchiectasis, endobronchial malignancy, embolization with infarction, and pneumonia. If embolization is suspected, the physician must inquire about pleuritic chest pain, leg edema, and other symptoms of deep vein thrombophlebitis (see Chapter 22), in addition to such risk factors as chronic venous insufficiency, inactivity, and—in young women—the use of oral contraceptives and pregnancy. Careful inquiry for historical evidence of recurrent pulmonary embolization is particularly important if pulmonary hypertension is encountered.

Physical Examination should begin with a check for tachycardia, tachypnea, fever, and hypertension. Weight increase must not be forgotten, for it may be an early sign of worsening CHF (see Chapter 32). The patient's respiratory efforts need to be observed carefully to obtain an estimate of the amount of work expended in breathing; contractions of the accessory muscles of respiration suggest severe difficulty. Retraction of the supraclavicular fossa implies tracheal stenosis that has become critical. Pursed-lip breathing and a prolonged expiratory phase are signs of significant outflow obstruction. The best way to observe air flow obstruction is to have the patient take a deep breath and blow out as hard and as fast as possible. The chest is examined for increased anterior–posterior diameter (suggestive of COPD) and deformity resulting from kyphoscoliosis or ankylosing spondylitis. Retraction of the intercostal muscles on inspiration is characteristic of emphysema.

The chest should be percussed for dullness and hyperresonance and auscultated for wheezes, crackles, and quality of breath sounds. Unfortunately, eliciting wheezing on maximal forced exhalation has proved neither sensitive nor specific for the diagnosis of asthma and cannot be recommended as a technique for uncovering underlying airway hyperreactivity. Crackles suggest fluid in the airway, as occurs with bronchitis, pneumonitis, and CHF. Normal findings on lung examination do not rule out pulmonary pathology but do lessen its probability and the likelihood that it is severe. The cardiac examination should focus on signs of left-sided heart failure (see Chapter 32), detection of left-sided heart murmurs (see Chapter 21 and Chapter 33), and signs of pulmonary hypertension and its consequences (accentuated and delayed pulmonic valve component of S$_2$, right ventricular heave, right ventricular S$_3$, right-sided systolic regurgitant murmur of tricuspid insufficiency, jugular venous distention, and peripheral edema). It is important to recognize that many of the signs of right-sided heart failure may be a consequence of longstanding pulmonary disease and therefore are not specific for a cardiac etiology. The abdomen is examined for ascites and hepatojugular reflux; the legs are checked for edema and other signs of phlebitis (see Chapter 16 and Chapter 30). Finally, the patient's mental status is checked for manifestations of an anxiety disorder; particularly germane is excessive sighing.

Laboratory Studies. The *chest radiograph* is essential to evaluation and should be studied for pulmonary venous redistribution, effusions, interstitial changes, hyperinflation, infiltrates, enlargement of the pulmonary arteries (indicative of pulmonary hypertension), cardiac chamber enlargement, and valve calcification. Upper zone redistribution of pulmonary blood flow is among the earliest radiographic findings of CHF (see Chapter 32); however, redistribution may also occur in COPD because of destruction of vessels in the lower lung fields. The radiographic diagnosis can be made with a high degree of accuracy if any two of the following criteria are met: depression and flattening of the diaphragm with blunting of the costophrenic angles on posterior–anterior film; irregular lucency of the lung fields; abnormally enlarged retrosternal space; diaphragmatic flattening or concavity on the lateral film. Chest radiography is sometimes useful for the detection of interstitial lung disease because physical findings may be minimal. However, radiographic findings may also be unimpressive, so that further study is necessary (see below). When an infiltrate is present, *Gram's stain* of the *sputum* and *culture* are often informative, especially when the patient is febrile, is coughing more than usual, or reports a change in sputum.

Sputum cytology is indicated under similar circumstances, particularly if hemoptysis has developed. A *Ziehl-Neelsen stain* for acid-fast bacilli and *sputum culture for tuberculosis* are also important components of the workup when an infiltrate is detected (see Chapter 49).

Simple *pulmonary function tests* can be reliably performed in the office on an inexpensive spirometer. *Forced expiratory volume in 1 second* (FEV$_1$) and *vital capacity* are the most informative of these measurements for detecting obstructive and restrictive defects and determining their severity. The ratio of FEV$_1$ to vital capacity is markedly reduced in clinically important obstructive disease. In restrictive disease, the ratio is close to 1.0, but the vital capacity is significantly reduced. An FEV$_1$ determination can also provide prognostic information. A reading of less than 1.0 L/s is associated with a poor 5-year survival rate among patients with COPD (see

Chapter 47). Patients suspected of having tracheal stenosis may require *flow–volume studies* to identify the lesion and determine its severity; referral is indicated.

Arterial blood gas determinations are not routinely available in most office settings, but they are worth obtaining when deteriorating ventilation is suspected. Hospitalization should be considered when the carbon dioxide tension (PCO_2) is inappropriately elevated for the respiratory rate and repeated determinations reveal further increases in PCO_2. Measuring arterial blood gases before and after exercise is helpful in assessing the severity of diffuse interstitial disease. A fall in oxygen tension (PO_2) is evidence of a significant degree of interstitial disease. When use of accessory muscles is noted and the patient's condition appears to be worsening, prompt hospital admission should be arranged without time taken to determine arterial blood gases in the office.

A reduction in *single-breath carbon monoxide diffusing capacity* (DLCO) may be the earliest sign of interstitial fibrosis. The test is particularly useful in the evaluation of dyspnea associated with suspected occupational interstitial disease (see Chapter 39 and Chapter 46).

Sometimes, the combination of history, physical examination, chest radiography, and pulmonary function testing is not sufficient to determine the relative contributions of heart disease and lung disease to a case of dyspnea. When findings are equivocal, it may be helpful to order a *cardiac ultrasonographic* examination, a readily available, noninvasive means of determining chamber size, valvular anatomy, and left ventricular function. The ejection fraction will be reduced in the setting of left ventricular dysfunction and relatively preserved in patients with predominantly pulmonary disease. Cardiac ultrasonography in conjunction with *Doppler* study is an excellent means of detecting important treatable causes of pulmonary hypertension, such as tight mitral stenosis (see Chapter 33) and sometimes pulmonary embolization. An old-fashioned but occasionally useful parameter, the *circulation time*, is prolonged by 4 seconds or more beyond the upper limit of normal (16 seconds) in patients with CHF.

The neurotic patient with anxiety-induced dyspnea often benefits from undergoing chest radiography and simple pulmonary function testing; the confirmation of a well-functioning respiratory system may provide some reassurance and lessen concern over bodily symptoms. At times, a *walk with the patient* up and down a few flights of stairs is just as convincing for both physician and patient. Climbing stairs with a patient complaining of dyspnea is also useful if cardiopulmonary disease is suspected, as exercise tolerance can be quantified in terms of the number of flights climbed and the heart and respiratory rates attained.

Evaluation of Pulmonary Hypertension. Finding evidence suggestive of pulmonary hypertension (dyspnea, signs of right-sided heart strain on physical examination and electrocardiogram, prominent main pulmonary artery and hilar vessels in conjunction with decreased peripheral vessels on chest x-ray film) necessitates consideration of its treatable causes, such as recurrent pulmonary embolization, sleep apnea (see Chapter 8), and mitral stenosis (see Chapter 33). Although pulmonary hypertension is typically quite advanced by the time the diagnosis is made, efforts at earlier recognition and identification of treatable causes are imperative if the prognosis is to be improved.

Echocardiography has shown considerable promise in the noninvasive diagnosis of cor pulmonale and pulmonary hypertension and their antecedent conditions. The *perfusion lung scan* has proved to be a safe, noninvasive means of screening for recurrent pulmonary embolization and differentiating it from primary pulmonary hypertensive disease. In primary disease, the scan findings may be normal, or the scan may show a subsegmental or diffuse patchy peripheral distribution of labeled albumin. In secondary disease resulting from recurrent pulmonary emboli, the scan shows multiple segmental or large subsegmental defects. Any segmental or large subsegmental perfusion defect in a patient with pulmonary hypertension is an indication for consideration of *pulmonary angiography*. Ventilation scanning usually does not add enough specificity to the evaluation in this context to obviate the need for angiography.

SYMPTOMATIC MANAGEMENT AND PATIENT EDUCATION

The relief of dyspnea requires attention to *exacerbating factors* in addition to the underlying etiology. Symptomatic management begins with correcting reversible forms of airway obstruction (see Chapter 47 and Chapter 48) and precipitants of left ventricular dysfunction (see Chapter 32). Any concurrent respiratory tract infection requires treatment (see Chapter 52). If a large pleural effusion (see Chapter 43), a severe anemia (see Chapter 82), or an acute situational stress (see Chapter 226) is present, it too should receive prompt attention. Environmental irritants ought to be eliminated (see Chapter 39). All patients with dyspnea should be advised to stop smoking; often, the onset of even mild dyspnea is a sufficient stimulus to quit, especially when combined with the physician's urging (see Chapter 54).

Attention to the underlying cause cannot be overemphasized, whether it is heart disease (see Chapter 30, Chapter 32, and Chapter 33), lung disease (see Chapter 47, Chapter 48, and Chapter 52), a mechanical factor such as massive obesity (see Chapter 233), or an anxiety disorder (see Chapter 226). Dyspneic patients with such disorders greatly appreciate knowing the cause of their discomfort and its prognosis, especially when it differs from what their perception has been.

Many patients with chronic dyspnea request *home oxygen therapy*. Such requests are reasonable if the patient has a condition causing chronic hypoxemia, provided that no evidence of carbon dioxide retention, with its attendant risk of suppression of respiratory drive, is present. Nocturnal oxygen therapy is particularly useful in preventing pulmonary hypertension in patients with chronic hypoxemia, but it must be used with care (see Chapter 47). Patients without significant hypoxemia—even those with chronic emphysema—do not benefit from oxygen therapy.

Selected patients with lung or heart disease may benefit from an *exercise program*; exercise tolerance often improves, although the effect on survival remains unproven (see Chapter 18, Chapter 30, Chapter 31, and Chapter 47). It is important that patients be reminded to note the level of activity that they can tolerate and report any decrease. Precipitants of worsening exercise tolerance should also be monitored.

The use of *anxiolytics* is helpful only in patients whose dyspnea is a manifestation of a severe anxiety disorder. Even then, extreme caution must be exercised in the long-term use of such medications (see Chapter 226). Prescribing tranquilizers for a patient with heart or lung disease who is anxious because of trouble with breathing is more likely to exacerbate the respiratory problem than to help it.

INDICATIONS FOR REFERRAL AND ADMISSION

For patients with underlying heart or lung disease who experience a worsening of their chronic dyspnea, prompt hospital admission should be considered, especially if the change is rapid. It may represent acute left ventricular decompensation, ventilatory failure, or hypoxemia. Acute anxiety can superficially mimic cardiopulmonary decompensation and needs to be ruled out (see above) before hospitalization is authorized. Pulmonary consultation may be helpful in the patient with suspected pulmonary hypertension, both for design of the diagnostic assessment and for selection of the treatment plan if a secondary cause is identified. For the patient found to have pulmonary hypertension secondary to recurrent pulmonary embolization, referral to a surgeon experienced in performing thromboendarterectomy should be considered.

CHAPTER 41 EVALUATION OF CHRONIC COUGH

A chronic cough (one lasting longer than 3 weeks) poses a challenging evaluation problem because the list of causes ranges from the trivial to the life-threatening. Patients present because they fear that "something is wrong"; AIDS, cancer, tuberculosis (TB), and pneumonia lead the list of concerns. Relief from symptoms is another reason for patient presentation. The primary physician must keep in mind more worrisome causes (e.g., bronchogenic carcinoma and TB) and be aware that cough may be an important although atypical presentation of such common conditions as asthma and gastroesophageal reflux. The objective is to conduct a complete yet efficient evaluation that avoids both unnecessary testing and excessive delay.

PATHOPHYSIOLOGY AND CLINICAL PRESENTATION

The physiologic function of cough is to remove foreign substances and mucus from the respiratory tract. It is a three-phase mechanical process that involves a deep inspiration, increasing lung volume, muscular contraction against a closed glottis, and sudden opening of the glottis. The maneuver produces and sustains a high linear air velocity to expel material from the respiratory tree.

Cough is a reflex response that is mediated by the medulla but is subject to voluntary control. The afferent limb may involve receptors in the larynx, respiratory tree, pleura, acoustic duct, nose, sinuses, pharynx, stomach, or diaphragm. The receptors respond to mechanical, inflammatory, or irritant stimuli. The trigeminal, glossopharyngeal, phrenic, and vagus nerves can carry the afferent signal. The efferent limb of the cough reflex involves the recurrent laryngeal, phrenic, and spinal motor nerves, which innervate the respiratory muscles.

The most common cause of chronic cough is *cigarette smoking*, which may trigger the cough reflex by direct bronchial irritation; alternatively, smoking may induce inflammatory changes and the production of mucus, which stimulates a self-propagating productive cough. Chronic bronchitis may ensue. Chronic cough and decreased flow rates have been observed in adolescents after only 3 to 5 years of smoking. Pipe and cigar smoking cause lesser degrees of difficulty.

Environmental Irritants play a major role in the production of cough in patients living in industrialized urban areas. Pollutants that are frequently involved are heavy smog, sulfur dioxide, nitrous oxide, and industrial gases such as ammonia. In Britain, the relationship between air quality and production of cough has been documented. The dusts and particulate matter that are capable of producing pneumoconioses contribute to the problem (see Chapter 39). The excessive drying of normal airway moisture that takes place in centrally heated homes (humidity may fall below 10% unless a humidifier is utilized) can result in a persistent dry cough during the winter months.

Carcinoma of the Lung may present with cough in its early stages, particularly when an endobronchial lesion is present. Often, the cigarette smoker notes a change in the pattern of a chronic "cigarette cough." *Hemoptysis* is noted in about 5% to 10% of early cases. Other clues are localized wheezing and purulent sputum suggestive of obstruction. In later stages, cough is present in conjunction with weight loss, anorexia, and dyspnea. In some instances, a systemic syndrome (e.g., inappropriate secretion of antidiuretic hormone, hypertrophic pulmonary osteoarthropathy, dermatomyositis, peripheral neuropathy) may precede the appearance of tumor.

Asthma. Cough may be the predominant manifestation. Studies of asthmatic patients have emphasized that cough can occur in the absence of wheezing or abnormalities on routine pulmonary function testing. The cough is characteristically worse at night and can be triggered or exacerbated by exposure to environmental irritants, allergens, or cold. Exercise is a common stimulant. In such cases, the bronchorrheal component of asthma predominates, but methacholine or carbachol challenge will often unmask the obstructive manifestations (see Chapter 48).

Inflammation anywhere along the upper or lower respiratory tract is capable of producing cough; receptors capable of transmitting impulses that stimulate cough are believed to be distributed throughout the respiratory system. The greater the inflammatory stimulus, the larger the white cell response and the more purulent the sputum. (The green coloration of very purulent sputum is caused by the degeneration of white cells.) A number of patients experience a dry, persistent cough after an upper respiratory infection; the cough may last more than 8 weeks and is unrelated to postnasal drip or airway hyperreactivity. The pathophysiology of this cough is believed to be related to airway epithelial damage.

Chronic Bronchitis is among the most common causes of chronic cough and sputum production. The condition is defined clinically as the presence of a productive cough that persists for at least 3 months for two consecutive years. A morning cough is often prominent, and bronchospasm is a frequent accompaniment (see Chapter 47). *Bronchiectasis* is also characterized by cough and sputum production, but it differs clinically from bronchitis in that repeated bouts of hemoptysis and pneumonia are more likely to occur. Copious amounts of purulent sputum are often produced. Chronic cough and sputum production commonly persist between episodes of pneumonia. Focal destruction of supporting lung tissue leads to dilation of bronchi and focal findings of rhonchi and wheezes on physical examination. A history of suppurative pneumonia in childhood is sometimes elicited.

Nasal and Otic Problems are often overlooked as sources of chronic cough. *Chronic allergic rhinitis* (see Chapter 222) with resultant postnasal drip ranks as one of the leading causes of chronic cough productive of clear sputum. The nasal mucosa may be edematous and the pharyngeal mucosal "cobblestoned" in appearance. Similarly, *sinusitis* (see Chapter 219) may be associated with a persistent cough and sputum production secondary to excessive retropharyngeal drainage of mucus. It accounts for up to a third of patients with postnasal drip. Sinus tenderness and purulent nasal drainage are typical manifestations, but they may be absent even in the presence of significant mucosal thickening on sinus films. Even impacted cerumen and external otitis have been implicated in stimulating the cough reflex (see Chapter 218).

Interstitial Lung Disease and Extraluminal Compression may stimulate mechanical receptors and result in a nonproductive cough. Fibrotic diseases of the interstitium and pulmonary edema are examples of intrapulmonary causes, and hilar adenopathy, aortic aneurysm, and neoplasm are important extraluminal mass lesions. *Chronic interstitial pulmonary edema* is associated with nocturnal cough because venous return is increased at night, which worsens heart failure (see Chapter 32). When failure is severe, frothy pink or blood-tinged sputum may be noted.

Psychogenic Cough is more prevalent in children but may occur in adults; characteristically, it is nonproductive, occurs at times of emotional stress, and ceases during the night.

Gastroesophageal Reflux sometimes leads to chronic cough. In fact, it is among the three most common causes identified in case series of patients with persistent chronic cough. Mechanisms include (a) esophageal irritation with stimulation of an esophageal–tracheobronchial reflex and (b) nocturnal aspiration of gastric juices. Cough may be the only presenting symptom.

The advent of *angiotensin-converting enzyme inhibitors (ACE,* inhibitors has been associated with an unexpectedly high incidence of dry nocturnal cough, with reports of 10% to 15% of patients being affected. First reported with use of enalapril, the cough has been associated with most long-acting ACE inhibitor preparations. Patients complain of an irritated feeling. The cough usually does not respond to a switch to another ACE inhibitor, although reducing the dose may help. In about 50% of instances, the cough is so annoying that ACE inhibitor therapy must be terminated.

DIFFERENTIAL DIAGNOSIS

The common causes of chronic cough are listed in Table 41.1. In a series of 139 consecutive cases of chronic cough encountered in the community setting, the cause was hyperactive airway disease in 21%, postnasal drip in 19%, postinfectious status in 9%, chronic bronchitis in 4%, gastroesophageal reflux in 4%, and, in a few cases, occupational lung disease and psychiatric illness. In a referral setting study, a postnasal drip syndrome accounted for 41% of cases, asthma for 24%,

esophageal reflux for 21%, and chronic bronchitis for 5%. Cough was the sole presentation of asthma in 28% of asthmatic patients and of reflux in 43% of patients with reflux. In a fourth of cases, more than one cause was identified. Sinusitis accounted for 38% of cases of postnasal drip. Rarer causes of chronic cough include irritation of the pleura, diaphragm, or pericardium. Osteophytes of the cervical spine and pacemaker malfunction have been reported as truly rare causes of cough.

Environmental Irritants
Cigarette smoking (cigar and pipe smoking to a lesser degree)
Pollutants (sulfur dioxide, nitrous oxide, particulate matter)
Dusts (all agents capable of producing pneumoconioses)
Lack of humidity
Lower Respiratory Tract Problems
Lung cancer
Asthma (including variant asthma)
Chronic obstructive lung disease (especially bronchitis)
Interstitial lung disease
Congestive heart failure (chronic interstitial pulmonary edema)
Pneumonitis
Bronchiectasis
Upper Respiratory Tract Problems
Chronic rhinitis
Chronic sinusitis
Disease of the external auditory canal
Pharyngitis
Angiotensin-converting enzyme inhibitors
Extrinsic Compressive Lesions
Adenopathy
Malignancy
Aortic aneurysm
Psychogenic Factors
Gastrointestinal Problems
Reflux esophagitis

Table 41.1. Important Causes of Chronic or Persistent Cough

WORKUP

Although in some cases the cause of a chronic cough is readily apparent, presentations of even the common underlying conditions may be subtle, so that careful investigation is necessary. During the initial workup, the physician should consider serious causes (cancer, TB, heart failure) while checking for the much more common treatable causes (asthma, esophageal reflux, postnasal drip). In a detailed study of workup for chronic cough, history offered the highest yield, with 70% of patients having a true-positive finding; physical examination was second, with 49%, and laboratory studies were third, with an average of 22% of patients having true-positive findings.

History. A careful history and description of the cough, combined with a review of aggravating and alleviating factors and any associated symptoms, can provide useful information, although presentations overlap to a considerable degree. A cough that worsens when the patient lies down suggests postnasal drip, esophageal reflux, bronchiectasis, bronchitis, and heart failure. One accompanied by the production of clear sputum is consistent with a hypersensitivity mechanism, whereas persistent purulence suggests chronic infection (e.g., chronic sinusitis, bronchiectasis, or TB), and bloody sputum raises the specter of cancer, TB, and bronchiectasis (see Chapter 42). Associated symptoms of orthopnea, dyspnea on exertion, and paroxysmal nocturnal dyspnea implicate heart failure; dyspnea may also reflect pneumonitis or asthma. By definition, chronic bronchitis is diagnosed by the history of a chronic productive cough 3 months of the year for two consecutive years. The diagnosis is reinforced by a reduction in coughing with cessation of smoking or avoidance of environmental irritants.

Although postnasal drip, throat clearing, and nasal discharge are characteristic of conditions causing a postnasal drip syndrome, some of these symptoms may also occur in patients with asthma or even esophageal reflux. Chronic throat clearing is also consistent with a psychogenic etiology. Although heartburn or a sour taste in the mouth are reported by most patients whose cough is caused by reflux, as many as 40% of those whose cough proves to be linked to reflux do not report these symptoms. Hoarseness is usually indicative of tracheobronchial disease with laryngeal involvement but may represent a tumor impinging on the recurrent laryngeal nerve.

The history should also detail smoking habits, environmental and occupational exposures, and use of ACE inhibitors and should include a review for previous allergies, asthma, sinusitis, recent respiratory infection, and TB exposure.

Physical Examination should emphasize the upper respiratory tract, chest, and cardiovascular system. The physician needs to examine the skin for cyanosis and clubbing; the pharynx for postnasal discharge, mucosal edema, and tonsillar enlargement; the nose for polyps, discharge, and obstruction; the sinuses for tenderness; and the ears for impacted cerumen or otitis. The trachea is palpated for position and the neck for masses and adenopathy. Auscultation and percussion of the lungs (including the apices) are performed to detect wheezing, crackles, and signs of consolidation or effusion. Generalized wheezing is associated with obstruction from asthma or bronchitis, but localized wheezing may be a sign of tumor. Wheezing only on maximal forced exhalation was found to be neither sensitive nor specific for the diagnosis of variant asthma. During cardiac examination, the physician should evaluate the jugular venous pulse for elevated systemic venous pressure, palpate for chamber enlargement, and listen for a third heart sound, all indicative of heart failure.

Laboratory Studies. Testing can very often be held to a minimum when a careful history is taken and a thorough physical examination performed. For example, when the history is suggestive of chronic rhinitis causing a postnasal drip, one can proceed directly to a diagnostic trial of antihistamines and decongestants without resorting to laboratory testing. Alternatively, a topically active corticosteroid nasal spray may be used for the trial. Similarly, the patient with suspected asthma may be given a diagnostic trial of inhaled steroids (see Chapter 48). In most cases of chronic cough, only a few, well-chosen studies are usually necessary. *Chest radiography* is essential when historical or physical evidence raises the question of carcinoma, pneumonitis, tuberculosis, heart failure, or bronchiectasis. However, the test is overused and not necessary in the nonsmoker who presents with a persistent cough after a recent upper respiratory infection and whose physical examination findings are normal. The chest film may be used to provide reassurance, but a careful explanation and follow-up in 4 to 6 weeks should suffice. The search for pneumonitis should be reserved for patients with a history of disease related to HIV infection or findings suggestive of ongoing infection (persistent production of purulent sputum, night sweats, fever, respiratory rate >25/min, rales, asymmetric respirations, increased vocal fremitus).

Sinus films are usually unnecessary when the history is positive for postnasal drip. In fact, the correlation between the appearance on films and symptoms considered typical of sinusitis may be poor. In rare instances, a patient who has eluded diagnosis may have an occult sinusitis identified by sinus films, with mucosal thickening of more than 6 mm identified on radiographic study. However, routine sinus films are unnecessary.

When purulent sputum is present or an infiltrate has been identified on chest x-ray films, every effort should be made to obtain *sputum for examination*. Patients with a history of producing purulent sputum in conjunction with cough, but who cannot raise sputum at the time of examination, should be instructed to drink a few glasses of water and remain a while to see if sputum can be raised. Inducing sputum by use of a saline spray may also be helpful. A surprisingly common omission in evaluating a cough productive of purulent sputum is failure to obtain and examine the sputum.

An important component of the sputum examination is the *Gram's stain*. In persons at high risk for TB (e.g., recent immigrants, immunocompromised hosts), an *acid-fast stain* for tubercle bacilli is needed. *Culturing* the sputum is also important, especially when TB is a possibility, because the acid-fast examination is not very sensitive and the diagnosis cannot be ruled out with certainty until three early-morning sputum samples have failed to produce growth by 4 to 6 weeks (see Chapter 38 and Chapter 49).

Sputum cytology—in which three early-morning sputum samples are obtained—can be a useful screening test for pulmonary neoplasm (see Chapter 37, Chapter 42, and Chapter 53) when clinical findings raise suspicion (history of smoking, hemoptysis, nodule on chest x-ray film). Pulmonary histiocytes must be demonstrated on each specimen to prove that the sample of pulmonary secretions is adequate. A "negative" test result in the absence of histiocytes is the source of many false-negative readings.

Because sputum cytology is not a particularly sensitive test, it cannot be used to rule out lung cancer. When tumor remains in the differential diagnosis, *fiberoptic bronchoscopy* should be considered. It is also helpful in the evaluation of obstructing lesions and infiltrates that elude diagnosis, as biopsy specimens, washings, and cultures can be taken. However, if the chest radiographic findings are normal and no hemoptysis or history of smoking is present, then the yield from bronchoscopy is very low, and further workup for cancer is unlikely to be productive.

Cough of Obscure Cause. When the cause remains elusive despite the extensive workup described above, *postnasal drip syndrome, variant asthma,* and *gastroesophageal reflux* should be considered. These conditions account for a substantial proportion of hard-to-diagnose cases of chronic cough. As noted earlier, the history and physical examination may not reveal the symptoms and signs typically associated with them. Starting empiric therapy with decongestants, first with

bronchodilators and then histamine$_2$ antagonists, is a reasonable approach. If testing is to be effective and a false-positive diagnosis avoided, a knowledge of test accuracy in identifying these conditions in patients with chronic cough is necessary. Traditional *spirometry* with *bronchodilator administration* was found in one study to have only a 50% positive predictive value in patients with chronic cough because of a high false-positive rate (33%), although its sensitivity was excellent (approaching 100%). *Methacholine challenge* to induce bronchospasm has a similarly high degree of sensitivity but a lower false-positive rate (22%), so that it has a slightly better positive predictive value (60%). Both tests rule out asthma if results are normal. A positive test result needs to be confirmed by a response to bronchodilator therapy.

The diagnosis of esophageal reflux is harder to make in the absence of typical symptoms. Whereas a history of retrosternal burning traveling upward has a predictive value of more than 90% for gastroesophageal reflux, its absence does not rule it out. Prolonged *monitoring* of *esophageal pH* has proved to be the most effective test for esophageal reflux in patients with chronic cough. In the best study of its efficacy, the test had a positive predictive value of more than 95%, with few false-positive and false-negative results. Monitoring of pH was far superior to barium swallow, which had a high false-negative rate. As noted above, an alternative to pH monitoring is a *diagnostic trial of therapy with a histamine$_2$ blocker* (see Chapter 61). However, 1 to 2 months of therapy may be necessary to demonstrate a definitive reduction in cough. Thus, pH monitoring may be the most rapid means of diagnosis of reflux-induced cough. Patients with reflux symptoms do not need radiologic study or endoscopy unless cancer or obstruction is a concern (see Chapter 61).

SYMPTOMATIC THERAPY AND PATIENT EDUCATION

The most effective means of stopping the cough is to identify and treat the underlying cause (see Chapter 47, Chapter 49, Chapter 61, and Chapter 222). An empiric trial of an etiologic therapy can be highly effective in providing a diagnosis as well as relief of symptoms (see above); however, certain etiologic therapies should not be used empirically—especially antibiotics in the absence of proven infection. Symptomatic management is distinguished from empiric etiologic therapy. It is directed at eliminating precipitants and suppressing the cough. The goal is to prevent the complications that may result from prolonged forceful coughing, such as sleeplessness, musculoskeletal pain, rib fractures, pneumothorax, exhaustion, pneumomediastinum, posttussive syncope (see Chapter 24), and rupture of subconjunctival or nasal veins. The occurrence of any of these complications may be a reason for occasionally suppressing a cough that has not been completely diagnosed.

The first priority and simplest manipulation is to remove or reduce irritants. Of paramount importance is *cessation of smoking* and passive exposure to cigarette smoke; this alone eliminated cough in 77% and reduced it in another 17% of patients within a month. Second, an appropriate *humidity* should be maintained. If a humidifier is used, it should be kept clean because it can become colonized with bacteria or fungi and cause infection or hypersensitivity pneumonitis. Third, adequate internal *hydration* should be encouraged, with at least 1,500 mL of fluid consumed daily. These simple measures alone may abolish cough in many patients.

The patient with a chronic cough secondary to established underlying lung disease requires careful education. The patient must be informed that sputum should be expectorated when possible. Patients with chronic bronchitis or bronchiectasis can be taught how to cough with quiet, forceful expirations and how to perform *postural drainage* to promote removal of mucus from the bronchioles. Postural drainage is best performed before meals and at bedtime. *Ipratropium* is sometimes helpful in reducing nighttime cough in the patient with chronic obstructive pulmonary disease (see Chapter 47).

Patients with chronic cough often request *temporary cough suppression* to allow uninterrupted sleep; such suppression is also required when complications of cough arise. A wide variety of agents have been used to treat cough. The most effective are the *narcotic antitussives*, which act centrally to suppress the medullary cough center. Other preparations are expectorants or mucolytic agents, which merely help to mobilize sputum. They can also have a mild placebo effect, although it is not impressive. When cough significantly interferes with sleeping or eating, a narcotic cough suppressant should be used. *Codeine* is the drug of choice. It should be given in relatively small doses of 8 to 15 mg at intervals of 3 to 4 hours, according to the patient's needs. In many instances, a dose before bedtime will suffice. Liquid and tablet preparations are equally effective. If a small dose does not suppress the cough, doses of up to 60 mg every 3 to 4 hours may be tried. It is worth noting that many patients expect to use a syrup for cough suppression; prescribing the drug in syrup form may provide some psychological benefit. Patients for whom a narcotic antitussive is prescribed should be given small quantities and followed closely to ensure that the cough resolves and excessive use does not result. The obvious exception to this precaution is the patient with incurable lung cancer, who should receive the doses necessary to provide relief from the discomfort of persistent cough.

Non-narcotic antitussives lack addiction potential but are not as effective as codeine. The most popular and effective over-the-counter cough suppressant is *dextromethorphan*, which has a mild suppressant effect. Many over-the-counter preparations contain *alcohol, sympathomimetics*, and *antihistamines*. The mucolytic effects of alcohol are minimal. The sympathomimetics are of little use except in patients whose cough derives from chronic vasomotor rhinitis (see Chapter 222). The antihistamines are most useful for patients with allergic upper airway disease (see Chapter 222) and are a helpful adjunct for inducing sleep when taken at bedtime. Some over-the-counter agents dull the peripheral sensory receptors; this is the rationale for putting mild topical anesthetics in sprays, syrups, and cough lozenges. They are of questionable utility.

Expectorants are heavily consumed. More than 60 preparations containing guaifenesin are available; terpin hydrate is another popular expectorant. These agents are often combined with an effective cough suppressant and, as such, produce a beneficial effect, but by themselves they have no proven effect and represent an unnecessary expense. They are given when the patient insists on something for cough but clear indications for cough suppression are lacking, or when the patient believes expectorants will help.

Patients with cough secondary to asthma respond to inhaled topically active *corticosteroids* and *bronchodilators* (see Chapter 48). Topical steroid therapy may also help in allergic rhinitis (see Chapter 222). Patients with persistent cough after a recent respiratory tract infection and no signs of pneumonitis may benefit from a short course of inhaled steroid therapy, which presumably lessens residual inflammatory changes. Time is another effective therapy.

Patients with suspected reflux should respond to a course of antireflux therapy with *antacids* and *histamine$_2$* blockers (see Chapter 61), although, as noted above, the benefits may not become apparent for several weeks.

INDICATIONS FOR REFERRAL

Although endobronchial cancer is feared, it is not a common cause of chronic cough in the absence of other findings, especially in the patient with normal chest radiographic findings. However, the patient without a diagnosis who has risk factors for cancer (smoking, occupational exposure) requires a consultation for consideration of bronchoscopy, particularly if the chest radiographic findings are abnormal. The patient with a normal chest radiographic findings and no risk factors can be followed expectantly without resort to bronchoscopy because the likelihood of a positive study result is small.

CHAPTER 42 EVALUATION OF HEMOPTYSIS

Because of its well-known associations with cancer and tuberculosis, hemoptysis is an alarming symptom for both patient and physician. Hemoptysis is the coughing up of either blood-tinged or grossly bloody sputum. In the office, the primary physician is usually confronted with a patient who has noted sputum streaked with blood. Most patients prove to have inconsequential lesions, but a thorough evaluation is necessary because the seriousness of the underlying cause does not correlate with the amount of blood coughed up.

PATHOPHYSIOLOGY AND CLINICAL PRESENTATION

Inflammation of the tracheobronchial mucosa accounts for many cases of hemoptysis. Minor mucosal erosions can result from *upper respiratory infections* and *bronchitis*; blood-streaked sputum is often noted, especially if coughing has been vigorous and prolonged. Patients with *bronchiectasis* are more subject to recurrent episodes of grossly bloody sputum because necrosis of the bronchial mucosa can be quite severe. Up to 50% of patients with bronchiectasis experience hemoptysis. In the United States, hemoptysis occurring with *tuberculosis* (TB) is usually caused by mucosal ulceration, although potentially fatal bleeding can occur when a blood vessel adjacent to a cavitary lesion ruptures. About 10% to 15% of patients with TB report some form of hemoptysis; most of these episodes are minor and involve sputum tinged with small amounts of blood. Endobronchial inflammatory injury from granuloma formation is the mechanism of hemoptysis associated with *sarcoidosis*;small amounts of blood-streaked sputum are occasionally noted.

Mucosal injury can also be a consequence of *bronchogenic carcinoma*. Disruption of endobronchial tissue may be minor and cause little more than minimal hemoptysis from time to time; hemorrhage is rare. Between 35% and 55% of patients with proven bronchogenic carcinoma report at least one episode of hemoptysis during the course of their illness; it is the presenting symptom in about 10% of cases. The amount of bleeding can vary considerably and need not be impressive. For example, in one study, malignancy was the cause in 25% of patients with minimal hemoptysis. However, most patients have a positive smoking history and abnormal chest radiographic findings.

Carcinoma metastatic to the lung rarely results in hemoptysis. *Bronchial adenomas* are quite vascular, and they are commonly central and endobronchial in location; as a consequence, they frequently bleed, and recurrent episodes of hemoptysis are reported in about half of cases.

Injury to the pulmonary vasculature is an important source of hemoptysis. *Lung abscess* may result in damage to adjacent vessels and frequently presents with bloody and purulent sputum. *Necrotizing pneumonias*, such as those produced by *Klebsiella*, can cause substantial vascular disruption; 25% to 50% of patients cough up tenacious, bloody sputum referred to as "currant jelly." *Aspergillomas* are also capable of causing vascular injury; hemoptysis is the most common symptom of the condition. The patient with an aspergilloma is typically a compromised host with prior cavitary disease from TB, bronchiectasis, or the like. *Pulmonary infarction* secondary to embolization is characterized by the sudden onset of pleuritic pain in conjunction with hemoptysis; embolization without infarction does not cause hemoptysis. Pulmonary contusion resulting from blunt *chest trauma* may present with hemoptysis following a nonpenetrating blow to the thorax.

Marked elevations in pulmonary capillary pressure can cause vascular injury and extravasation of red cells. The pink, frothy sputum of *pulmonary edema* is a manifestation of this process. More grossly bloody sputum sometimes occurs in severe mitral stenosis when a dilated pulmonary–bronchial venous connection ruptures. Vasculitic injury is responsible for the hemoptysis found in *Wegener's granulomatosis* and *Goodpasture's syndrome*. Hematuria often accompanies both conditions. Hereditary vascular malformations are subject to recurrent bleeding. *Arteriovenous malformations* may be accompanied by an audible bruit on auscultation of the lung. In *hereditary hemorrhagic telangiectasia*, a family history of bleeding problems is often present, or prior episodes of bleeding from multiple sites have been noted; telangiectases may be visible in the buccal cavity and on the skin. Bleeding into the interstitium characterizes *idiopathic pulmonary hemosiderosis*. This rare disease, uncommon in adults, is manifested by diffuse interstitial infiltrates, anemia, and hemoptysis.

Hemoptysis may be the first sign of a *bleeding disorder* or *excessive anticoagulant therapy*; however, an underlying bronchopulmonary lesion is usually also present.

DIFFERENTIAL DIAGNOSIS

Acute and chronic bronchitis are the most common causes, followed by bronchogenic carcinoma, TB, pneumonia, and bronchiectasis. Most prevalence figures are obtained from chest clinics and inpatient units serving preselected populations of patients with either abnormal chest radiographic findings or unexplained hemoptysis; therefore, they cannot be readily extrapolated to the primary care setting. In everyday office practice, the nasal mucosa and oropharynx are more often the source of blood-tinged sputum than is the lower respiratory tract. The high incidence of pulmonary infections associated with HIV, the more widespread use of fiberoptic bronchoscopy, and increases in cigarette smoking and lung cancer in women also must be kept in mind when data from published clinical series that are more than 10 years old are being interpreted. In a fiberoptic bronchoscopy study performed in a general hospital setting that included both inpatients and outpatients, bronchitis accounted for 37% of cases, bronchogenic carcinoma for 19%, TB for 7%, and bronchiectasis for only 1%. The briskness of bleeding did not correlate with the cause. In a review of studies comprising a total of nearly 1,000 patients with hemoptysis and normal chest radiographic findings, lung cancer was eventually diagnosed in 5.4%. Most cancers that cause hemoptysis are endobronchial, but about 15% are parenchymal. The more common and important causes of hemoptysis are listed in Table 42.1.

Gross Hemoptysis
Tuberculosis (with cavitary disease)
Bronchiectasis
Bronchial adenoma
Bronchogenic carcinoma (uncommon)
Aspergilloma
Necrotizing pneumonia
Lung abscess
Pulmonary contusion
Arteriovenous malformation
Hereditary hemorrhagic telangiectasia
Bleeding disorder or excessive anticoagulant therapy
Mitral stenosis (with rupture of a bronchial vessel)
Immune alveolar disease
Blood-Streaked Sputum
Any of the causes of gross hemoptysis
Upper respiratory tract infection
Chronic bronchitis
Sarcoidosis
Bronchogenic carcinoma
Tuberculosis
Pulmonary infarction
Pulmonary edema
Mitral stenosis
Idiopathic pulmonary hemosiderosis
Immune alveolar disease

Table 42.1. Important Causes of Hemoptysis

WORKUP

As noted earlier, most cases of blood-tinged sputum encountered in the primary care setting, especially during the winter, originate in the upper respiratory tract. Such cases do not require further investigation. To avoid unnecessary workup for a pulmonary cause, the history and physical examination should first focus on the nasal and oropharyngeal mucosa. Only in the absence of an upper respiratory source of bleeding need further workup proceed in the manner detailed in the following paragraphs.

History. Evaluation of the patient with a suspected lower respiratory source of hemoptysis should begin with consideration of the epidemiology of the serious underlying causes. Concern about pulmonary neoplasm should be highest in the older man with a long history of heavy smoking or asbestos exposure. The elderly patient with evidence of old disease on chest x-ray films should be presumed to have reactivated TB infection. The adolescent with hemoptysis may have a new

infection resulting from recent TB exposure. The compromised host with previous cavitary disease is at risk for an aspergilloma.

The patient's description of the sputum associated with hemoptysis can be of some diagnostic help. Pink sputum is suggestive of pulmonary edematous fluid; putrid sputum is indicative of a lung abscess; material resembling currant jelly points to a necrotizing pneumonia; copious amounts of purulent sputum mixed with blood are consistent with bronchiectasis. The commonly described blood-streaked sputum is nonspecific.

The patient should be asked about previous episodes of bleeding, any family history of hemoptysis, hematuria, concurrent pleuritic chest pain, known heart murmur or history of rheumatic fever, lymph node enlargement, blunt chest trauma, symptoms of heart failure (see Chapter 32), and use of anticoagulant drugs. Determining the amount of blood produced is not particularly helpful for diagnostic purposes. As noted above, it is important to be certain that the patient has no history of a coexisting nasopharyngeal problem or a source of gastrointestinal bleeding that may be mistaken for true hemoptysis.

Physical Examination is directed at detecting nonpulmonary sources of bleeding in addition to evidence of chest and systemic disease. The vital signs should be checked for fever and tachypnea, the skin for ecchymoses and telangiectases, and the nails for clubbing. Clubbing is associated with neoplasm, bronchiectasis, lung abscess, and other severe pulmonary disorders (see Chapter 45). Nodes are examined for enlargement, which is suggestive of sarcoidosis, TB, and malignancy (see Chapter 12 and Chapter 51). The neck is noted for jugular venous distention, consistent with heart failure and severe mitral disease. Examination of the chest should include a search for bruits, signs of consolidation, wheezes, crackles, and chest wall contusion.

The history and physical findings can be used to determine the pace at which workup should proceed, in addition to the selection and sequence of laboratory tests. Patients with minimal hemoptysis may be evaluated on an outpatient basis as long as they are given explicit advice to return immediately if severe bleeding ensues. The patient with a suspected bleeding diathesis should not be sent home.

Laboratory Studies. *Chest radiography* is essential to assessment. As alluded to earlier, the vast majority of patients with hemoptysis resulting from bronchogenic carcinoma have abnormal chest radiographic findings. In addition to uncovering a mass lesion, chest films may reveal an abscess, infiltrate, interstitial change (see Chapter 46), hilar adenopathy, signs of congestive failure (see Chapter 32), or evidence of significant mitral stenosis (see Chapter 33). Less common radiologic findings include peribronchial cuffing, indicative of bronchiectasis, and a crescentic radiolucency surrounding a coin lesion, characteristic of an aspergilloma. However, in most instances, the appearance of the chest film is normal, and consideration of further study is warranted.

A *sputum Gram's stain* is essential if the sputum appears grossly purulent or the patient is febrile. An *acid-fast stain* for tubercle bacilli is also essential, not only for diagnosis but for a rough assessment of infectivity (see Chapter 49). The sensitivity of the acid-fast smear depends on the diligence with which the search for pathogenic organisms is made. In one series, only 20% of culture-positive samples were identified in advance by acid-fast smear. It should be noted that despite the very high specificity of a positive smear, its predictive value may be as low as 50% when the sputum specimens of low-risk patients are examined. A *tuberculin skin test* should be performed if the patient's PPD (purified protein derivative) reactivity status is not known. However, approximately 7% of all adults (25% of adults over age 50) will have positive reactions (see Chapter 38 and Chapter 49).

Sputum cytologies should be obtained in all patients without a clear diagnosis. It used to be thought that the sensitivity of a single sputum cytology examination was about 70% in the detection of squamous cell lesions, and that three consecutive cytologic examinations increased the sensitivity to 90%. However, data from the large screening trials suggest a lower sensitivity, at least for early cancers. The specificity of sputum cytology is greater than 99% when the specimen is reviewed by an experienced cytopathologist.

Fiberoptic bronchoscopy can be extremely helpful for diagnosis when used thoughtfully. Its most common indication is to exclude the possibility of tumor. However, the test should not be viewed as a routine part of the evaluation for hemoptysis because the yield is extremely low in situations in which the risk for malignancy is very low (e.g., a nonsmoker under the age of 50 with normal chest radiographic findings). Bronchoscopy enhances the sensitivity of cytologic and bacteriologic studies when washings for specimens are obtained during the procedure, and the test has proved capable of detecting otherwise occult endobronchial cancers in patients at increased risk for lung malignancy (e.g., older than 50 years, male gender, history of smoking), even if the chest radiographic findings are nonlocalizing. Patients with a high-risk profile, "positive" or "suspect" cytology, or a radiologic abnormality are appropriate candidates for bronchoscopy. Subjecting low-risk patients to bronchoscopic examination is wasteful and unlikely to affect management or outcome. Moreover, the cost and morbidity associated with bronchoscopy are not trivial.

Serious complications are rare with fiberoptic bronchoscopy, but they do occur. In a review of 48,000 procedures, fewer than 100 life-threatening cardiovascular or respiratory complications were reported, most often in older persons with chronic obstructive pulmonary disease and coronary disease. Hypoxia occurs commonly following bronchoscopy.

Bronchoscopy is mandatory in all patients with massive hemoptysis who are being seriously considered for surgery, to localize the site of bleeding. Rigid bronchoscopy is preferred in this situation.

Chest computed tomography (CT) may better define a suspect lesion seen on chest x-ray films and may be indicated for some patients with normal chest radiographic findings to increase the sensitivity for parenchymal lesions. CT will also identify endobronchial tumors with a sensitivity of approximately 80%. However, the specificity of CT-visualized endobronchial lesions for cancer is somewhat limited (approximately 65%).

Parameters of bleeding, such as the prothrombin time (PT), partial thromboplastin time (PTT), platelet count, and bleeding time, should be determined if more than one site of bleeding is noted.

Cryptogenic Hemoptysis is hemoptysis occurring in patients with normal or nonlocalizing chest radiographic findings and nondiagnostic findings on fiberoptic bronchoscopy. What to do in such a situation can be perplexing. The prognosis appears to be favorable, with more than 90% of these patients experiencing resolution of their hemoptysis by 6 months and no cases of cancer, active TB, or other serious pathology emerging after the initial evaluation. A careful history and physical examination, in combination with chest radiography and the proper use of bronchoscopy, appear to exclude cancer, active TB, and other must-not-miss diseases effectively, so that repeated bronchoscopy, pulmonary angiography, CT, and bronchography are of little use in these patients. In one study, bronchial inflammation (bronchitis) was the most common cause, followed by the sequelae of old tuberculous disease.

A.G.M.

INDICATIONS FOR REFERRAL AND ADMISSION

Patients with hemoptysis who are believed to be at increased risk for an underlying malignancy (abnormal chest radiographic findings, male sex, older than 50, smoking history) are candidates for bronchoscopy. Patients with brisk bleeding require urgent hospitalization.

CHAPTER 43 EVALUATION OF PLEURAL EFFUSIONS

Most pleural effusions encountered in the office are discovered as incidental findings, and they often pose a diagnostic challenge because the cause is frequently unclear. Of major concern are the possibilities of tumor and infection. Outpatient evaluation of a pleural effusion requires that the physician be skilled in performing a diagnostic thoracentesis in the office and in differentiating a transudate from an exudate. The primary physician should be able to carry out the initial evaluation of a pleural effusion safely in the ambulatory setting, provided the patient's respiratory status is satisfactory and no evidence of serious acute illness is present.

PATHOPHYSIOLOGY AND CLINICAL PRESENTATION

The pleural cavity normally contains a small volume of serous fluid that serves as a lubricant. About 17 mL of such fluid is formed each day by transudation from the parietal pleural surface and is reabsorbed predominantly by the visceral pleura through lymphatic stomata into the lymphatic system. When the transudation of fluid is excessive or an exudative process involving the pleural surfaces is present, an effusion forms. Once more than 200 mL is formed, the effusion becomes visible radiographically. Effusions are classified pathophysiologically as transudates or exudates. Clinically, the distinction is based on pleural fluid protein and lactate dehydrogenase (LDH) concentrations. An effusion is *transudative* if any two of the following three criteria are met: (a) the ratio of *pleural fluid protein to serum protein is less than 0.5,* (b) *the ratio of pleural fluid LDH concentration to serum LDH concentration is less than 0.6,* and (c) *the pleural fluid LDH concentration is less than two-thirds the upper limit of normal for the serum LDH concentration*. If these ratios or levels are exceeded, the effusion is exudative.

Transudates

Increased hydrostatic pressure in the pulmonary interstitium and decreased colloid oncotic pressure produce transudates. Increased hydrostatic pressure below the diaphragm, as occurs in ascites or peritoneal dialysis, can also result in a transudative pleural effusion. Because transudates are rarely associated with pleural inflammation, they are not usually accompanied by pleuritic pain, but they may lead to shortness of breath if they are large enough to interfere with respiratory mechanics. They may be unilateral but are often bilateral. Physical examination of the lung reveals dullness and diminished breath sounds. If the effusion has produced some atelectasis, bronchial breath sounds and increased vocal fremitus above the effusion may be present. Most transudates have a protein concentration of less than 3.0 g/100 mL, but chronic transudates may show higher concentrations and mimic an exudative process.

Congestive Heart Failure is among the most common causes of transudative effusions. Left-sided heart failure increases the pulmonary capillary pressure (see Chapter 32), which forces excess fluid into the interstitium. Right ventricular failure contributes by raising central venous pressure, which elevates the hydrostatic force in the capillaries of the parietal pleura and diminishes fluid reabsorption. Most effusions associated with congestive failure are *bilateral*, but at times an *isolated right-sided* effusion is seen; isolated left-sided effusions resulting from congestive failure are rare. The reason for the right-sided preference is unknown. Symptoms and signs of congestive failure (see Chapter 32) are usually evident. In more than 85% of effusions resulting from heart failure, the protein concentration is less than 3.0 g/100 mL. The concentration may be greater if the effusion is chronic or the patient has recently been undergoing a brisk diuresis. The pleural fluid is usually clear, but it may be bloody with red cell counts in excess of 5,000/mL.

Pulmonary Embolization is accompanied by pleural effusion in up to 50% of cases. The effusions are usually small and do not depend on the occurrence of pulmonary infarction. Cell count, differential, and protein concentration vary considerably. The transudative effusion associated with a pulmonary embolus may result from localized interstitial edema. The effusions that result from infarction are more likely to be bloody. Bilateral effusions can be seen when emboli affect both lungs. A small effusion on chest x-ray films in a patient with pleuritic chest pain can be an important clue (see Chapter 20).

Other Causes of Transudation. In the *nephrotic syndrome*, a similar but more generalized interstitial edema may ensue and lead to effusion. *Overexpanded extracellular volume* as a consequence of severe *hypoalbuminemia* or *salt retention* can produce a transudative effusion, but edematous fluid first collects in parts of the body where hydrostatic pressures are greatest (e.g., lower extremities) before fluid appears in the pleural space. Cardiomegaly may be in evidence, but overt signs of congestive failure are usually absent. Generalized edema is rare before the serum albumin level falls below 2.0 to 2.5 g/100 mL.

Intraabdominal diseases are occasionally responsible for transudative effusions. A *right-sided* pleural effusion develops in between 5% and 10% of patients with *ascites* resulting from *cirrhosis*; the composition of the effusion resembles that of the ascitic fluid. In cases of *pancreatitis* or a *subphrenic abscess*, a "*sympathetic effusion*" with the characteristics of a transudate sometimes forms; it soon changes into an exudate.

Pleural effusions are common after *coronary bypass graft surgery* and do not imply serious pathology. The same holds for the postpartum patient. Transudates may form in the setting of *pericardial disease, myxedema*, and *sarcoidosis*; the mechanism(s) remain unknown.

Exudates

Exudates result from inflammatory or infiltrative disease of the pleura and its adjacent structures; damage occurs to capillary membranes, and protein-rich material accumulates in the pleural space. Obstruction to lymphatic flow can also produce an exudative effusion. Because most exudates form as a consequence of pleural injury, they are often accompanied by pleuritic chest pain, especially in the acute phase, when a friction rub may be heard before much fluid accumulates. The fluid is initially free-flowing but may become walled off and loculated when a marked inflammatory response develops. The protein content is usually greater than 3.0 g/100 mL. The fluid is typically deep yellow or cloudy in appearance. The leukocyte count is often above 1,000/mL; a count above 10,000/mL is suggestive of an empyema, particularly if most of the cells are neutrophils.

Neoplasms are often responsible for the development of effusions. Most pleural fluid accumulations caused by malignancies have the characteristics of exudates, although at times the protein concentration is less than 3.0 g/100 mL. Mechanisms of exudate formation include pleural metastasis with increased permeability and obstruction of lymphatic outflow. The formation of a malignant effusion is often a poor prognostic sign, particularly if the pH of the fluid is less than 7.3 and the glucose level is less than 60 mg/dL, which indicates extensive pleural involvement with tumor.

Bronchogenic carcinoma is the tumor most frequently associated with a pleural effusion. Fluid collects in most instances as a direct result of pleural invasion; unilateral effusions are the rule. Patients report dyspnea when the effusion is large and occasionally complain of pleuritic chest pain. The pleural fluid is usually clear and straw-colored, but it may be bloody and the glucose level may be very low. The white cell count is typically around 2,500/mL, with most cells being lymphocytes. Malignant cells are found in about 60% of instances. Unfortunately, the disease and its effusions are progressive; thoracentesis is followed by rapid reaccumulation.

Pleural effusions caused by *metastatic carcinoma* are more likely to be bilateral than are those associated with bronchogenic carcinoma because they occur as a consequence of lymphatic obstruction or diffuse seeding of the pleura. When effusions are caused by seeding, results of cytologic examination of the pleural fluid are positive in up to 90% of cases. Carcinoma of *the breast* is the leading metastatic tumor producing pleural effusions, accounting for 25% of all malignant effusions. The characteristics of the pleural fluid are similar to those of effusions caused by bronchogenic carcinoma. *Lymphoma* is another major cause of malignant bilateral pleural effusions, responsible for up to 20% of cases. The formation of a large effusion is a sign of advanced disease; evidence of pleural, parenchymal, and lymph node involvement is often present by the time a significant effusion appears. The pleural fluid may be a transudate or an exudate; most of the cells are lymphocytes. Cough and dyspnea accompany parenchymal involvement, but pleuritic pain is rare.

Mesotheliomas have become an increasingly important source of effusion as the incidence of *asbestos exposure* has increased. Only malignant mesotheliomas produce important pleural fluid accumulations. The latent period for mesothelioma formation ranges from 20 to 40 years after asbestos exposure; the degree of exposure may appear inconsequential (see Chapter 39). Chest pain, cough, and shortness of breath result from extensive pleural disease and large effusions. The fluid may be bloody and often contains malignant cells, but they are sometimes hard to identify cytologically, so that chromosomal analysis is necessary. The fluid

may be high in *hyaluronic acid*. Because the tumor is only locally invasive, no signs of extrathoracic disease are present.

Impressive effusions can form as a consequence of *benign ovarian neoplasms (Meigs' syndrome)*. The tumor produces ascites, and fluid tracks across the diaphragm and into the thorax. The effusion is typically on the right but may be left-sided or even bilateral; it is exudative in quality, free of malignant cells, and similar in composition to the ascitic fluid from which it derives. Removal of the ovarian tumor results in prompt resolution of the effusion.

Infections are an important source of exudative pleural effusions, but effusions are uncommonly associated with the *acute bacterial pneumonias* encountered in ambulatory patients. For example, an effusion develops in only about 5% of patients with *pneumococcal pneumonia*, and it is usually small and transient. Such effusions are termed *parapneumonic* to imply that bacteria need not have entered the pleural space to cause the effusion. The term *empyema* is reserved for cases in which organisms are recovered from the pleural fluid, either by Gram's stain or culture. Empyema is a rare but worrisome event, seen in fewer than 1% of the cases of pneumococcal pneumonia that present in the outpatient setting; most cases occur when proper antibiotic therapy is delayed. Cough, sputum production, fever, chills, and pleuritic pain may be prominent. Early on, the pleural fluid appears serous and may be sterile, but it quickly turns purulent and positive for organisms when empyema develops. In some instances, the pleural fluid offers the only opportunity for recovery of the causative organism. Characteristics of the pleural empyema fluid include a white cell count in excess of 5,000 to 10,000/mL, with neutrophils predominating. The concentration of glucose is typically less than 20 mg/100 mL. Pleural scarring may be substantial if the empyema fluid is allowed to remain.

Viral pneumonitis and *mycoplasmal pneumonia* are sometimes associated with pleural effusions in the course of illness, but the effusions are small, transient, and of little consequence (see Chapter 52).

The effusion caused by postprimary tuberculosis (TB) represents a delayed hypersensitivity reaction to spillage of organisms into the pleural space during early bacteremia or subclinical parenchymal disease (see Chapter 49). The effusion is almost always unilateral. The patient may be relatively free of symptoms or exhibit lethargy, fever, and weight loss; at times, the clinical picture is dominated by acute onset of pleuritic pain and fever. Cough and sputum are conspicuously absent. The chest radiograph may show little more than an isolated effusion, but the result of an intermediate-strength tuberculin skin test is usually positive. The pleural fluid has the qualities of an exudate; the glucose concentration may be low. The white cell count averages 1,000 to 2,000/mL; lymphocytes predominate; mesothelial cells are scarce (<2%). Neutrophils may be seen early in the course of the illness. Organisms are rarely found on acid-fast stain of the fluid and can be cultured from the fluid in only 25% of cases. Most of these effusions resolve spontaneously within a few months and leave little or no residual; however, symptomatic pulmonary parenchymal involvement eventually develops in more than half of such patients (see Chapter 47).

Rheumatoid Diseases, particularly systemic lupus erythematosus, can produce transient pleuropericardial inflammation during their course, usually after other signs and symptoms have appeared. There may be a brief period of pleuritic pain. On occasion, pleural involvement may be the initial clinical presentation of the disease. In most instances, the pleural fluid has the characteristics of a exudate and may demonstrate low glucose and serum complement levels.

Rheumatoid arthritis is much less likely to produce a pleural effusion than is lupus, but the fluid often persists. Fewer than 5% of patients experience pleuropericardial involvement; these people usually have a history of extraarticular manifestations and joint symptoms. Occasionally, the effusion is the first manifestation of rheumatoid disease. The effusion is an exudate, with a predominance of lymphocytes and a very low (<20 mg/100 mL) glucose concentration. Although the fluid may contain rheumatoid factor, its presence is not unique to this disease.

Intraabdominal Pathology can lead to the production of an exudative pleural effusion, particularly when recent abdominal surgery, intestinal perforation, or hepatobiliary disease is complicated by development of a *subdiaphragmatic abscess*. In addition to gastrointestinal symptoms, pleuritic pain, fever, weight loss, and malaise may be present. Often, the symptoms are nonspecific, so that patients put off the decision to seek medical help. The diaphragm on the involved side (which is the right in two thirds of cases) is elevated and moves poorly on fluoroscopy. A pathognomonic subdiaphragmatic air–fluid level may be present on chest film. The pleural fluid is usually sterile, although it may have a high leukocyte count. If the diaphragm has been perforated, an empyema can form. The pleural effusion associated with *pancreatitis* may begin as a transudate but usually becomes exudative. The effusions are most often on the left but may be bilateral or right-sided. The fluid characteristically has a *high amylase* concentration and is blood-tinged in one third of cases.

DIFFERENTIAL DIAGNOSIS

Although the causes of pleural effusion can be conveniently divided into those conditions that produce transudates and those that result in exudates (see Table 43.1), it is important to keep in mind that a number of conditions can cause both. Insuch conditions, the initial effusion is transudative but turns exudative as the disease process continues. Chronic congestive heart failure is the most frequently encountered such condition in the ambulatory population. Neoplasms account for the majority of cases seen in referral populations. In a series reported from the Mayo Clinic, bronchogenic carcinoma was the leading cause of malignant pleural effusion, accounting for 30% of cases, followed by breast carcinoma (25%) and lymphoma (20%). Infection is the third most common cause of accumulation of fluid in the pleural space, with TB still accounting for a substantial proportion of effusions subjected to full evaluation. Bloody effusions are most often caused by neoplasms but are also seen in congestive heart failure, pulmonary embolization with infarction, TB, and pancreatitis. About 15% of effusions remain unexplained; most idiopathic effusions are exudates.

Transudates
 Congestive heart failure
 Hypoalbuminemia, severe
 Salt-retention syndromes
 Ascites secondary to cirrhosis
 Early phases of a sympathetic effusion
 Neoplasm (on occasion)
 Peritoneal dialysis
 Postpartum
 Cardiac bypass graft surgery
Exudates
 Neoplasms
  Bronchogenic carcinoma
  Breast cancer
  Lymphoma
  Mesothelioma
  Meigs' syndrome
 Infections
  Tuberculosis (and atypical myobacteria in AIDS patients)
  Bacterial pneumonia (including empyema)
  Viral pneumonitis
  Mycoplasmal pneumonia
  Pneumocystis pneumonia
 Pulmonary embolization
 Connective tissue disease
  Rheumatoid arthritis
  Systemic lupus erythematosus
 Intraabdominal disease
  Subphrenic abscess
  Pancreatitis
 Idiopathic

Table 43.1. Important Causes of Pleural Effusions

Among AIDS patients, infections cause more than two thirds of effusions, with bacterial, mycobacterial, and *Pneumocystis* pneumonias accounting for most. Hypoalbuminemia is the leading noninfectious cause of effusion among patients with advanced HIV disease.

WORKUP

The diagnosis of pleural effusion is usually suggested by the findings of dullness and diminished breath sounds upward from the lung base and confirmed by chest radiography. The first task after identifying the effusion is to assess the degree, if any, of respiratory compromise associated with the effusion. The vital signs should be checked for tachypnea and tachycardia, the skin should be checked for cyanosis, and the chest should be checked for use of accessory muscles of respiration. Patients with objective evidence of substantial respiratory compromise should be admitted to the hospital for further workup. Those who are comfortable can be assessed on an outpatient basis. Although radiologic features may suggest a diagnosis, the history and physical examination complemented by examination of the pleural fluid are essential to an accurate assessment.

History. The patient should be asked about the presence of fever, cough, sputum production, chest pain, dyspnea, edema, and abdominal pain; prior history of malignant, hepatic, renal, or HIV disease; exposure to TB or asbestos; and symptoms of rheumatoid disease (see Chapter 146). Cough, fever, and sputum production in conjunction with pleuritic chest pain suggest pneumonitis with pleural involvement. Pleuritic pain is also consistent with embolization, malignancy, and pleural inflammation with adjacent pericarditis resulting from connective tissue disease. Dyspnea may be induced by the effusion alone, but the symptom is indicative of congestive heart failure when accompanied by orthopnea and paroxysmal nocturnal dyspnea. A history of peripheral edema raises the possibilities of hypoalbuminemia, volume overload, and congestive failure. A history of alcohol abuse, recent abdominal surgery, or abdominal pain or distention points to a source

below the diaphragm.

Physical Examination. In addition to the assessment for respiratory compromise, the vital signs are checked for fever and weight change. The integument is inspected for petechiae, purpura, spider angiomata, jaundice, clubbing (see Chapter 45), manifestations of rheumatoid disease (see Chapter 146), and rashes. The neck is noted for jugular venous distention and tracheal deviation, the lymph nodes are checked for enlargement, and the breasts are checked for masses. On lung examination, the level of the effusion and extent of involvement are determined. It is worth noting any compression of adjacent lung, suggested by egophony and bronchial breath sounds heard above the effusion. A pleural friction rub may be audible but is usually lacking when a considerable amount of fluid has accumulated. The heart should be checked for a third sound, indicative of pump failure, and a three-component friction rub, suggestive of pericarditis. The abdomen is examined for signs of ascites, organomegaly, focal tenderness, and peritonitis (see Chapter 58). A pelvic examination is performed to rule out the presence of an ovarian mass, and the extremities are noted for edema, calf tenderness, and signs of joint inflammation.

Laboratory Evaluation. The centerpieces of the laboratory workup are the chest radiograph and pleural fluid analysis. The *chest radiograph* should be studied for pleura-based densities, infiltrates, signs of congestive heart failure (see Chapter 32), hilar adenopathy, coin lesions, and loculation of fluid (detection of which requires lateral decubitus views). The elevation of a hemidiaphragm and the presence of a subdiaphragmatic air–fluid level are important radiologic signs of a subphrenic abscess. The location of the effusion may be helpful. Among transudative effusions caused by cardiac failure, unilateral effusions tend to be right-sided, and bilateral effusions usually are asymmetric with more fluid on the right side. On the other hand, effusions associated with pericarditis or pancreatitis tend to be left-sided.

When a cause is not readily evident from the history, physical examination, and chest film, then a *diagnostic thoracentesis* is indicated. In some instances, of course, a thoracentesis neednot be performed on the first visit. Such instances include the afebrile patient with clinical evidence of congestive heart failure, the postpartum woman who is otherwise well, the patient who has undergone bypass graft surgery, and the young patient with a small effusion in conjunction with a viral or mycoplasmal pneumonia. These patients can be followed expectantly with repeated chest films; failure of the effusion to clear with resolution of the presumptive cause is an indication for thoracentesis.

A diagnostic thoracentesis can be performed safely and comfortably in the office on patients who have free-flowing effusions confirmed by lateral decubitus films. Ultrasonography has been increasingly used to help guide thoracentesis, but it has not been shown to enhance the safety or yield of the procedure except in situations of very small effusions. Thoracentesis for loculated effusions is more difficult and is associated with a greater risk for pneumothorax; it is best not to tap such effusions in the office.

A few pitfalls in thoracentesis technique must be avoided. A common error is for the examiner to enter the chest too far below the meniscus of the effusion, thereby risking penetration of the diaphragm or entry into the diaphragmatic sulcus, which is likely to be sealed off from the effusion by lung tissue. To define the proper entry point, the lung fields should be percussed and auscultated to determine the upper border of the effusion. Because pleural fluid rises in a meniscus where it comes in contact with the parietal pleura, the needle should be passed into the chest one interspace *above* the upper border of the effusion as determined by examination. A few millimeters of penetration into the pleural space at the level of the meniscus allows full drainage without the complications of a low entry. Injury to the neurovascular bundle along the inferior surface of the rib is avoided by aiming the needle just above the *superior* margin of the rib, which is accomplished by "walking the needle" over the anesthetized surface of the rib. Pneumothorax is minimized by withdrawing or changing the needle position as soon as air bubbles begin to appear or one feels the visceral pleura contacting the needle tip; the onset of coughing is common at this stage. The patient should be advised to resist the impulse to cough because during coughing the lung may become impaled on the needle. Use of a large-bore Intracath (14 or 16 gauge) minimizes the risk for needle injury to the lung. A chest x-ray film should be obtained after thoracentesis to be sure that a significant pneumothorax has not been produced.

The laboratory analysis of pleural fluid should begin with determination of the *protein* and *LDH concentrations.* A simultaneous serum sample should also be sent for protein and LDH levels. As noted earlier, the three most useful findings to distinguish a pleural exudate from a transudate are a *pleural fluid LDH level above 200 U*, a *pleural-to-serum LDH ratio above 0.6*, and a *pleural-to-serum protein ratio above 0.5.* Fulfillment of any two of these three criteria has a sensitivity in excess of 90% and a specificity of 99%. If this first step indicates that the effusion is a transudate, no further laboratory analysis of the fluid is indicated. In fact, because of the poor specificity of white and red blood cell counts, glucose and amylase levels, and even bacterial cultures (as a consequence of contamination), such tests performed on transudates may be misleading.

If any of the criteria for an exudate are met, the laboratory analysis should include a *differential cell count, bacterial culture* (including cultures for anaerobes and mycobacteria), and *cytologic examination.* Although a high white blood cell count may indicate infection, it is a nonspecific finding. A lymphocyte predominance is suggestive of TB or malignancy but does not help in distinguishing between the two. The sensitivity of cytologic examination depends on the mechanism of the malignant effusion and extent of disease; it may be as high as 95% in advanced disease with extensive pleural involvement, but as low as 50% in early disease. However, a positive result of cytology are highly specific when reported by an experienced pathologist.

In certain circumstances, other tests may be useful. A *low pleural fluid glucose level* (<60 mg/dL) is associated with TB, other serious infections, and advanced pleural involvement with malignancy. A *low pleural fluid pH* (<7.30) has a similar meaning. Conversely, when the pleural fluid pH is low, the result of the pleural fluid cytologic examination is likely to be positive if an underlying cancer is present. Very low glucose levels (<30 mg/dL) are most consistently associated with the effusion of rheumatoid arthritis. An elevated *amylase* level may point to pancreatitis as the cause of effusion, but it can also be seen in malignant effusion. Specific tumor markers have not proved useful, except in the case of *chromosomal analysis* for identifying malignant mesothelioma. Similarly, measurement of *complement levels* (CH_{50}, C3, and C4) should be reserved for the rare instance when it is necessary to confirm that an exudative effusion in a patient with rheumatoid disease is caused by the underlying disorder and not another condition. Pleural fluid antinuclear antibody (ANA) measurement may be useful in further establishing the diagnosis of lupus pleuritis.

In about 15% of cases, the cause of an exudative effusion is not evident after complete laboratory analysis of the pleural fluid from an initial thoracentesis. If malignancy is still suspected, repeated thoracentesis is indicated. Sensitivity approaches 90% with submission of fluid specimens from three separate pleural taps in patients with underlying malignancy. Test sensitivity is particularly high in cases of advanced pleural involvement by tumor, as suggested by a pleural fluid pH of less than 7.30 and a glucose level below 60 mg/dL. *Pleural biopsy* alone may be less sensitive than cytologic examination of pleural fluid in detecting malignancy, but the two tests are complementary, with a sensitivity in excess of 90% when used together. Pleural biopsy is most useful in detecting TB, having a sensitivity of 60% to 80%. Again, the biopsy information is complementary; fluid culture or examination of pleural tissue (or both) will yield a diagnosis of TB in up to 95% of those with the disease. Both pleural tissue and pleural fluid should be submitted for mycobacterial culture.

When pleural biopsy is contemplated, it should be anticipated that most specimens will disclose only nonspecific inflammatory changes. Although the diagnosis of malignant effusion will eventually be made in as many as 20% of such patients, in most cases the effusion will resolve spontaneously without serious sequelae. When a history of hemoptysis is present or a pulmonary abnormality is noted on chest radiography, *fiberoptic bronchoscopy* may prove useful.

INDICATIONS FOR ADMISSION AND REFERRAL

The patient with respiratory discomfort is best evaluated on an inpatient basis, especially if HIV-positive; inpatient evaluation is also indicated when embolization, severe congestive failure, acute empyema, or an intraabdominal crisis is likely. Few of these patients present to the physician in the office; however,the patient with a chronic but enlarging collection of pleural fluid is apt to be encountered. The person who appears to be tolerating the effusion without much discomfort can be evaluated and managed on an outpatient basis as long as no evidence suggests an empyema or a subphrenic abscess, conditions that require surgical attention. Referral is appropriate when malignancy or TB is suspected and pleural biopsy or fiberoptic bronchoscopy is deemed necessary.

SYMPTOMATIC MANAGEMENT

The patient can be made comfortable before a diagnosis is established. Pleuritic pain often responds to indomethacin; the drug has an advantage over narcotics in that it does not produce any suppressive effect on respiration. Removal of fluid is indicated when the effusion is compromising respiratory efforts. Usually, no more than a liter should be removed at one time to avoid intravascular volume depletion on reequilibration. Malignant pleural effusions are notoriously difficult to treat in the setting of advanced disease with marked pleural involvement (pleural fluid pH <7.30 and glucose level <60 mg/dL). Comfort measures are preferable to repeated attempts at sclerosing therapy under such circumstances (see Chapter 92).

CHAPTER 44 EVALUATION OF THE SOLITARY PULMONARY NODULE

Solitary nodules are found at a rate of one to two per 1,000 routine chest radiographs. The discovery is a worrisome finding because it raises the possibilities of primary lung cancer and solitary metastasis from a nonpulmonary source. The patient is usually asymptomatic and undergoing chest radiography for either an unrelated issue or screening. Granulomas and hamartomas account for the majority. About 30% prove to be malignant. Pulmonary malignancies with the greatest potential for cure present as solitary nodules. Consequently, thorough assessment is of the utmost importance. On the other hand, themajority of these lesions are not cancers, and to subject all patients to invasive studies and excision can lead to much unnecessary morbidity. The primary physician needs to determine the likelihood of malignancy on the basis of clinical and radiologic findings and identify the patient who requires referral for consideration of bronchoscopy, percutaneous needle biopsy, or thoracotomy. Workup can be performed on an outpatient basis.

PATHOPHYSIOLOGY AND CLINICAL PRESENTATION

Solitary pulmonary nodules characteristically appear in the middle or lateral lung fields, surrounded by normal lung and unaccompanied by satellite lesions. They have smooth contours and are usually round ("coin" lesions) or oval. Neoplastic, granulomatous, vascular, and cystic processes are the principal pathologic mechanisms responsible for nodule formation. The nodule displaces normal aerated lung parenchyma and does not cause symptoms unless airway obstruction, pleural invasion, interference with respiratory mechanics, or involvement of blood vessels or nerves occurs. Inflammatory lesions double in volume in less than 5 weeks, malignancies take between 1 and 18 months to double, and benign nodules take longer. A solitary nodule that does not change in size for 2 years is benign. The older the patient, the greater the chances that the nodule is malignant; the probability is less than 2% below age 30 and increases by 10% to 15% with each succeeding decade. A history of smoking greatly increases the probability that the nodule is malignant, as does concurrent weight loss, headache, or bone pain.

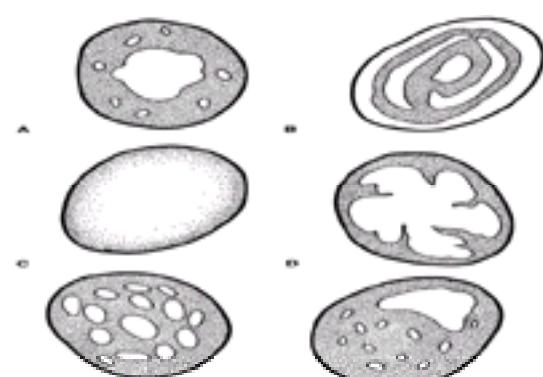
Benign and malignant solitary lung nodules may have a similar appearance on chest x-ray films. However, the distribution *patterns of calcification* are different and of diagnostic utility. Benign lesions tend to have calcium deposited in central, peripheral, concentric, "popcorn," or homogeneous patterns, whereas eccentric patterns of calcification are more characteristic of malignancies (see below and Fig. 44.1).


FIG. 44.1. Patterns of calcification in solitary pulmonary nodules include central (**A**), laminated (**B**), diffuse (**C**), "popcorn" (**D**), stippled (**E**), and eccentric (**F**). A through D are virtually always benign; E and F may be benign or malignant.

Among lung cancers, adenocarcinomas tend to be located peripherally; squamous and small-cell cancers are usually more central in location. However, squamous cell cancers that are located peripherally tend to show cavitation.

DIFFERENTIAL DIAGNOSIS

Healed infectious granulomas account for the majority of solitary nodules. In most series, 20% to 40% prove to be cancers. Of these, more than 75% are *primary lung cancers*, and the remainder are *metastatic lesions*. Tumors of the *breast, colon,* and *testicles* are particularly prone to metastasize to the lung. Of the 60% to 80% of solitary pulmonary nodules that prove to be benign, 85% to 90% are granulomas; most are *tuberculous*, but in endemic areas, *histoplasmosis* and *coccidioidomycosis* are important considerations. Benign pulmonary tumors such as *hamartomas* account for about 5% of benign nodules. The remainder are *bronchogenic cysts, hydatid cysts, pseudolymphomas, arteriovenous malformations*, and *bronchopulmonary sequestrations*. Extrapulmonary lesions, such as skin lesions, moles, nipples, chest wall and rib lesions, and pleural plaques, may be confused with solitary lesions of lung parenchyma.

WORKUP

The major issue posed by a solitary nodule is the chance of an early resectable lung cancer. Many surgeons argue that the risk of thoracotomy is small and the potential benefit considerable, as resection of a nodule that proves to be an early primary lung cancer may provide the patient with a chance for cure. They note that for resected bronchogenic carcinomas and solitary lung metastases presenting as solitary nodules, average 5-year survivals are 60% and 35%, respectively. On the other hand, pulmonologists have argued that lesions that possess many of the criteria of benignity can be managed conservatively, and that definitive tissue diagnosis can be approached by bronchoscopy or needle biopsy without resorting to early thoracotomy, which has a surgical mortality ranging from 1% to 10%. A review of the literature reveals passionate advocates on both sides. Conclusive data taking into account morbidity and mortality of both approaches are still lacking.

The task of the primary care physician is to make the best possible clinical estimate of cancer risk based on history, physical examination, and appearance of the nodule on chest x-ray films and computed tomography (CT), with the possible addition of positron emission tomography (PET). Proper patient selectionis the best means of maximizing the yield from invasive study and surgical intervention and minimizing the rate of false alarms and unnecessary morbid procedures.

History

The age of the patient and a history of smoking are important determinants of cancer risk. The likelihood ratio for malignancy in men increases markedly with age, estimated at 0.1 for those below age 35 to 5.7 for those over 70. Likelihood ratios for smoking range from 0.15 for those who have never smoked to 3.9 for those currently smoking more than two packs per day. The probability of cancer is 50% for patients in their 60s but less than 2% for those under 30. Although symptoms are often absent, it is worth inquiring into bone pain, headache, weight loss, and other symptoms suggestive of malignancy. A history of hemoptysis, even if minimal (see Chapter 42), and of known previous breast, bowel, or testicular cancer also increases the likelihood of malignancy. A history of exposure to tuberculosis (TB) or residence in an area in which histoplasmosis or coccidioidomycosis is endemic raises the possibility of a granulomatous etiology but does not rule out malignancy. A family history of hemorrhagic telangiectasia can be a valuable clue.

Physical Examination

The physical examination is generally unrevealing, but the presence of a breast or testicular mass, occult blood in the stool, clubbing (see Chapter 45), cutaneous or mucosal telangiectasia, or an audible bruit over the chest wall (suggestive of a vascular etiology) should be excluded. Perhaps the most important part of the physical examination is careful palpation of lymph nodes, particularly those in the supraclavicular and axillary regions. If enlarged, such nodes can be sampled by biopsy,

which may eliminate the need for thoracotomy or other invasive procedures.

Laboratory Studies

Chest Radiography. *Appearance* of the lesion and its *doubling time* are among the most useful data for determining the chances of malignancy. An assessment of doubling time—the period during which the tumor doubles in volume—can be especially helpful, but this is possible immediately only if *previous chest films* are available. It is important to keep in mind that doubling refers to volume, not diameter. In doubling, the diameter of the lesion need increase by only 28%, not 100%. A doubling time of more than 2 years or less than 30 days makes malignancy unlikely.

Every effort should be made to locate old chest x-ray films before further studies are undertaken. If no old films are available and it is determined reasonable to follow the patient expectantly (see below), then serial films should be obtained, the first one 3 weeks after the time of initial evaluation and then others at intervals of 3 to 6 months for the next year. The interval can be decreased to every 6 to 12 months thereafter.

If previous films are unavailable, careful evaluation of the *radiologic appearance* of the nodule is indicated. A most helpful sign is the presence of *calcification*. Laminated or concentric calcification is specific for granulomas. Central, diffuse, or homogeneous patterns of calcification are, with rare exceptions, also associated with benign lesions. However, radiographically visible calcium in stippled or eccentric patterns can occur in both malignant and benign lesions. Moreover, a primary cancer may engulf a preexisting calcified granuloma or scar; eccentricity of the calcium in the nodule should raise this possibility (Fig. 44.1).

The *location, size*, and *shape* of the nodule on a chest x-ray film are less valuable distinguishing signs. Both cancers and tuberculous granulomas are more common in the upper and middle lobes than in the lower lobes. Small lesions are more likely to be benign or, if they are malignant, are still at a stage when detection and definitive diagnosis may have the greatest positive impact. Ill-defined borders suggest a primary malignancy, as does lobulation of the margin of the nodule. However, smooth borders are also seen with metastatic lesions. Cavitation occurs with nearly equal frequency in cancers and granulomas.

Computed Tomography has become the imaging technique of choice for evaluation of the solitary pulmonary nodule. It provides much better definition of the lesion and pattern of calcification than does chest radiography and reduces the false-negative rate associated with reliance on chest radiographic appearance alone. What appears to be a single nodule on plain film may actually be one of several lesions on CT and indicative of metastatic disease. CT is useful for guiding needle biopsy and allows assessment of the mediastinum, which is useful in staging lesions suspected to be malignant (although its sensitivity and specificity for staging have been found wanting in patients with lesions smaller than 3 cm; see Chapter 53).

Taking thin sections (high-resolution CT) or using iodinated contrast can sometimes uncover calcification not visible by standard CT, can better confirm hamartomas and arteriovenous malformations, and can enhance the appearance of malignant nodules.

Positron Emission Tomography with ^{18}F-2-fluoro-2-deoxy-D-glucose (FDG) has been shown to add useful discriminating information for nodules deemed indeterminate based on radiographic appearance. Studies suggest a sensitivity of 90% to 95% and specificity of 85% to 90%. Decision analysis suggests that a CT plus an FDG-PET strategy may be most effective and may actually be cost-saving among patients for whom the probability of cancer is between 0.12 to 0.69.

Magnetic Resonance Imaging is inferior to CT for imaging solitary pulmonary nodules. It does not detect calcification well but reveals the mediastinum better than does CT, and it is useful for imaging chest wall invasion, aortopulmonic window adenopathy, and superior sulcus tremors.

Ancillary Studies. An intermediate-strength *tuberculin skin test* should be implanted (see Chapter 38). If sputum is available, it should be stained for *acid-fast organisms* and *cultured for TB*. In endemic areas, *fungal cultures* and histoplasmin complement fixation titers may be of importance.

Sputum cytologic examination is the least invasive means of identifying a malignancy. Three first morning samples should be obtained on consecutive days. Yield is highest when the sample contains pulmonary histiocytes (a sign of a deep sample) and the lesion is in the upper lobes, centrally located, communicating with a bronchus, or larger than 2 cm in diameter(see Chapter 37). Although the specificity of the test is high in experienced hands, its sensitivity has been found wanting in many studies, with figures ranging from 13% to 77%. Thus, a negative study does not rule out the diagnosis. Moreover, because of the importance of distinguishing a small-cell carcinoma from cancers of other cell types (see Chapter 53), it is often necessary to obtain tissue for diagnosis. Because of these shortcomings, some have argued that sputum cytology is not worth the effort, except in patients who are too ill to undergo invasive study.

Diagnostic Approach

Conservative Approach to further evaluation is reasonable in patients determined to have little chance of cancer by noninvasive evaluation. Withholding invasive study is a legitimate management option in patients with lesions that have not enlarged in 5 years and in young, nonsmoking patients with radiologic evidence that suggests benignity (central, laminated, diffuse, or "popcorn" pattern of calcification; sharp borders). Careful follow-up with serial chest films taken according to the schedule noted above is essential because some malignancies can be slow-growing.

Invasive Diagnostic Measures deserve consideration if malignancy is still considered possible after noninvasive evaluation. Thoracotomy with resection represents the most direct and definitive means of diagnosis (and treatment), but it is associated with a perioperative mortality risk of 1% to 10% and considerable morbidity (see Chapter 53). Less morbid options include bronchoscopy with transbronchial biopsy and needle aspiration biopsy under fluoroscopic or CT control.

Fiberoptic bronchoscopic examination with bronchial brushing and biopsy may yield a diagnosis if a bronchus appears to enter the lesion on CT, but the sensitivity is substantially lower (10% to 30%) when nodules are small (<2 cm) and well circumscribed. *Transthoracic needle aspiration* is a far more valuable approach to diagnosis. Sensitivity for detection of malignancy approaches 95% when the nodule is accessible to the transthoracic approach. Accurate pathologic diagnosis is facilitated by using a large-bore needle rather than a "skinny" one and by taking multiple samples. Specific histologic types of malignant lesions can often be identified.

Mediastinoscopy and *thoracotomy* are indicated when the pre-procedure probability of an early resectable primary lung cancer is high (see Chapter 53) and the patient is a good operative risk. Patients with severe obstructive or restrictive disease should first undergo formal pulmonary function testing.

Choice of Diagnostic Approach depends on the estimated probability of malignancy, location of the lesion, ability and willingness of the patient to tolerate the event (or the uncertainty, if watchful waiting is a consideration), and availability of the needed technical expertise.

The high-probability patient who can tolerate surgery and whose lesion has been determined to be resectable (see Chapter 53) should undergo thoracotomy and resection. Patients with an intermediate probability of malignancy might be best approached by transthoracic needle biopsy if it appears technically feasible. Patients with a very low risk are reasonable candidates for careful follow-up by serial radiographic study.

In sum, the optimal approach to evaluation of the patient with a solitary pulmonary nodule remains problematic because outcome data are lacking. It appears that a conservative approach to evaluation is justified in patients judged to be at low risk for malignancy based on epidemiologic, historical, physical, and radiographic criteria. Patients at high risk for malignancy require a tissue diagnosis. Improvements in noninvasive evaluation techniques are reflected in the lower number of surgical procedures being performed for solitary nodules and the higher proportion of malignancies found among those that are sampled or resected. However, in a significant number of cases, substantial ambiguity remains after noninvasive evaluation. Formal clinical prediction rules have been developed based on elements of history (age, smoking, and prior cancer) and radiologic appearance (nodule diameter, presence of spicules, and upper lobe location), but they do not yield better results than does a clinician who considers these and other factors. Patients for whom the probability of malignancy is neither low enough for them to be followed conservatively nor high enough for them to undergo surgery face a dilemma. The uncertainty and possible outcomes of alternative approaches should be shared with these patients so that a satisfactory plan can be devised.

PATIENT EDUCATION AND INDICATIONS FOR REFERRAL

Patients suspected on clinical and radiologic grounds of having a malignancy should be referred for tissue diagnosis. Decisions regarding the need for and type of invasive procedure should be made in conjunction with surgical and radiologic consultants. When the probability of malignancy is unclear, the patient needs to be

informed about the lack of diagnostic certainty provided by noninvasive study, and about the nature of further tests that might be undertaken. Patients who cannot emotionally tolerate the uncertainty should be advised to undergo a definitive procedure to end the constant worry about the possibility of malignancy. The patient who can live with such uncertainty and is reluctant to undergo a thoracotomy or biopsy might be followed with serial chest films at 3- to 6-month intervals for 2 years.

CHAPTER 45 EVALUATION OF CLUBBING

The term *clubbing* refers to enlargement and sponginess of the nail beds of the fingers and toes and reduction in the angle created by the nail and the dorsum of the distal phalanx. Clubbing is sometimes accompanied by a chronic subperiosteal osteitis, *hypertrophic osteoarthropathy*. Patients rarely complain of clubbed fingers; it is the physician who detects this abnormality as an incidental finding on physical examination. Because clubbing or hypertrophic osteoarthropathy may be the first clinical sign of a serious underlying condition, such as a pulmonary neoplasm, it is important for the primary physician to recognize these findings and investigate their possible causes.

PATHOPHYSIOLOGY AND CLINICAL PRESENTATION

Hypotheses explaining the pathogenesis of clubbing and osteoarthropathy implicate autonomic influences, arteriovenous shunting, and blood-borne substances. The precise pathophysiology remains uncertain, but it is known that intrathoracic vagotomy can abolish clubbing and osteoarthropathy, as can correction of an arteriovenous shunt or removal of a pulmonary tumor.

The pathologic examination of clubbed fingers reveals increased vascularity. In hypertrophic osteoarthropathy, the periosteum is found to be edematous, hyperemic, and infiltrated by mononuclear cells. Periosteal elevation, new bone formation, and endosteal resorption in the distal ends of long bones, metacarpals, and metatarsals are all present. Soft-tissue swelling in the distal ends of the fingers and toes may lead to clubbing.

Clubbing is usually asymptomatic. Patients with hypertrophic osteoarthropathy may have pain in the wrists, ankles, hands, and feet; erythema and effusions are sometimes noted. Hypertrophic osteoarthropathy may precede clubbing or occur without it, but generally the two appear together. Clubbing often takes place in the absence of osteoarthropathy. Either finding may develop before the clinical presentation of one of the conditions associated with it.

Idiopathic hypertrophic osteoarthropathy, sometimes referred to as pachydermoperiostosis, is a benign condition that must be distinguished from hypertrophic osteoarthropathy secondary to systemic disease. These patients show periosteal new bone formation, swelling of the joints, and thickened and furred skin in addition to clubbing. The benign syndrome can be differentiated from secondary hypertrophic osteoarthropathy by development in adolescence, slow growth, a paucity of joint symptoms, and the absence of concurrent hepatic or pulmonary disease.

DIFFERENTIAL DIAGNOSIS

Clubbing and hypertrophic osteoarthropathy occur in 2% to 12% of patients with *lung cancer*, developing with equal frequency in patients with large-cell cancer, squamous cell cancer, or adenocarcinoma, but rarely in the setting of small-cell cancer. Clubbing alone may be more frequent, and the prevalence depends on the sensitivity of the diagnostic criteria used to designate digits as "clubbed." A recently proposed, sensitive, standardized measure identified clubbing in 37% of those with lung cancer and found no difference in prevalence among patients with squamous cell cancer, adenocarcinoma, or small-cell cancer. Metastatic lung tumors are rarely responsible for such changes. With the decline in the incidence of *chronic pulmonary infectious* diseases (such as tuberculosis, lung abscess, and bronchiectasis), carcinoma of the lung has emerged as the leading cause of hypertrophic osteoarthropathy. Clubbing and osteoarthropathy are seen in patients with cyanotic congenital heart disease with *right-to-left shunts*, subacute bacterial *endocarditis*, and *cystic fibrosis*. Clubbing is a classic sign of chronic *hypoxemia* in patients with chronic obstructive lung disease. In addition, there are *hereditary* or idiopathic forms of clubbing and hypertrophic osteoarthropathy that have no clinical significance. Unilateral clubbing is associated with impairment of the vascular supply to the arm that occurs with aortic, subclavian, or innominate artery lesions. Clubbing may develop in jackhammer operators.

Clubbing has also been described in a number of nonpulmonary conditions, including inflammatory bowel disease and chronic liver disease. Case reports of clubbing in association with a myriad of diseases have been published. Some of these include esophageal cancer, early HIV infection, and antiphospholipid antibody syndrome. Each of these reports includes disclaimers about the presence of comorbid pulmonary disease. Nonetheless, it is difficult to judge their significance.

Clubbing must be differentiated from a number of other phalangeal conditions that resemble it. In many normal people, particularly African-Americans, curvature of the nails is increased. Infections of the terminal phalanges, such as felon and chronic paronychia, may be confused with clubbing, as may thyroid acropathy.

WORKUP

The evaluation of clubbing should begin with confirmation of the characteristic physical findings: *loss of the angle* made by the nail and *increase* in the *ballotability* of the nail bed. Hypertrophic osteoarthropathy is identified by *radiography of the long bones*; the typical changes are increase in periosteal thickness and new bone formation at distal ends. Once it is clear that clubbing or hypertrophic osteoarthropathy is present, evaluation for an underlying cause can commence.

History. Before an elaborate search for a serious illness is undertaken, it should be established whether clubbing has been lifelong and is present in other family members, which would be indicative of the harmless familial variety. Symptoms such as cough, sputum production, hemoptysis, and dyspnea point to a respiratory problem and may have already triggered an evaluation of the lungs (see Chapter 40, Chapter 41 and Chapter 42). The patient should be questioned about history of a heart murmur and exercise intolerance, and about prior liver disease, cramping lower abdominal pain, diarrhea, bloody stools, and joint problems. Smoking and other risk factors related to the development of lung cancer (see Chapter 37) should be assessed. Exposure to tuberculosis also needs to be ascertained (see Chapter 38).

Physical Examination requires a check for fever, tachypnea, tachycardia, cyanosis, tobacco stains, jugular venous distention, barrel chest, wheezes, rhonchi, rales (crackles), signs of consolidation or effusion, heart murmur, skin lesions of hepatocellular disease, and signs of cirrhosis. Lymph nodes should be palpated for enlargement, and joints should be checked for hypertrophic changes and signs of inflammation.

Laboratory Studies. The only mandatory laboratory study is a *chest radiograph*, as early pleural, pulmonary, or mediastinal neoplasm may be asymptomatic. A complete blood cell count and stool examination for occult blood may be of help. Further evaluation of the liver, thyroid, heart, or bowel should be undertaken only if symptoms or physical findings suggest disease in these areas. Patients with new onset of clubbing and a long history of smoking should be followed for the development of pulmonary neoplasm; periodic examinations including sputum cytology and chest radiography are appropriate.

Differentiating Osteoarthropathy from Rheumatoid Disease can be difficult. An extensive review of patients with clubbing and lung cancer showed that the symptoms of osteoarthropathy were often mistaken for arthritis and predated the diagnosis of neoplasm by a mean of 4.9 months. Frequent complaints of bilateral joint discomfort in the small joints, such as the wrists and hands, and an adequate response to aspirin or nonsteroidal agents tended to persuade physicians that they were dealing with rheumatologic disease. Also noteworthy were the findings of acute elevation in acute phase reactants and the presence of rheumatoid factor in 1 of 14 and antinuclear antibody in 5 of 12. The symmetric involvement of small peripheral joints and the tendency to development of synovitis present a significant diagnostic dilemma, with some patients having a syndrome indistinguishable from that of an inflammatory arthritis.

SYMPTOMATIC MANAGEMENT AND PATIENT EDUCATION

No symptomatic therapy is available for clubbing. It is an innocuous cosmetic disturbance. Discomfort in the bones and joints secondary to hypertrophic osteoarthropathy can be treated with aspirin. Rarely, joint symptoms are disabling; these may require extreme therapies such as corticosteroids or intrathoracic vagotomy. Resection of the underlying lung cancer may reduce joint pain and swelling of the fingers. Such therapeutic options should be undertaken in consultation with a specialist familiar with the problem.

Patient education is important in any condition in which the physician discovers a potential sign of disease that is not obvious to the patient. It is likely that patients will be disturbed by the investigation and by the possibility of serious disease. The physician must take time to inform the patient that clubbing can be a harmless finding in addition to a helpful guide to the early diagnosis of disease. The patient who smokes should be strongly advised to quit (see Chapter 54).

CHAPTER 46 APPROACH TO THE PATIENT WITH SLEEP APNEA

Obstructive sleep apnea is estimated to affect up to 2% to 4% of middle-aged men and women and even greater proportions of the elderly. Despite its high prevalence, the condition is often overlooked because its symptoms (e.g., daytime tiredness, snoring) may be mistaken for normal phenomena of everyday life. Insufficient recognition in primary care practice continues despite the growing appreciation of the frequency and potentially serious consequences of this condition (e.g., motor vehicle accidents and deaths, cardiovascular morbidity and mortality, pulmonary hypertension). The primary care physician needs to be cognizant of the early and varied manifestations of sleep apnea so that a timely workup can commence and treatment can be instituted before the onset of potentially life-threatening consequences.

PATHOPHYSIOLOGY AND CLINICAL PRESENTATION

Definitions. *Sleep apnea* is defined as five or more episodes of apnea or hypopnea per hour of sleep; more than 20 episodes per hour is classified as clinically significant disease because it correlates with an increased risk for adverse outcomes. Sleep apnea may result from *central suppression of* respiration (as occurs with congestive heart failure and carbon dioxide retention) or from *upper airway obstruction*. In the former condition (*central sleep apnea*), air flow ceases because of the loss of central respiratory drive; in the latter (*obstructive sleep apnea*), air flow ceases because of obstruction despite chest and abdominal respiratory efforts during apnea. Obstructive sleep apnea is the most common form of sleep apnea encountered in the office setting. *Upper airway resistance syndrome* is an intermediate category, in which air flow is maintained by increased respiratory effort despite partial airway obstruction.

Mechanisms. Obstructive sleep apnea occurs when the patency of the nasopharyngeal airway become insufficient during sleep. Anatomic risk factors include nuchal obesity (cricothyroid neck circumference >17 inches for men, >16 inches for women), deviated septum, nasal polyps, enlarged uvula and soft palate, small chin with deep overbite, enlarged tonsils, and hypertrophy of the lateral pharyngeal musculature. Although obesity appears to be a major factor (causing fat deposition in the tongue and pharyngeal tissues), persons who are not obese are also at risk if they manifest other anatomic risk factors. In addition to being anatomically predisposed, patients with obstructive sleep apnea appear to be unable to sustain sufficient oropharyngeal muscle dilator activity during sleep to prevent airway collapse during the negative pressure of inspiration. The suppressive effects of alcohol and sedatives on such neuromuscular function may explain their role in exacerbating obstructive sleep apnea. Hypothyroidism may be a risk factor.

When the obstruction is mild and not physiologically disturbing, *snoring* is the only manifestation, and sleep is not interrupted. With increasing degrees of obstruction, snoring becomes louder and compensatory respiratory efforts are triggered, causing electroencephalographically detectable *arousals from sleep*. Frequent arousals during the night disrupt normal sleep "architecture" and result in *daytime sleepiness*. In the upper airway resistance syndrome, near-normal air flow is maintained by compensatory respiratory efforts, but at the cost of sleep arousals. More severe degrees of obstruction can lead to *hypopnea* (50% reduction in air flow with oxygen desaturation ¾4%) or *apnea* (cessation of air flow for at least 10 s). The more severe and more prolonged the obstruction, the more likely and more severe are blood *oxygen desaturation* and *hypoxemia*, consequences of ventilation–perfusion mismatching as a result of the perfused lung not being adequately ventilated.

The adverse cardiovascular consequences of sleep apnea are related to hypoxemia. The decline in arterial oxygen increases pulmonary vascular resistance; when severe and chronic, it can lead to sustained *pulmonary hypertension* and ultimately *cor pulmonale*, particularly in persons with underlying chronic obstructive pulmonary disease or morbid obesity. Airway obstruction, episodes of apnea, and hypoxemia trigger compensatory increases not only in ventilatory effort but also in sympathetic tone, which may explain the association between severe degrees of sleep apnea and *systemic hypertension, cardiac arrhythmias*, and increased *cardiovascular morbidity* and *mortality*. Sleep apnea is an independent risk factor for hypertension. Severe degrees of obstructive sleep apnea can also lead to hypercarbia and *central suppression* of respiration, as seen in persons with the *obesity–hypoventilation (pickwickian)* syndrome. *Dysmenorrhea* and *amenorrhea* are consequences in women of reproductive age.

The disturbance in sleep caused by obstructive sleep apnea may impair *cognition* and *psychomotor performance*. In severe sleep apnea, hypersomnolence develops, markedly increasing the risk for injuries during work and driving. The risk ratio for *traffic accidents* increases to 6.3 and appears independent of other risk factors.

Clinical Presentations. Often, the patient presents at the insistence of a bed partner who is bothered or worried by *loud and intermittent snoring, disturbed* or *restless sleep*, periods of *irregular* or *halted breathing*, and *choking* or *gasping*. Patients presenting with obstructive sleep apnea typically complain of excessive *daytime sleepiness*; they may note falling asleep at work or at a meeting. Women are somewhat more likely to report *chronic fatigue*. Patients find they awaken not feeling refreshed and may have a morning *headache. Work performance* may be suffering, and the history of a work-related or automobile *accident* resulting from sleepiness may be elicited. Family and friends may note a *personality change. Obesity* is common but is not a necessary part of the clinical presentation; nearly half of premenopausal women with disordered nocturnal breathing are thin but have another contributing anatomic feature, such as a *severe overbite* or a *high hard palate*. A positive *family history* is noted, usually in persons with a contributing anatomic factor or obesity.

DIFFERENTIAL DIAGNOSIS

Because obstructive sleep apnea may present as daytime tiredness, it must be differentiated from other causes of chronic fatigue (see Chapter 8). In patients who present with interrupted sleep, other sleep disturbances deserve consideration (see Chapter 232). In those whose presentation is predominantly one of difficulty in breathing at night, heart failure (see Chapter 32), chronic obstructive lung disease (see Chapter 47), and other causes of snoring (see Chapter 223) should be considered.

WORKUP

History. A high index of suspicion is appropriate when a patient, whether obese or not, presents with symptoms of excessive daytime sleepiness, tiredness, or fatigue. A history of very loud intermittent snoring, irregular respiratory activity with spells of gasping or choking that interrupt sleep, or witnessed episodes of apnea is strongly suggestive. Also worth noting are any accidents, job performance difficulties, and personality changes or cognitive difficulties, especially if occurring in the context of daytime sleepiness. Risk factors that help in identifying patients with obstructive sleep apnea include marked obesity (body mass index >28 kg/m ^{2}), increasing age, obstructive upper airway abnormalities, regular use of sedatives or alcohol, and hypothyroidism.

Physical Examination. The blood pressure should be checked for elevation and the integument noted for any cyanosis, clubbing, or signs of hypothyroidism (see Chapter 104). The upper airway is examined for overbite, a high hard palate, other potentially obstructing nasopharyngeal lesions (e.g., nasal polyps, tonsillar hypertrophy, large uvula), and nasopharyngeal narrowing. The neck circumference should be measured to document any nuchal obesity. In persons with suspected severe obstructive sleep apnea, one should check for signs of pulmonary hypertension and cor pulmonale (e.g., right ventricular heave, loud pulmonic component of the second heart sound, jugular venous distention, leg edema).

Laboratory Studies. Currently, the definitive and most cost-effective diagnostic procedure in symptomatic patients clinically suspected of obstructive sleep apnea is a formal *polysomnographic study*, which includes overnight monitoring of the electroencephalogram, eye movements, muscle activity, chest movements, air flow, and blood oxygen saturation. Although such testing is expensive, it is nevertheless the most cost-effective of the available diagnostic modalities at present; the high sensitivity and specificity minimize both false-positive results (which generate unnecessary, expensive long-term therapy) and false-negative results (which lead to the failure to treat disease and the risk for considerable morbidity and mortality).

Home-monitoring methods for diagnosis are improving, but they still lack the sensitivity and specificity of polysomnography. Although the sensitivity and specificity of the most sophisticated home methods are reported to exceed 95%, and although the positive predictive value of a positive result can be high (approaching 99% in patients in whom obstructive sleep apnea is strongly suspected clinically), the negative predictive value and false-negative rate of these tests remain disappointing

(77% and 23%, respectively). Based on these performance characteristics, some health care systems recommend screening with a high-quality home-monitoring method (simple periodic oximetry is insufficient), with referral to formal polysomnography reserved for those in whom obstructive sleep apnea is strongly suspected clinically but whose home-monitoring test results are negative. The cost-effectiveness of such a two-step strategy in comparison with polysomnographic testing of all patients with suspected obstructive sleep apnea remains to be determined.

Few routine laboratory studies are of value. A *thyroid-stimulating hormone* (TSH) determination is indicated if clinical evidence of hypothyroidism is present. Unless the patient has very severe disease with signs of cor pulmonale, the measurement of *hematocrit, arterial blood gases*, and *pulse oximetry* in the office is likely to be of little value.

PRINCIPLES OF MANAGEMENT

Selection and Initiation of Therapy. Treatment does improve the survival and functional status of patients with obstructive sleep apnea, but a proper matching of disease severity with treatment intensity is critical to achieving the best possible outcome. Unfortunately, few evidence-based criteria are available to guide patient selection and timing of therapy. *Positive findings on polysomnography*, demonstrating more than 20 apneic periods per hour in a symptomatic patient with arterial desaturation during sleep, provides the strongest grounds for initiation of therapy; the risk for complications of obstructive sleep apnea is high in such persons, particularly those with underlying lung disease. A lesser frequency of apneic episodes (<20/h) is a more common finding and necessitates careful consideration of the overall clinical picture before treatment is recommended. At present, no prospective data are available on outcomes in persons with milder disease (<20 episodes per hour) to help in treatment selection. Clinical judgment is required. Patients with preexisting lung disease plus sleep apnea have a worse prognosis than do those with no underlying lung disease, and they should be treated more aggressively. Minimally symptomatic patients with no concurrent pulmonary disease or evidence of impairment might first be prescribed a few potentially useful, noninvasive, simple measures (e.g., weight reduction if obese, changes in sleeping position) and followed expectantly. However, because the consequences of sleep apnea are potentiallyserious, *empiric therapy* based on clinical suspicion without reference to polysomnography is not recommended because clinical estimates lack the sensitivity and specificity required for a condition in which lifelong therapy may be necessary.

Weight Reduction. A *weight reduction program* should be recommended for patients with mild disease who are obese. Weight reduction is also the centerpiece of the treatment program for those with more symptomatic disease because it can greatly reduce or even cure sleep apnea. The implementation of a comprehensive, personalized program of weight reduction is essential to a successful weight loss effort (see Chapter 233).

Sleep Position. The position one assumes when sleeping can affect airway patency. Lying on one's back increases the risk for apneic episodes; sleeping on one's side reduces the risk. A trial of patient education to change sleeping position is worth a try, but most persons rotate at night during sleep. (One investigator suggested that patients try taping a tennis ball to their back at night to prevent lying in a supine position.)

Continuous Positive Airway Pressure. Nighttime nasal continuous positive airway pressure (CPAP) is becoming an important component of the treatment program for obstructive sleep apnea. A sealed nasal mask is worn at night connected to a blower apparatus that pneumatically sustains sufficient airway pressure to maintain upper airway patency. Patient acceptance is steadily improving, and compliance now exceeds 80% in reported trials (probably closer to 50% in everyday practice), facilitated by advances in apparatus design. CPAP improves survival in persons with more than 20 episodes of apnea per hour. Efficacy in those with less severe disease remains to be established.

Surgery. Surgical approaches are worth considering only if symptoms are severe, more conservative measures have failed, and an obvious obstructing anatomic anomaly is identified. Surgical excision of obstructing tonsils, a nasal mass, or a pharyngeal tumor can be curative. Surgery has also been performed in patients with severe obstructive disease, even in the absence of a single, identifiable obstructing lesion. The procedure used most for this purpose has been the *uvulopalatopharyngoplasty* (UPP). In performing the UPP, the surgeon excises the uvula, part of the soft palate, and any redundant pharyngeal tissue. The problem with recommending such surgery is that only about half of patients obtain a satisfactory result. Moreover, it has not been possible to predict in advance who will benefit from the surgery, and durable results are not always achieved. As a result and with the improvements in CPAP therapy, UPP is becoming a less utilized treatment option.

Oral Appliances. Dental appliances that correct such precipitants as a deep overbite have been tried. Acceptance is variable; long-term efficacy remains to be established. In patients with no such risk factor, but who cannot tolerate CPAP, an oral appliance that keeps tongue from falling back is sometimes tried. Efficacy and compliance are, at best, in the 50% range.

Pharmacologic Approaches. The most important pharmacologic intervention is avoidance of agents that might suppress respiration or neuromuscular function. Patients with sleep apnea should stop using alcohol and drugs with sedative activity. Because apneic episodes are most frequent during REM (rapid eye movement) sleep, the use of nonsedating agents that interfere with the REM phase of sleep, such as the nonsedating tricyclic antidepressant *protriptyline*, has been tried. Another approach is to administer drugs that might stimulate respiration, such as *medroxyprogesterone*. Neither approach has shown much promise and is not recommended. In contrast, treatment of underlying hypothyroidism with *thyroid hormone replacement* is effective in those with documented hypothyroidism as the cause of sleep apnea. *Nocturnal oxygen supplementation* can reduce the desaturation caused by sleep apnea, and some suggest that it be used; however, it can also prolong an apneic episode and should not be administered except in carefully controlled circumstances when an underlying chronic hypoxemia is present (see Chapter 47). Its effect on long-term outcome remains to be established.

INDICATIONS FOR REFERRAL

A patient with daytime tiredness and hypersomnolence should be considered a candidate for referral and consideration of a formal sleep study, especially if the patient's bed companion corroborates a history of loud snoring, disturbed sleep, abnormal respirations, and apneic periods. The presence of marked obesity and difficult-to-control hypertension should further raise the level of suspicion about an obstructive sleep disorder and prompt a consultation. Referral is best made to a pulmonary specialist experienced in the conduct and interpretation of polysomnography; however, it should be made clear that the purpose of the consultation is assessment of the appropriateness of formal sleep testing, and not automatic performance of a polysomnographic study. Consultation with a pulmonary specialist experienced in the treatment of sleep disorders can also be very useful for a patient who fails to improve with weight loss and for whom CPAP and surgical approaches to therapy need to be considered.

PATIENT EDUCATION

Patients brought in by a spouse complaining of their excessive snoring must be given detailed information on the potential seriousness (accidents, cardiovascular morbidity and mortality) of this seemingly harmless condition. Unless they suffer from disabling daytime tiredness and excessive sleepiness, they are unlikely to appreciate the significance of their condition. Patient education is also essential regarding treatment. Because weight loss is so effective in alleviating upper airway soft-tissue obstruction in obese patients, instruction about a comprehensive approach to weight reduction (see Chapter 233) is an essential component of the office encounter. Also important is advice regarding the avoidance of sedatives and alcohol.

CHAPTER 47 MANAGEMENT OF CHRONIC OBSTRUCTIVE PULMONARY DISEASE

Chronic obstructive pulmonary disease (COPD), or chronic bronchitis/emphysema, is a major cause of total disability, second only to coronary artery disease, and the fourth leading cause of death. Its prevalence approaches 30/1,000. Although COPD is incurable and often irreversible, improvements in functional status and survival are possible with good care, most of which can be delivered in the outpatient setting by the primary care physician. In many instances, functional impairment can be minimized and exercise tolerance improved. The primary physician needs to know the indications for bronchodilators, corticosteroids, oxygen supplementation, antibiotics, immunizations, and rehabilitative measures in addition to the potential value of surgical approaches. A positive attitude on the part of the physician is an important determinant of patient motivation and success.

PATHOPHYSIOLOGY, CLINICAL PRESENTATION, AND COURSE

Common Mechanisms and Presentations. COPD is a subset of the obstructive pulmonary diseases (which also include asthma, bronchiectasis, and cystic fibrosis). These diverse conditions share a pathophysiologic common denominator: *obstruction* of air flow and a reduction in the expiratory flow rate. This slowing manifests itself as a *reduction in the ratio of forced expiratory volume (FEV$_1$) to forced vital capacity (FVC, VC).* In COPD, the *small airways* are the site of involvement, with an increase in small-airway resistance being the first detectable manifestation.

Airway *inflammation* plays an important pathophysiologic role in many of the obstructive pulmonary diseases. In stable COPD, the inflammation appears to be predominantly *neutrophilic.* Of the cytokines measured in COPD, those that attract neutrophils (e.g., interleukin-8) are the most markedly elevated. Although lymphocytes are present in increased numbers, they are mainly type 1 helper CD8 T cells. In contrast, the predominant cells in asthma are eosinophils, mast cells, and type 2 helper CD4 T cells. During an acute exacerbation of COPD, the number of eosinophils found in bronchial biopsy specimens is increased 30-fold. These differences in inflammatory cell infiltrates may help to explain the disparate responses to corticosteroids seen in the two conditions and in different phases of COPD (see below).

Despite the differences in inflammatory mechanisms between COPD and asthma, evidence is emerging that the inflammatory pathophysiology of *chronic asthma* might *predispose* patients to COPD, especially smokers. Asthmatic patients who smoke manifest an increased rate of deterioration in FEV$_1$ over time in comparison with nonasthmatic smokers and asthmatic patients who do not smoke. Moreover, bronchial hyperresponsiveness to methacholine challenge is a powerful independent predictor of progression of COPD in smokers. Perhaps the underlying inflammatory process in asthma is an important contributor to the development of COPD in smokers and may account for the steroid responsiveness seen in a subset of COPD patients.

Smoking remains the principal risk factor for the development of COPD; nearly 90% of cases occur in the context of long-term heavy smoking, which increases the risk for COPD 30-fold. Cigarette smoking in excess of 70 pack-years is highly predictive of COPD. The marked increase in COPD prevalence (especially among women) noted since 1980 reflects the heavy smoking habits of the U.S. population in the decades after World War II.

The patient with COPD may present clinically with any combination of *cough, sputum production, wheezing,* and *shortness of breath.* The presentation is a function of the severity of illness and the relative contributions of chronic bronchitis and emphysema to the clinical picture. Most patients have mixed disease, although one pathophysiology may predominate.

Emphysema is characterized by pathologic enlargement of the air spaces distal to the terminal bronchioles as a consequence of destruction of the alveolar walls and their constituent components. This destructive process remains incompletely understood but appears linked to *excessive alveolar protease activity.* Alveolar tissue contains both proteases and antiproteases, with neutrophil-derived elastase being the most important protease and a$_1$-antitrypsin being the prime antiprotease. When antitrypsin activity is reduced or elastase levels are increased, alveolar wall destruction is believed to result. Cigarette smoking may contribute to COPD by triggering the influx of elastase-rich neutrophils into the alveoli or by the oxidative inactivation of antitrypsin. Patients who are homozygous for a hereditary deficiency of a$_1$-*antitrypsin* (<80 mg/L) are at greatly increased risk for the development of emphysema. (They represent fewer than 2% of cases overall but account for many cases among nonsmokers without other environmental risk factors; they present with onset of clinical disease before age 50 and have a positive family history of early-onset emphysema.)

The net result of this pathologic process is fragmentation of the pulmonary elastic tissue, which leads to *destruction of the alveolar architecture* and the *capillary bed* that lies within the alveolar wall. Because both air space and the vascular bed are destroyed, ventilation and perfusion do not become markedly mismatched, and marked hypoxemia does not ensue. Expiratory flow rates decline with loss of the normal elastic recoil of the lung and radial traction on airways; the poorly supported noncartilaginous airways collapse during expiration. In many patients, a *reversible cholinergic component* of airway obstruction is also present that is responsive to muscarinic blockade.

Inspiratory flow rates are normal because airway caliber is normal during inspiration. *Pulmonary compliance* increases with the decline in elasticity. The size of the pulmonary capillary bed is reduced, causing the *carbon monoxide diffusing capacity* (D$_{LCO}$) to drop. The reduction in size of the vascular bed parallels the fall in alveolar surface area. Thus, ventilation still roughly matches perfusion, and significant hypoxemia does not ensue.

The *clinical picture* is dominated by *dyspnea,* particularly on exertion. Cough is only a minor complaint, and sputum production is scant. The patient with advanced disease is *thin* and *tachypneic,* often using accessory muscles of respiration and *pursed-lip breathing.* The latter helps keep noncartilaginous airways from collapsing during expiration. Cyanosis is uncommon because the oxygen tension (P$_{O_2}$) is only minimally reduced—hence the term "*pink puffer.*" The neck veins may seem distended, but only during expiration. The *anterior–posterior diameter* of the chest is *increased,* the percussion note is hyperresonant, and the *breath sounds* are *distant.* Usually, no signs of cor pulmonale are present, although the right ventricular impulse may be prominent because of displacement by hyperinflated lungs. As noted, hypoxemia is minimal and little, if any, carbon dioxide retention occurs until the end stages of the disease. Chest radiography demonstrates hyperinflation and hyperlucency, especially at the apices, except in patients with antitrypsin deficiency, whose radiographic changes are greatest at the bases.

Chronic Bronchitis. Inflammation of the cells lining the bronchial wall in conjunction with hyperplasia of the mucous glands and narrowing of the small airways are the predominant pathologic features of chronic bronchitis. Causes of the condition are poorly understood, but chronic infection and airway hyperreactivity are believed to play important roles. Smoking is the major precipitant, along with prolonged exposure to air pollution and other bronchial irritants. However, even after withdrawal of such irritants, the inflammatory process often continues unabated. Airway edema, excess mucous production, and loss of ciliary transport result. Obstruction to air flow occurs with both inspiration and expiration. Widespread bronchial narrowing and mucous plugging produce *hypoxemia* because of mismatching of ventilation and perfusion. *Hypercarbia* results from impeded ventilation. Chronic hypoxia and hypercarbia increase pulmonary arterial resistance and may lead to the development of *pulmonary hypertension* and eventually *cor pulmonale.* Sudden worsening may precipitate acute right-sided heart failure in severe chronic bronchitis. Compared with emphysema, chronic bronchitis causes much less parenchymal damage; diffusing capacity, lung volumes, and compliance are not greatly altered.

Patients with chronic bronchitis are typically *colonized* with *Haemophilus influenzae* and *Streptococcus pneumoniae; Moraxella* is also found. However, the role of *infection* in the genesis of acute exacerbations remains unsettled, although evidence from classic double-blind, randomized, placebo-controlled trials demonstrates little difference in outcome between patients given prophylactic tetracycline and those given a placebo. When administered to patients with acute exacerbation of COPD, antibiotic therapy produces a small improvement in outcome in comparison with placebo.

The person with chronic bronchitis is often a *smoker* who presents with a history of chronic, productive cough. By definition, the *cough* must be present for at least *3 months each year during two consecutive years.* At first, the sputum production and cough occur just in the winter months, but soon the patient becomes symptomatic year-round, with a history of frequent exacerbations. By the time dyspnea on exertion sets in, the disease is well advanced. Patients may report having to sit up at night to breathe; at times, this may be a manifestation of congestive heart failure, which is not uncommon, but more careful questioning often reveals that the difficulty

is precipitated by cough and relieved by raising sputum. As noted above, cor pulmonale and right-sided heart failure may ensue if chronic hypoxemia and pulmonary hypertension are present.

The chronic bronchitic patient is typically a man in his fifties at the time of presentation, and is often already at a late stage of disease. He may appear *plethoric* and *cyanotic.* The term "*blue bloater*" has been used to describe such patients. Tobacco stains on the fingers and teeth are common, and signs of *cor pulmonale* may be present (distended neck veins, right ventricular heave, right ventricular gallop, and peripheral edema). The lungs sound noisy; *crackles* and *wheezes* are readily evident. The expiratory phase of respiration is prolonged. Because of the mismatching of ventilation and perfusion, *hypoxemia* may be found on measurement of arterial blood gases. The carbon dioxide tension (Pco_2) rises as the ability to move air effectively declines. *Secondary polycythemia* is common, and the chest x-ray film shows increased bronchial vascular markings.

Clinical Course and Estimatation of Prognosis. The clinical course of COPD is generally *progressive*, although some patients seem to reach a plateau clinically—especially if they stop smoking. Early on, before the onset of symptoms, one can often detect an increase in the *closing volume* and a decrease in the *maximum midexpiratory flow rate* (sensitive measures of small-airway disease); measures of large-airway resistance are usually within normal limits during this phase of illness. The presymptomatic, *small-airway stage* of COPD may represent a period of reversible disease; however, early fibrotic changes have been found in airways of such patients. It has not been resolved whether intervention at the time of early small-airway abnormalities will alter the course of disease and improve the prognosis.

Longitudinal studies of symptomatic patients have shown a *steady deterioration* in pulmonary function with time. When the FEV_1 is used as the measure of obstruction, an annual average decrease in flow rate of 50 to 70 mL/s has been noted. By the time the FEV_1 declines to 1 L/s, the mean annual mortality approaches 10%. The rate of decline in FEV_1 can be markedly slowed if the patient stops smoking. The onset of resting tachycardia and signs of cor pulmonale are other indicators of a poor prognosis.

Several parameters are emerging as prognostically useful (Table 47.1). In one important study, significant reductions in 12-year survival were found among patients with a marked reduction in the *ratio of FEV_1 to FVC*, a substantial drop in FEV_1 or FVC, *hypoxemia, hypercarbia*, cor pulmonale, or *decreased diffusing capacity*. The FEV_1 may be a more useful predictor of prognosis in advanced disease than the ratio of FEV_1 to FVC. In late disease, the rate of decline of the FEV_1 often slows and the FVC may fall more rapidly, so that the ratio is preserved even in the setting of clinical deterioration. However, once the FEV_1 falls below 1 L/s, it is a less effective means of distinguishing survivors from nonsurvivors. Other predictors of poor prognosis included *heavy smoking* and a more rapid rate of decline of expiratory flow rates over time. Interestingly, the group with the lowest 12-year probability of survival still had a 40% chance of remaining alive.

FEV₁ <40% of predicted, especially <1.0 L/sec
FEV₁/FEV <0.40
Arterial Po₂ <55 mm Hg
Presence of cor pulmonale
Carbon dioxide retention
FVC <80% of predicted
Decreased single-breath diffusing capacity
Decreased mixed venous oxygen concentration

FEV₁, forced expiratory volume in 1 second; FVC, forced vital capacity; Po₂, oxygen tension.

Table 47.1. Predictors of Poor Prognosis in Chronic Obstructive Pulmonary Disease

Differences in patient populations make rigid extrapolation from studies of prognosis to individual patients unwise, but the parameters identified can be of qualitative use clinically. It remains difficult to predict survival in individual patients. Although the prognosis for patients with COPD is not very good, therapy does prolong survival (see below). Cessation of smoking is critical.

WORKUP

Although the selection of treatment modalities is partially empiric, it is still helpful to identify the predominant pathophysiologic defects, their severity and effect on the patient's functional status, and any aggravating or precipitating factors. Clarification of these issues can help focus therapy and serve as a baseline for monitoring efficacy of treatment.

History. One should obtain a careful description of symptoms and limitations of activity experienced in daily life, both at rest and during exercise. A detailed *smoking history* and *environmental* or *work exposures* to pulmonary irritants should be sought and specified. Quasi-quantitative estimates of *exercise capacity* (e.g., number of flights of stairs that can be climbed or distance that can be walked on level ground) are helpful, as is some indication of the progression of symptoms over time. The presence of *leg edema* and worsening exercise tolerance suggest onset of right-sided heart failure in the patient with chronic bronchitis.

Physical Examination. It is important to note any tachypnea, tachycardia, prolongation of the expiratory phase, cyanosis, clubbing, use of accessory respiratory muscles, wheezes, signs of consolidation, diminution of breath sounds, and evidence of cor pulmonale (jugular venous distention, peripheral edema, right ventricular heave, loud pulmonic closure sound, and right ventricular third heart sound).

Laboratory Studies. Testing helps to quantify the degree of the obstructive defect, determine the response to bronchodilators and steroids, and estimate prognosis.

Spirometry is essential to these tasks. The *peak expiratory flow rate*, measured by a hand-held peak flow meter in the office or at home, is a good screening test predictive of obstructive abnormalities on formal spirometry. A measurement ofless than 350 L/min is an indication to proceed with formal measurement of lung volumes and flows. The *closing volume* and *maximal midexpiratory flow rate* are useful measures of early small-airways disease; they are most useful in presymptomatic stages of COPD, when other measures of air flow may be normal. Later on, the degree of obstruction in larger airways can be readily assessed by measuring expiratory flow rates with an office spirometer. The most helpful measurement is the *ratio of FEV_1 to VC*. Crude estimates of obstruction can be provided by the FEV_1 alone. Results are compared with predicted values. Patients with a 50% reduction in FEV_1 are often dyspneic and hypoxemic on exertion; by the time the FEV_1 falls to 25% of the predicted value, they may note shortness of breath at rest. Determination of the FEV_1 *before and after* inhalation of a *bronchodilator* (e.g., albuterol) can provide a quick estimate of the benefit a patient may derive from bronchodilator therapy. The failure to obtain an improvement in flow rate after a few inhalations of a bronchodilator does not rule out the possibility of benefit, but it suggests the likelihood is not great.

Sputum Examination. Gram's stain and *culture* of sputum can be helpful when acute pneumonitis is suspected, especially in patients exposed to multiple courses of antibiotics, but one must remember that prior colonization with *S. pneumoniae, H. influenzae*, or *Moraxella* may make interpretation difficult. Preliminary data suggest that examination of an *induced sputum specimen* for *eosinophils* may help predict responsiveness to glucocorticosteroids.

Chest Radiography is helpful, principally to rule out complications of COPD (e.g., pneumonia, pneumothorax) and other forms of chest disease that may present as dyspnea (e.g., heart failure, interstitial lung disease; see Chapter 40). Of the various forms of COPD, only severe emphysema is diagnosed radiologically; the criteria for radiologic diagnosis are the presence of two or more of the following findings: flattening of the diaphragm and blunting of the costophrenic angle on posterior–anterior view, irregularity of lung field lucency, enlargement of the retrosternal space, and flattening or concavity of the diaphragmatic contour on lateral view.

Measurement of Arterial Oxygen Saturation and Blood Gases is worth considering in patients with an FEV_1 less than 50% of the predicted value, a point at which hypoxemia is a possibility, especially in persons with chronic bronchitis. *Pulse oximetry* can be used as a screening test; it provides a measure of arterial oxygen

saturation (Sao_2). If the Sao_2 is less than 92%, then measurement of the arterial blood gases is indicated to assess oxygenation and ventilation. Hypoxemia and hypercarbia are indications of severe chronic bronchitis. Blood gas measurement is particularly useful for documenting acute decompensation. In patients with severe chronic bronchitis (FEV_1 <35% predicted), baseline and serial studies of blood gasses should be performed, so that measurements of gases obtained at times of marked subjective worsening can be compared with baseline determinations.

Hematocrit and Hemoglobin Concentration provide a rough indication of the severity and chronicity of hypoxemia and the possible need for phlebotomy. Measurement should be undertaken in persons with a Pao_2 of less than 50 mm Hg.

Electrocardiogram should be studied for sinus tachycardia, multifocal atrial tachycardia, peaked P waves (P pulmonale), and signs of right ventricular hypertrophy (e.g., tall R wave in lead V_1 and deep S wave in lead V_6). The electrocardiographic abnormalities that appear in COPD generally reflect the severity of lung disease and the presence of cor pulmonale.

PRINCIPLES OF MANAGEMENT

The prime goals of treatment are improvement of functional status, prolongation of survival, and avoidance of complications. The principal components of management to achieve these goals are elimination of precipitants and risk factors, prevention and treatment of infection, control of bronchospasm, mobilization of secretions, and reversal of chronic hypoxia. The success of treatment is strongly influenced by the physician's interest and the participation of patient and family in the program.

Removal of Precipitants and Prophylaxis against Infection

Smoking Cessation. Regardless of the severity of their disease or the types of deficits present, all patients with COPD *must stop smoking* and should be urged to do so in emphatic terms. As noted earlier, disease progression is accelerated by continued smoking and can be greatly slowed by its cessation. Nonetheless, a surprisingly large number of patients report receiving little or no warning about smoking from their physicians; studies indicate that the physician's urging can be critical to achieving cessation of smoking, especially for those who are symptomatic (see Chapter 54).

A reduction in exposure to other pulmonary irritants should be advised. Readily avoidable pulmonary irritants include aerosol deodorants, hairsprays, paint sprays, and insecticides. An occupational history should be reviewed (see Chapter 39) for important workplace irritants. A change in job or residence (for patients living in areas of severe air pollution) may be necessary but should be urged only when the relationship between exposure and disease is strong; otherwise, the advice might cause more harm than good.

Immunization against Influenza is essential for all patients with COPD. Reductions in outpatient visits, hospitalization, and mortality in elderly persons with COPD have been demonstrated with administration of influenza vaccine. Trivalent influenza vaccine should be given each fall, at least 6 weeks before the onset of the influenza season. Serious reactions are rare unless the patient is allergic to egg protein. Mild fever and myalgias are sometimes noted. Because of ever-changing viral strains, vaccination must be performed yearly (see Chapter 6). Should an outbreak of influenza occur, protection for patients who were not immunized can still be provided (see Chapter 6).

Pneumococcal Vaccine is equally important for patients with COPD. Available preparations incorporate the capsular antigens of 23 species that are responsible for 90% of the cases of pneumococcal pneumonia occurring in the United States. Mild erythema and pain at the injection site are the only common adverse reactions to the vaccine, which is administered as a single IM injection of 0.5 mL. A repeated dose in 5 years may help maximize antibody titers in the elderly (see Chapter 6). The antibody response is not blunted nor is the frequency of adverse reactions increased when the pneumococcal and influenzavaccines are given simultaneously. The only disadvantage is difficulty in determining the cause of hypersensitivity should a reaction occur.

Question of Prophylactic Antibiotics. Evidence regarding the use of prophylactic antibiotics is conflicting. The original studies performed in England suggested a benefit from the prophylactic use of antibiotics during the winter months, with a reduction in the number of exacerbations and days lost from work. Studies in the United States and Canada show a more modest benefit from antibiotic use in general, limited mostly to patients with severe COPD who experience an acute exacerbation of symptoms accompanied by purulent sputum (see below). Long-term antibiotic prophylaxis is not recommended.

Bronchodilation

Bronchodilators remain a mainstay of treatment, providing symptomatic relief of dyspnea in about 50% of patients through reduction of airway resistance. The mechanisms of action are diverse, complex, and less well understood than previously thought. In addition to bronchodilation, positive effects on mucociliary clearance, diaphragmatic action, cardiac contractility, and inflammatory mediator release have been described.

It is not always possible to predict who will respond to bronchodilators on the basis of the response to a single exposure to an inhaled b-agonist. Many patients fail to show a response to a single exposure but demonstrate a significant improvement in symptoms or ventilatory function on repeated testing or after an empiric clinical trial. Those who show considerable improvement in FEV_1 are the best candidates, but all patients with COPD and evidence of a severe obstructive defect should be considered for a trial, even those with air flow obstruction that appears fixed and irreversible (i.e., <15% improvement in FEV_1 after inhalation of a bronchodilator). Although a limited empiric trial is probably reasonable for all patients, bronchodilator therapy should not be continued unless a subjective or objective benefit is clearly shown. No evidence suggests that bronchodilator therapy improves the prognosis.

b-Agonists constitute the *first line* of bronchodilator therapy. Their principal role is to provide prompt relief as necessary from acute dyspnea induced by bronchospasm. In patients with mild or moderate disease, b-agonist therapy often suffices. In patients with more severe disease, b-agonists are used in conjunction with longer-acting bronchodilators (see below). The *metered-dose inhaler* (MDI) formulations of the topically active, semiselective *inhaled b_2-agonists* (e.g., *albuterol, metaproterenol*) are preferred for their rapid onset of action, minimal systemic side effects (the drugs are relatively bronchoselective), and reasonable duration of action (2 to 4 hours). Oral formulations of these drugs are available but less desirable because they tend to produce a greater number of systemic side effects (especially cardiac effects) without any prolongation in duration of action. At high doses, the relative bronchoselectivity of the inhaled b_2-agonists is lost.

At present, only short-term, as-needed use of these agents is indicated. The advent of long-acting b_2-agonist formulations (e.g., inhaled *salmeterol*) may provide an opportunity for long-term bronchodilation with b_2-agonist therapy, but at present, data are insufficient to recommend salmeterol over an inhaled muscarinic blocker (see below).

The use of inhaled b-agonists must be accompanied by thorough patient education. Their convenience and rapid onset of action sometimes lead to excessive use, so that development of *tachyphylaxis* is a risk. Conversely, dosing may be inadequate with improper MDI technique (see Chapter 48). The purported advantage of administering b-agonist therapy by means of an *intermittent positive pressure breathing* apparatus has been carefully studied in COPD and found to be lacking in the outpatient setting, even among such potentially relevant subgroups as patients with relatively severe disease, copious sputum, or emphysema. MDI administration is the delivery system of choice in the outpatient setting.

Anticholinergic Agents. Muscarinic blockers provide longer-acting bronchodilation ($6 hours), which makes them useful as a *second line* of bronchodilator therapy, complementing the shorter-acting b-agonists. An MDI formulation of *ipratropium* (a topically active muscarinic blocker that is poorly absorbed) is the principal means of delivering anticholinergic therapy. The rather slow onset of action of ipratropium, combined with a more sustained effect, makes it best suited for maintenance therapy in persons with persistent bronchospasm-induced dyspnea. It provides more effective bronchodilation than that afforded by round-the-clock use of b-agonists, although patients still benefit from "rescue" doses of a b-agonist when acute worsening occurs. Some patients use ipratropium at bedtime and a b-agonist as needed during the day. MDI application allows convenient delivery with a minimum of systemic side effects. The typical systemic anticholinergic side effects (e.g., blurred vision, urinary outflow obstruction, rapid heart rate) are rarely a problem when the drug is given in proper doses. Sputum volume can be reduced without increasing its viscosity.

Theophylline and its derivatives (e.g., aminophylline) have been relegated to *third-line* bronchodilator status in COPD, reserved for patients in whom b-agonists and ipratropium do not suffice. Although these methylxanthines are inexpensive and symptomatically helpful, they have demonstrated an inconsistent ability to improve

objective measures of air flow, a considerable number of cardiovascular side effects, and a narrow therapeutic range. Nonetheless, some patients report subjective benefit, perhaps related to effects other than bronchodilation (e.g., improved diaphragmatic and myocardial function, inhibition of inflammatory mediators). Improvements in respiratory function and dyspnea have been demonstrated in patients with severe COPD, although much of the benefit appears related to enhanced respiratory muscle performance. Patients who experience a worsening of airway hyperreactivity at night despite ipratropium may benefit from the addition of a long-acting, controlled-release theophylline formulation before bed.

The methylxanthines are available for outpatient use in oral and rectal formulations, but only the oral route should be used because rectal administration is associated with erratic absorption and a potential for dangerous sudden rises in serum concentrations. Absorption of an oral dose approaches 90%. Sustained-release preparations can provide therapeutic serum levels (8 to 12 µg/mL) for 12 to 24 hours. The wide variability in levels for a given dose is a consequence of individual differences in clearance, which is predominantly hepatic. Decreased clearance and increased serum levels occur with heart failure, hepatocellular disease, and drugs that inhibit the hepatic cytochrome oxidase system (e.g., cimetidine, macrolide antibiotics); smoking and intake of barbiturates increase clearance.

Serious side effects include *supraventricular* and *ventricular dysrhythmias* and *seizures*. Such adverse effects usually occur only when serum levels rise precipitously, but they can also occur while serum levels are in the "normal" range if concurrent heart failure or hypoxemia develops.

Choice of Agent and Utility of Combination Therapy. The decision to employ bronchodilators and the choice of agent are somewhat empiric; trial and error are usually necessary to arrive at an optimal program. A stepwise program has been recommended by some authorities, in which as-needed use of an inhaled b-agonist is the first line of treatment; the addition of inhaled ipratropium is the second line of bronchodilator therapy, used to maintain control in persons with relatively severe disease. Oral sustained-release theophylline is the third-line of therapy, usually reserved for persons who continue to experience difficulty at night despite administration of first- and second-line therapies. The benefit of reduced-dose combination therapy over full-dose single-agent therapy is not established, but many patients appear to benefit from combination programs.

Corticosteroids

With the growing appreciation for the role of inflammation in COPD has come a renewed interest in glucocorticosteroid therapy. Although steroids have become the mainstay of asthma therapy (see Chapter 48), their usefulness in COPD remains much less well established. In theory, steroid-induced antiinflammatory effects (e.g., suppression of cytokines, inhibition of eosinophils, stabilization of mast cells) have the potential to reduce the acute mucosal edema and bronchoconstriction of COPD flares and the subsequent airway remodeling and progressive loss of lung function of chronic active disease. In reality, well-designed prospective clinical trials have revealed marginal benefit at most. For example, in persons with an acute COPD flare requiring hospitalization, 2 weeks of systemic steroids was found to provide only a modest improvement in rate of treatment failures, length of stay, and pulmonary function. Eight weeks of therapy was no more efficacious than a 2-week course; at 6 months, no improvement in outcomes was demonstrated, and hyperglycemia severe enough to require treatment developed in many patients. In a 3-year trial of smokers with mild, stable COPD, the long-term use of high doses of inhaled steroids failed to reduce progressive loss of lung function. Metaanalytic study finds a modest (10%) chance of a reasonable (20%) improvement in FEV_1 among patients with stable, chronic COPD.

Some speculate that these spotty results and the lesser benefit of steroids in stable COPD than in asthma or COPD flares may be related to the nature of the underlying inflammatory reaction (predominantly neutrophilic in stable COPD and more eosinophilic in acute COPD flares and asthma). That only a small fraction of patients with stable COPD seem to benefit from steroids may reflect the heterogeneity of the COPD population, perhaps made up in part by asthmatic patients who have progressed to COPD yet remain at least partially steroid-responsive.

The current recommended role for glucocorticosteroids is as a *fourth line* of treatment, reserved for those who are not adequately controlled by the various forms of bronchodilator therapy. An *empiric 2-week trial* of full-dose *systemic steroids* (e.g., 40 mg of prednisone per day) is suggested, with measurement of FEV_1 to document objective improvement (i.e., >20%). Those who demonstrate objective benefit are continued on prednisone, which is tapered to the lowest effective dose, and then switched if possible to a program of *alternate-day prednisone* or an *inhaled nonabsorbable glucocorticosteroid* preparation (see Chapter 48) to limit adverse effects of steroids (see Chapter 105). At 8 weeks, the patient should be retested to confirm that objective benefit continues; otherwise, steroids should be discontinued. For patients with an acute flare necessitating hospitalization, a short course of systemic steroids is worth considering.

Improved means of rapidly identifying patients with steroid-responsive COPD are being sought; use of an induced sputum for the detection of increased numbers of eosinophils is under study.

Oxygen Therapy

Indications. Long-term *continuous oxygen therapy* prolongs survival and reduces the risk for cor pulmonale when administered to patients with COPD who are chronically hypoxemic (PO_2 <55 mm Hg). The more continuous the therapy, the better effect; round-the-clock oxygen therapy is superior to nocturnal oxygen administration. Maximum benefit requires continuous administration for at least *18 h/d*. Administration for less than 12 h/d is unlikely to be of any help. Although long-term *discontinuous oxygen therapy* at night or during activity is thought to be worthwhile for nonhypoxemic patients with COPD who manifest a drop in Pao_2 during sleep or low-level exertion, such therapy is not of proven benefit with regard to long-term survival or risk for pulmonary hypertension. Nonetheless, both forms of long-term oxygen therapy are reimbursable. (Current clinical criteria are listed in Table 47.2.) Most COPD patients with profound nocturnal hypoxemia also are hypoxic during the day and require continuous administration of oxygen. Concerns about the potential of continuous oxygen therapy to worsen carbon dioxide retention, especially during sleep, when carbon dioxide retention is at its worst, have not been borne out. Administration with nasal prongs usually suffices, and enough oxygen should be delivered to increase the resting PO_2 to 65 mm Hg and the exercise Sao_2 to more than 90%. Some recommend adding an additional 1 L of flow per minute during sleep and exertion.

Continuous long-term supplemental oxygen therapy
- Resting PO_2 < 55 mm Hg or
- Resting Sao_2 < 88% or
- Resting PO_2 of 56 to 59 mm Hg with evidence of concurrent right-sided heart failure or secondary polycythemia (hematocrit > 55%)

Noncontinuous long-term supplemental oxygen therapy (no resting hypoxemia)
- PO_2 < 55 mm Hg or Sao_2 < 88% with low-level exertion
- PO_2 < 55 mm Hg or Sao_2 <88% during sleep, especially with daytime sleepiness, cardiac arrhythmia, or cor pulmonale

Table 47.2. Accepted Indications for Reimbursable Long-term Oxygen Therapy

The need for *short-term supplemental oxygen* must be considered when *air travel* is planned. Prediction of the need for oxygen and tolerance of the cabin environment can be accomplished by preflight measurement of the arterial PO_2 and FEV_1. A formula has been derived based on these parameters to predict arterial oxygen levels at cruising altitude. Alternatively, one can have the patient inhale a hypoxic gas mixture (17.2% oxygen) that simulates the cabin environment of a jet aircraft at cruising altitude. Although no guidelines have been established for when to administer oxygen supplementation, a drop in PO_2 to below 50 mm Hg or the development of symptoms is a reasonable indication for oxygen supplementation during flights longer than 2 hours. Airlines will provide an oxygen supply if notified at least 48 hours in advance of travel; their units provide flows of 2 to 4 L of 25% or 30% oxygen per minute. Patients are usually not allowed to bring their own oxygen tanks into the cabin of domestic airlines.

Brief administration of oxygen has been touted to *improve exercise tolerance* in COPD patients. In unblinded studies, exercise tolerance improves, but in blinded, placebo-controlled study, little benefit has been demonstrated. Most hypoxemic COPD patients are chronically hypoxic and require continuous oxygen supplementation; brief administration is of no value to them. The small subset of patients who are hypoxemic and markedly dyspneic only with exercise might be

candidates for a trial of short-term oxygen supplementation. A convenient means of identifying such patients is to measure their diffusing capacity during routine pulmonary function testing, rather than trying to measure arterial blood gases just after or during exercise. A diffusing capacity above 55% has been shown to be 100% specific in excluding arterial hypoxemia during exercise; sensitivity is 68%. If oxygen is to be tried, it should be limited to those who have a reduced diffusing capacity and demonstrate consistently better performance on oxygen than on air when both are administered in single-blind fashion. Pulse oximetry during exercise is another means of identifying patients who might benefit from oxygen supplementation.

Initiating and Monitoring Therapy. Arterial blood gas measurement is the preferred determination for initiating oxygen therapy and adjusting it, particularly in patients who are at risk for retention of carbon dioxide with application of oxygen. Pulse oximetry is a convenient although slightly less precise substitute for blood gas measurement; it is most useful when therapy is being adjusted, especially if impaired ventilation is not a concern and measurement of the P$_{CO_2}$ is not necessary.

Control of Secretions

Secretions. Patients bothered by heavy, tenacious sputum may obtain benefit by maintaining good *fluid intake*, ensuring adequate *humidification* of the indoor environment (particularly in centrally heated homes), and practicing *postural drainage* when clearance of secretions is difficult and cough is incapacitating. The simplest method of postural drainage is to have the patient lean over the side of the bed, rest the elbows on a pillow placed on the floor, and cough as a family member or visiting nurse gently pounds on the chest. For hydration, ultrasonic nebulizers are no better than the simple maintenance of good systemic hydration, although the moisture they deliver does reach deep into the tracheobronchial tree. Occasionally, bronchospasm can be triggered by a nebulizer, and its reservoir can become contaminated and serve as a source of airway infection. Nebulized detergents are of no proven use, but *mucolytic agents* such as acetylcysteine are capable of thinning secretions; they are usually reserved for patients on respirators and not commonly used in outpatient practice. Oral *expectorants* are very popular with some bronchitic patients, who report improved ability to raise sputum; however, they are without proven clinical efficacy. These preparations need not be denied to the patient who feels that they are of benefit, but they should not be the mainstay of the therapeutic program. Glyceryl guaiacolate and potassium iodide are the most frequently prescribed expectorants; many are available without a prescription.

Exercise Training and Rehabilitation

The main elements of a pulmonary rehabilitation program are exercise training, breathing retraining, chest physiotherapy, psychosocial support, and patient education. Often, the program is carried out as an intensive intervention at a rehabilitation center for patients with advanced disease who are functionally limited; however, some elements can be initiated at home in earlier phases of the illness (e.g., exercise). The evidence of benefit is strongest for exercise training and psychosocial interventions. The benefit derived from a program of comprehensive pulmonary rehabilitation appears to decline with time after completion of the program, especially after a year; no improvement in survival has been demonstrated.

Exercise Training. Among the simplest and most effective measures for improving exercise tolerance is an *exercise training program. Walking* has proved to be the best form of exercise for increasing duration and intensity of activity in COPD patients. Exercises that involve the arms and upper body appear to compromise respiratory mechanics. Three or four sessions per day of walking are recommended, ranging from 5 to 15 minutes each. The pace and duration of activity are matched to the patient's capabilities; most begin the program walking at a half-maximal pace and build gradually through a period of several weeks. At the end of the training period, heart and respiratory rates for a given level of activity are decreased; oxygen consumption also falls. Parameters of ventilatory function are not significantly changed, but increases of 25% are attained in maximum duration and intensity of exercise. Many patients enjoy marked improvement in ability to carry out their daily activities. Although exercise training is often not implemented until patients become severely impaired, there is no reason why a walking program cannot be instituted earlier for most COPD patients.

Breathing Exercises may have some beneficial effect, especially psychologically, in those who readily panic and hyperventilate when dyspneic or show evidence of respiratory fatigue. Teaching the anxious patient to take slow, deep, relaxed breaths and exhale against pursed lips can lessen the work of moving air, provide a sense of control over breathing, and encourage a more relaxed respiratory pattern. Inspiratory muscle training is popular in some centers, with encouraging reports ofimprovement in exercise performance among patients who experience respiratory muscle fatigue. However, the importance of diaphragmatic dysfunction and the need for exercises continue to be debated.

Psychosocial Support in a comprehensive rehabilitation program entails group and individual meetings with a psychiatrist or other mental health professional in addition to sessions that include families or spouses to help them cope with the depression, anxiety, fear, and family dysfunction that COPD brings upon a household. Behavioral approaches are sometimes taught to patients, such as the breathing relaxation techniques noted above.

Chest Physiotherapy

See above.

Patient Education

See below.

Antibiotics for Acute Exacerbations

The relationship between an acute exacerbation of COPD and infection remains a subject of debate, as does the benefit of antibiotics for COPD flares. Metaanalysis of randomized trials of antibiotics for COPD flares find a positive but modest benefit that is most likely to be of clinical significance in persons with severe disease, especially those who require hospitalization. Because *pneumococci* and *H. influenzae* are the predominant organisms colonizing patients with COPD (*Moraxella* may also be a colonizer), *amoxicillin* or *trimethoprim/sulfamethoxazole* is a reasonable first choice of antibiotic when evidence of infection (fever, increased sputum production, increased sputum purulence) is present. For patients allergic to penicillin and sulfa drugs, *doxycycline* is a reasonable alternative, although not as effective against pneumococci. More broad-spectrum, penicillinase-resistant antibiotic coverage is worth considering in persons with severe disease who have four or more exacerbations a year or have concurrent heart failure or diabetes. Such patients are at increased risk for infection with gram-negative and resistant organisms. Under such circumstances, amoxicillin/clavulanate, a second- or third-generation cephalosporin, a macrolide, or a fluoroquinolone should be considered. Culturing the sputum can help rationalize antibiotic choice.

Management of Cor Pulmonale

Patients with chronic cor pulmonale can often be made more comfortable by careful attention to their volume status, degree of hypoxemia, and hematocrit. Reduction of excess intravascular volume can reduce edema; *diuretic therapy* (see Chapter 32) is an effective means of volume control. As noted earlier, continuous *low-flow oxygen therapy* is indicated in patients with cor pulmonale who are chronically hypoxic. Survival is improved, although the precise mechanism of improvement is unknown; pulmonary vascular resistance and secondary polycythemia are only modestly decreased. Whether oxygen therapy prevents the development or worsening of cor pulmonale is unsettled.

Focus is shifting to examination of cardiac output as a determinant of survival in patients with cor pulmonale. Augmented cardiac output is a normal response to a fall in PO$_2$. Many patients with cor pulmonale maintain a high cardiac index. It is suspected that a fall in cardiac output may be a determinant of poor prognosis. If this proves to be the case, then increased efforts at improving cardiac output may be indicated.

Previous attempts at inotropic therapy have produced equivocal results. *Digoxin* seems to help some patients, but not uniformly or predictably. The incidence of digitalis toxicity, which is aggravated by hypoxemia, is high; the clinical response is often equivocal. The drug is worth a try in patients with reduced cardiac output, especially if concurrent left ventricular dysfunction is present (see Chapter 32), but it should be continued only in those who show an objective in addition to a subjective response to therapy. Patients who do appear to improve with digitalis should be given a minimum maintenance dose and should be monitored closely for manifestations of digitalis toxicity (see Chapter 32).

Vasodilators (calcium channel blockers and angiotensin-converting enzyme inhibitors) have proved disappointing, with little improvement in cardiac output or

pulmonary artery resistance noted during sustained use in most patients. In some instances, systemic hypotension and even hypoxemia may result.

Phlebotomy is indicated only for urgent treatment when secondary erythrocytosis is severe enough to cause a marked reduction in blood viscosity, significant impairment of oxygen delivery, and exacerbation of cor pulmonale. The risk for such decompensation is greatest when the hematocrit rises above 55%.

Augmentation Therapy for a_1-Antitrypsin Deficiency

The rare patient with emphysema who has significant antitrypsin deficiency (<80 mg/dL) is a possible candidate for augmentation therapy (weekly or monthly infusions of a_1-antitrypsin). Only symptomatic patients with clinical evidence of emphysema and sufficiently low antitrypsin levels are considered appropriate for augmentation therapy because emphysema does not develop in all patients with low concentrations. A history of smoking rules out candidacy.

Surgical Interventions

Bullectomy is worth considering in the rare COPD patient with a few giant bullae unilaterally taking up more than a third of a hemithorax. Additional clinical criteria include being relatively free of severe emphysema and bullae in the contralateral lung, having chest computed tomographic evidence of bullae compressing lung parenchyma, and having an FEV_1 below 50% of the predicted value.

Lung Volume Reduction. This investigational surgical intervention for patients with late-stage nonbullous emphysema entails removing the most severely involved sections of emphysematous lung to improve pulmonary mechanics and gas exchange. Although initial reports are enthusiastic and encouraging, mortality at 1 year can be high (up to 25%). The place of such surgery in the management of emphysema remains to be determined.

Lung Transplant. Although transplant of a single lung has a reasonable 3-year survival rate (up to 70%), most COPD patients are not candidates because of advanced age, continued smoking, or concurrent cardiovascular disease, not to mention the fact that available lungs are in very short supply.

Monitoring Therapy

Functional status and *symptoms* remain among the most important measures of efficacy. Semiquantitative reports from the patient regarding such parameters as number of stairs climbed or distance walked can be useful. Subjective assessment of bronchospasm has been found to correlate surprisingly well with FEV_1 measurement in asthmatic patients, and this probably is valid for COPD patients also. Important aspects of the physical examination to be monitored include ratio of inspiration to expiration, respiratory rate, heart rate, jugular venous pressure, right ventricular impulse, and condition of extremities (edema). In a patient with known carbon dioxide retention, the presence of asterixis is an indication of worsening ventilatory status, further carbon dioxide retention, and encephalopathy. Serial determination of Sao_2, *arterial blood gases, FEV_1,* and *hematocrit* can help in objectively following the course of disease and detecting acute deterioration.

PATIENT EDUCATION

The first priority is to stress the importance of *cessation of smoking*; this should be followed by the design of a specific program (see Chapter 54). Patients should be encouraged to maintain as much activity as possible and be provided with an exercise program if they can be motivated to comply. Patient, family, and physician should be involved in setting reasonable and realistic activity goals. Advice regarding adequate hydration and pulmonary toilet is basic to the care of patients with chronic bronchitis. Patients likely to panic and hyperventilate when they become dyspneic often benefit from being taught how to institute slow, relaxed, deep breathing in such circumstances.

Careful instructions regarding the indications and adverse effects of therapy can help the patient to carry out the prescribed program properly. Complex regimens should be written down and reviewed with both patient and family. It is essential to warn patients with carbon dioxide retention against unauthorized use of tranquilizers and sedatives because of the risk for further suppression of their respiratory drive. Patients for whom inhalers have been prescribed should be thoroughly instructed in their proper use (see Chapter 48); many treatment failures are a consequence of poor technique. Such patients also must be warned that excessive use of b_2-agonists can lead to tachyphylaxis and cardiac side effects; persistent overdoses of inhaled steroids (more than 20 puffs per day) can cause adrenal suppression.

Part of the patient education process should aim to restore a modicum of self-confidence and self-reliance. Instruction in self-adjustment of the medical regimen, in monitoring and reporting functional status, and in implementation of a daily exercise program can have very positive effects on morale. The synergistic interaction of an involved patient and an interested and concerned physician has the potential to enhance the quality, if not the duration, of life for COPD patients.

INDICATIONS FOR ADMISSION AND REFERRAL

The patient with acute respiratory decompensation, especially if accompanied by signs of encephalopathy (e.g., asterixis, lethargy), should be urgently admitted to the hospital; no oxygen should be administered on the way to the hospital for fear of further suppressing the respiratory drive. Those with an acute exacerbation of cough, dyspnea, wheezing, and sputum production that is not immediately responsive to bronchodilator therapy might also require inpatient management and would possibly benefit from a pulmonary consultation. Pulmonary referral is also indicated when the patient remains chronically incapacitated despite a comprehensive program of standard medical therapy. Surgical consultation is not recommended without the prior recommendation of a pulmonary specialist.

THERAPEUTIC RECOMMENDATIONS

Basic Measures for All Patients

- Review the entire treatment program thoroughly with the patient and family; encourage patient participation in setting goals and monitoring functional status.
- Insist on complete *cessation of smoking* and design a comprehensive smoking cessation program (see Chapter 54).
- Advise the patient to reduce exposure to known environmental irritants and allergens (see Chapter 39, Chapter 48 and Chapter 222).
- Design, with patient participation, an *exercise program*; walking is probably best, although any aerobic exercise will suffice. Begin with an easily achieved level of activity (e.g., half-maximal pace) and increase slowly in small increments. Frequency is three to four times daily, with duration ranging from 5 to 15 minutes.
- Administer trivalent *influenza vaccine* (0.5 mL IM) in the fall of each year, at least 6 weeks before the usual winter onset of the flu season, to all patients with COPD (except those having a known allergy to eggs). Consider administering antiviral therapy to unvaccinated COPD patients during an influenza epidemic (see Chapter 6).
- Administer *pneumococcal vaccine* to all COPD patients. The dose is 0.5 mL IM, and it can be given at the same time as the influenza vaccine. Repeated administration after 5 years may needed in elderly persons (see Chapter 6).
- Advise patients bothered by heavy sputum production to keep well hydrated and to humidify the indoor environment (particularly those living in centrally heated homes). Nebulized detergents and oral expectorants are of no proven benefit. Teach postural drainage techniques to patients bothered by difficulty in raising sputum.
- Perform pulmonary function testing on all patients with a peak flow rate below 350 L/min, obvious bronchospasm, or dyspnea on exertion. Measure FEV_1 before and after inhalation of a rapidly acting bronchodilator (e.g., albuterol) to determine candidacy for bronchodilator therapy.

Stable Disease: Bronchodilator and Antiinflammatory Therapies

- Begin bronchodilator therapy in those who manifest an increase in FEV_1 of more than 200 mL/s or more than 12% in response to bronchodilator inhalation. Also consider an *empiric trial of a bronchodilator* for those who are symptomaticallydyspneic or show a substantial reduction in expiratory flow rate (e.g., FEV_1 <1.5 to 2 L/s or FEV_1/FVC <0.50), even if they do not demonstrate a response to a single dose of albuterol (single-dose response does not necessarily predict response to continuous bronchodilator therapy).
- For patients with mild, intermittent symptoms, begin with an MDI formulation of a rapidly acting b_2-*agonist* (e.g., 1 to 2 puffs of *albuterol* every 4 to 6 hours as needed). Carefully instruct the patient in proper MDI use (see Chapter 48) and warn that the dose is not to exceed 12 puffs in 24 hours. Exert caution in prescribing for patients with heart disease because these agents are relatively cardioselective at low to moderate doses.

- For patients who require or are not adequately controlled by round-the-clock b-agonist therapy, begin an MDI formulation of a topically active, nonabsorbed *anticholinergic* (e.g., 2 to 3 puffs of *ipratropium* four times daily) and supplement as needed with albuterol (1 to 4 puffs as needed for an acute flare or 2 puffs four times daily). Instruct patients to avoid getting ipratropium spray in their eyes, especially if they have narrow-angle glaucoma. The sequencing and timing of combination inhaler therapy do not seem to matter.
- Judge response to bronchodilator therapy on the basis of change in exercise tolerance and expiratory flow rates after about 4 weeks of therapy. Response to a single dose of inhaled bronchodilator does not predict response to continuous treatment. If no response can be demonstrated, then halt inhaled bronchodilator therapy.
- If some bronchodilator response is noted but control of symptoms remains inadequate, especially at nighttime, then consider adding a sustained-release oral *theophylline* preparation before bed (e.g., 200 to 400 mg of generic sustained-release theophylline daily at bedtime). Monitor symptoms closely for a response after about 4 weeks of therapy before deciding to continue therapy longer. Check serum theophylline level and adjust dose to achieve a therapeutic range of 8 to 12 µg/mL. Do not prescribe for patients with cardiac arrhythmias and prescribe with caution for persons with underlying heart disease. Do not use anal suppository preparations.
- Consider initiation of an empiric trial of *glucocorticosteroids* in persons who respond inadequately to bronchodilator therapy and remain symptomatic.
- For patients with stable COPD who fail to achieve adequate control of symptoms with bronchodilators, begin a 2-week trial of oral *prednisone* (40 mg/d) and check FEV_1 for objective improvement (>20%). If a response is noted, try switching to a topically active *inhaled corticosteroid* MDI formulation (e.g., 2 puffs of *beclomethasone* four times daily or 4 puffs twice daily), an alternate-day prednisone program, or the lowest effective dose of daily prednisone.
- After 6 to 8 weeks, evaluate for sustained response; if no symptomatic or objective improvement is noted, then stop inhaled steroid therapy.

Stable Late-stage Disease

- For patients with advanced disease who are functionally limited, consider referral for a comprehensive program of *pulmonary rehabilitation* that includes exercise training, breathing retraining, chest physiotherapy, psychosocial support, and patient education. Emphasis should be on those elements that have proved most beneficial (i.e., exercise training and psychosocial support).
- Teach slow, relaxed, deep breathing to patients likely to hyperventilate when dyspneic; consider targeted inspiratory muscle training in patients with severe COPD; a respiratory therapist may be of help in the teaching effort.
- Be sure the program includes detailed patient and family education to help sustain the benefit of a rehabilitation program once it is completed.
- Begin long-term *continuous oxygen therapy* in patients who are chronically hypoxemic [resting PO_2 <55 mm Hg, or 56 to 59 mm Hg if evidence of concurrent right-sided heart failure or secondary polycythemia (hematocrit >55%) is present].
- Provide continuous administration for at least *18 h/d*. Administration for less time is unlikely to improve long-term outcome and prognosis.
- Consider supplemental *noncontinuous oxygen therapy* during exertion to improve exercise capacity in nonhypoxemic patients only if they exhibit desaturation on pulse oximetry during exercise or a reduced diffusing capacity on routine pulmonary function testing; the patient should demonstrate consistently better performance on oxygen than on air when both are administered in single-blind fashion.
- For patients with cor pulmonale, begin a diuretic program (e.g., 20 to 40 mg of *furosemide* daily) when peripheral edema begins to develop; increase program as needed to control fluid accumulation caused by systemic venous hypertension. Phlebotomize the patient with secondary erythrocytosis (hematocrit >55%) when acute decompensation (worsening of right-sided heart failure or hypoxemia) is present.
- Consider a short-term trial of *cardiac glycoside* therapy (e.g., 0.25 mg of *digoxin* daily) in patients with severe right-sided heart failure; treat for 2 weeks and check for objective signs of improvement (e.g., decreased edema, lower jugular venous pressure, reduced heart size). Use with care in the setting of hypoxemia, and check serum levels regularly. Monitor closely for evidence of digitalis toxicity (see Chapter 32).
- Refer for consideration of *surgical therapies* only severely emphysematous patients with incapacitating disease refractory to a comprehensive program of maximal medical therapy who could tolerate a major thoracic surgical procedure and who have ceased smoking.

Acute Exacerbation

- Initiate intensive MDI bronchodilator therapy with a rapidly acting b-*agonist* (e.g., 6 to 8 puffs of *albuterol* immediately, then repeated every 30 to 60 minutes). If response is inadequate (e.g., patient still manifests marked dyspnea and severe wheezing) or the drug is poorly tolerated (e.g., palpitations, chest pain), then hospitalize; if response is adequate, add 4 to 8 puffs of *ipratropium* every 6 hours, reduce albuterol to 2 puffs four times daily, and follow closely.
- Consider initiating empiric *antibiotic* therapy, but only for patients with a new onset or marked increase of grossly purulent sputum in conjunction with other signs of infection (e.g., fever, elevated white cell count). Prescribe *amoxicillin* (500 mg three times daily) or *trimethoprim/sulfamethoxazole* (one double-strength tablet twice daily); *doxycycline* (100 mg twice daily) is a reasonable alternative for penicillin-allergic patients.
- Use of a broad-spectrum, penicillinase-resistant antibiotic (e.g., amoxicillin/clavulanate, a later-generation cephalosporin, a second-generation macrolide, or a fluoroquinolone) should be considered only for patients with severe COPD who manifest signs of acute infection plus risk factors for a resistant organism (i.e., more than four exacerbations a year, concurrent heart failure, diabetes). Culturing the sputum in such patients may help rationalize antibiotic choice.
- Consider a 2-week course of *systemic corticosteroids* (e.g., oral *prednisone* starting at 40 mg/d) for those with a severe exacerbation. Taper or if possible switch to alternate-day or high-dose inhaled therapy as soon as possible (see Chapter 48 and Chapter 105).

Indications for Consultation

- Obtain pulmonary consultation when the patient remains incapacitated despite a comprehensive, fully implemented program of medical therapy. Surgical consultation is not recommended without the prior recommendation of a pulmonary specialist.
- Refer patients with known a_1-antitrypsin deficiency for consideration of augmentation therapy with a $_1$-antitrypsin only if they do not smoke, show signs of emphysema, are symptomatic, and have an antitrypsin level below 80 mg/dL.

CHAPTER 48 MANAGEMENT OF ASTHMA

ALLAN H. GOROLL

INTRODUCTION

Asthma is a chronic inflammatory disease of airways that affects an estimated 5% to 7% of the population, with prevalence and mortality greatest among inner city residents and increasing. A heightened appreciation for the underlying inflammatory pathophysiology of asthma has markedly altered the approach to therapy in the past decade. Antiinflammatory agents have superseded bronchodilators as the mainstay of treatment.

Although there are no cures for asthma, effective outpatient management is available. Many exacerbations leading to emergency room visits are preventable, so much so that the frequency of emergency room visits for asthma has become a common outcome measure and proxy for quality of primary care. The primary care physician needs to be skilled in asthma management and able to design a practical, cost-effective program that minimizes side effects, maximizes functional status, and reduces the frequency and severity of flares. Because patient involvement in asthma care is essential to a good outcome, the development of a strong patient–doctor relationship and the provision of detailed patient education are extremely important.

PATHOPHYSIOLOGY, CLINICAL PRESENTATION, AND COURSE

Pathophysiology

Airway inflammation underlies the pathology and pathophysiology of asthma; characteristic features are mast cell degranulation, eosinophilic infiltration, endothelial activation, and recruitment and proliferation of T cells. The normal respiratory epithelium is denuded and replaced by proliferating goblet cells. The resulting edema, inflammatory exudate, and such bronchial hyperresponsiveness lead to airway obstruction. Bronchial hyperresponsiveness is exacerbated by loss of the normal epithelial barrier and can be triggered by exposure to allergens, exercise, cold, and pharmacologic agents. Epidemiologically important allergens leading to *sensitization* include *dust mite* and *cockroach* antigens, which helps to explain the high prevalence of asthma among inner city residents. Air pollutants and occupational exposures sensitize others.

Many precipitants and mediators of the bronchoconstriction, edema, and mucous production that characterize asthma have been identified; however, their precise roles and interrelationships remain to be elucidated. The list of mediators includes *prostaglandin D_2*, *leukotrienes* (slow-reacting substance of anaphylaxis), *eosinophilic chemotactic factor*, and *histamine.* Leukotrienes are emerging as particularly important mediators of inflammation. They increase the migration of eosinophils, production of mucus, airway wall edema, and bronchial hyperresponsiveness. They appear to be important triggers of bronchoconstriction on airway exposure to cold dry air, as in exercise- and cold-induced asthma.

Asthmatic reactions have early and late phases. The *acute bronchoconstrictive phase* involves the rapid development of reversible airway obstruction in response to stimuli that fail to affect normal persons. Stimuli include allergens (e.g., molds, sulfites, animal dander, pollens), aspirin, exercise, emotional stress, viral respiratory infections, and respiratory irritants, such as perfumes and dusts.

In addition to the initial mediator-induced bronchospasm, asthmatic patients experience a second or *late-phase reaction* 6 to 12 hours later. This late-phase reaction is believed to be a manifestation of the inflammatory response that is more refractory to bronchodilator treatment than the initial one. Neutrophil chemotactic factor is believed to play a role. Even some patients with exercise-induced asthma experience a late reaction.

Elements of a *neurogenic pathway* have also been elucidated. Bronchial smooth muscle is responsive to autonomic influences; it has not been determined whether the effect is direct or by way of biochemical mediators. Vagal stimulation and cholinergic drugs cause bronchial constriction; *t*-adrenergic stimulation appears capable of countering the cholinergic influences. Bronchial irritants and emotional stress are thought to precipitate bronchospasm, in part, by way of triggering vagal reflexes. The nerve endings of asthmatic patients have been found to be devoid of the bronchodilator neuropeptide vasoactive intestinal polypeptide.

Traditionally, asthma has been divided clinically into "extrinsic" and "intrinsic" categories, with extrinsic disease believed to be a manifestation of immunologic reactivity to environmental antigens, and intrinsic disease thought to be unrelated to allergen exposure. However, patients in both groups have demonstrated reactivity related to immunoglobulin E (IgE), which challenges the notion of separate allergen-related and non–allergen-related categories of asthma. Nonetheless, the categories are still used clinically (see following discussion).

It used to be thought that asthma was not associated with any permanent sequelae, but *airway remodeling* has been detected pathologically. The full physiologic significance of this remodeling remains to be determined, but declines in pulmonary function over time have been identified in long-term epidemiologic studies.

Clinical Presentation

Regardless of precipitant, the pathophysiologic final common pathway is airway inflammation, with bronchial edema, smooth-muscle contraction, and excessive mucus production. Clinical manifestations include *wheezing, dyspnea, cough,* and *sputum.* Presentations range from pure bronchospasm, with little cough and sputum production, to a predominance of bronchorrhea and coughing that mimics bronchitis or an upper respiratory tract infection. In fact, cough and sputum production may be the initial symptoms of an asthmatic attack. *Nocturnal exacerbation* of symptoms is common, linked to the diurnal variation in blood levels of catecholamines and vagal tone.

Extrinsic Asthma. Although classifying asthma according to allergen responsiveness may be an oversimplification, the extrinsic and intrinsic categories do describe two relatively distinct clinical presentations. Patients with *extrinsic asthma* typically give a history of atopy, onset of symptoms during childhood or adolescence, predictable seasonal occurrence, and response to environmental stimuli. However, the condition can occur at any age, and attacks may take place seasonally or year-round, precipitated by such common household allergens as dust mites, animal dander, and fungal spores. Anxiety, inhalation of airway irritants, and exposure to perfumes and strong household odors can also precipitate asthmatic episodes in these patients. The course of attacks is usually self-limited, although some patients have severe bouts requiring hospitalization. Prognosis is relatively good, with 70% found to be symptom-free 20 years after onset.

Intrinsic Asthma. Patients with *intrinsic asthma* usually begin having symptoms in the third or fourth decade. Although no identifiable extrinsic allergen is associated with attacks in these patients, they do demonstrate elevations in serum IgE, similar to those of patients with intrinsic disease. Sputum production can be considerable, so that differentiation from chronic bronchitis is sometimes difficult. Minor upper respiratory tract infections often precipitate attacks. Some patients present with exertional dyspnea or cough and no demonstrable wheezing, although expiratory flow rates are clearly reduced. Intrinsic asthma is sometimes more refractory to treatment than is extrinsic disease.

Postexertional Asthma. Postexertional asthma is a form of airway hyperreactivity most common in children and adolescents. The stimulus is believed to be a reduction in the temperature of inhaled air, which leads to mediator release (especially leukotrienes) in susceptible patients. Both initial and late-phase reactions have been identified. Vigorous exercise on a cold, dry day is particularly apt to trigger an attack; airway temperature can become quite low in such circumstances. Although bronchospasm does not occur during exercise, it becomes marked shortly after exercise ends and can last for up to an hour.

Occupational Asthma. Occupational asthma has gained increasing recognition as an important cause of work-related disability. True occupational asthma involves the development of sensitization through inhalation exposure to an occupationally related allergen. Exposure to irritant or toxic pollutants in the workplace can also

trigger bronchospasm, especially in a person with preexisting airway hyperresponsiveness. Cold air, sulfur dioxide in low concentrations, fluorocarbons, and inert dusts are common irritants that stimulate reflex bronchospasm. Toxic gases such as sulfur dioxide in high concentrations, halogens, ammonia, acid fumes, and solvent vapors cause inflammatory bronchoconstriction. Important allergens include animal proteins, enzymes, grain and cereal dusts, seeds, vegetable gums, and legumes. Other substances have pharmacologic activity; histamine-releasing compounds are present in cotton dust, organic acids are found in wood dust, and numerous chemicals have anticholinesterase activity. Some agents provoke asthma through multiple mechanisms; toluene diisocyanate (TDI) has reflex, pharmacologic, *b*-blocking, and IgE effects.

Patients with occupational asthma caused by toxic or irritant substances characteristically report a direct relation between exposure and onset of symptoms. Those with allergen-induced disease note no symptoms at the time of the first exposure but marked wheezing after even minor repeated contact with the allergen (anamnestic response). Typically, patients with occupational asthma are symptom-free during days off from work, only to have a flare-up on returning (see Chapter 39).

Nasal Polyps and Aspirin Sensitivity. Nasal polyps and aspirin sensitivity comprise a curious but important familial asthma syndrome. The bronchospasm associated with aspirin intake may be marked. The finding of nasal polyps in a person with a history of asthma should lead to consideration of aspirin sensitivity.

Categories of Asthma. For management purposes (see below), four categories of asthma have been defined:

- *Mild intermittent asthma*: symptoms no more than twice weekly and nighttime symptoms no more than twice monthly; lung function [peak flow rate, forced expiratory volume in 1 second (FEV_1)] reduced to no less than 80% of predicted; patient asymptomatic between exacerbations and peak expiratory flow rates normal between attacks.
- *Mild persistent asthma*: symptomatic more than two times per week but less than once a day, and nighttime symptoms more than twice monthly; episodes may affect activity; pulmonary function is normal in between episodes and decreases to no less than 80% of normal during episodes.
- *Moderate persistent asthma*: daily symptoms, daily use of b_2-agonists, nocturnal symptoms more than once a week; attacks limit activity; pulmonary function declines to 60% to 80% of normal and may not return to normal after an exacerbation.
- *Severe asthma*: symptoms continuous; frequent acute exacerbations; frequent nocturnal symptoms; activity limited; pulmonary function always abnormal and less than 60% of normal without treatment.

Clinical Course and Natural History

Regardless of the type of asthma, subclinical but significant bronchospasm remains for days to weeks after the wheezing of an acute attack subsides. The continuing bronchial hyperresponsiveness is believed to be related to ongoing inflammation. Often, small airways may remain constricted even after large airways have relaxed. The clinical recurrences that commonly develop shortly after the apparent resolution of an acute attack are most often not new episodes but relapses.

The natural history of asthma and the consequences of airway remodeling that result from chronic airway inflammation remain to be fully established, but in population studies with long-term follow-up, asthmatic patients demonstrate a significant and steady decline in FEV_1 in comparison with those without asthma. This decline is exacerbated by smoking. Overall mortality for all forms of asthma is 0.1% annually; the rate increases markedly to 3.3% for patients with episodes of status asthmaticus. A disturbing increase in asthma mortality has occurred in the past two decades despite the availability of increasingly effective therapy. The cause for this increase is unclear, but much of it is localized to inner city populations in New York and Chicago, which suggests that increased exposure to potent allergens and air pollution may be contributing, in addition to inadequate access to proper health care.

PRINCIPLES OF MANAGEMENT

Strategy

The appreciation of the pivotal role of inflammation in the pathophysiology of asthma has led to a major restructuring of treatment, with *antiinflammatory therapy* emerging as the foundation of treatment for long-term control and *bronchodilators* relegated to a supporting role. The consensus view is that all patients with active disease should be started and maintained on continuous antiinflammatory therapy and that bronchodilators should be used as primary therapy only for those with infrequent, mild exacerbations and to prevent postexertional or cold-induced flares. The previous reliance on long-term bronchodilator therapy as first-line treatment has been largely abandoned because such therapy does not correct the underlying pathophysiology and is associated with poor outcomes (see below). *Patient education* takes on heightened importance because of the need for constant monitoring, compliance, and timely adjustment of the treatment program.

As always, when confronted with an acute attack of bronchospasm and before initiating therapy for asthma, the physician should not forget to consider briefly the other acute causes of wheezing (e.g., pulmonary edema, pulmonary embolization, laryngeal edema, airway obstruction by tumor or foreign body, chronic obstructive lung disease flare; see Chapter 32, Chapter 40, Chapter 41, and Chapter 42).

Review of the patient's medication list is also indicated. Concurrent use of noncardioselective beta-blockers in asthmatics with underlying hypertension or cardiovascular disease can cause bronchospasm and blunt the bronchodilating effects of beta-2 agonists. Concern about beta-blocker therapy has been reduced by the advent and judicious use of cardioselective (beta-1) beta-blockers (e.g., atenolol, metoprolol). Meta-analytic work found only a 7.5% reduction in FEV_1 in mild to moderate asthmatic patients with addition of a cardioselective beta-blocker and no impairment of the bronchodilating effects of beta-agonist therapy. Most asthmatic patients with a clear indication for beta-blockade (i.e., those with hypertension, coronary disease, or heart failure) need not forego or stop beta-blocker therapy as long as cardioselective preparations are used and doses are kept low. However, safety of cardioselective beta-blockade in those with severe asthma is not well established.

Updated: 01/31/03

Practice Guidelines. Recognizing the need to develop and promulgate a new treatment paradigm for asthma, the National Institutes of Health convened expert panels to develop *clinical practice guidelines* for asthma management and published them as the *National Asthma Education Program* (NAEP) (see below). A stepped approach to care is utilized, based on the category of asthma manifested. The regular use of topically active *inhaled corticosteroids* is recommended, supplemented by selective use of *inhaled b_2-agonist* bronchodilators. Oral steroids, other antiinflammatory agents, and other bronchodilators are used in adjunctive fashion. *Patient education* is a central feature of the guidelines because of the importance of compliance to successful management. Underuse of antiinflammatory therapy and failure to monitor peak flows correlate strongly with an increased number of emergency department visits and hospitalizations.

Implementation and Compliance. Like most practice guidelines, many of the NAEP recommendations are supported by the results of randomized, controlled trials (e.g., respective roles for inhaled steroids and bronchodilators), whereas others (e.g., approaches to monitoring and self-care) are based on expert opinion. Primary care physicians may need to customize for individual patients those elements that pertain to patient self-monitoring and self-treatment of an exacerbation. For example, treatment of an exacerbation might need to be stereotyped rather than based on peak flow, and the patient instructed to contact the physician if symptoms do not resolve within a few hours. Surveys indicate that fewer than 50% of asthma patients who should take inhaled steroids daily do so, and fewer than 20% measure their peak flow regularly. Some have suggested that time pressures and staffing limitations in primary care practices may limit the teaching effort and contribute to inadequate outcomes. They propose *disease management* strategies, which emphasize the use of information technology to identify patients, customize the teaching intervention, monitor care, and control costs. The efficacy of the disease management approach is being evaluated.

Treatment Guidelines (Incorporating the National Asthma Education Program Recommendations)

Mild Intermittent Asthma. The treatment of choice is *bronchodilator* therapy as needed with a *short-acting b_2-agonist*, such as albuterol (Table 48-1). As-needed use is preferred to regular use, which is no more effective and may induce tachyphylaxis. *Patient education* includes instruction in proper inhaler use and technique, the role of medication, and avoidance of environmental precipitants. If b_2-agonist therapy is needed more than twice weekly, therapy for mild persistent asthma should be considered.

Table 48-1. Drugs for Asthma

These agents are also effective as *prophylaxis* for mild episodes of exercise- or cold-induced asthma when taken a few minutes before the inciting activity. If exercise is going to be very prolonged or prolonged protection against unexpected exercise is desired, then one might consider an as-needed dose of a *long-acting b_2-agonist (e.g., salmeterol)*. Regular daily use of a long-acting b_2-agonist is not recommended because of the association of high-dose *b*-agonist therapy with adverse outcomes (see below). Alternatives for prophylaxis of mild exercise-induced asthma include inhalation of *cromolyn* or *nedocromil* powder before activity and once-daily oral use of *montelukast*.

Mild Persistent Asthma. Antiinflammatory therapy is added to the program to provide long-term control. A *low-dose inhaled glucocorticosteroid* is the treatment of choice (see [Table 48-1]). Alternatives include *cromolyn* or *nedocromil*. Use of a leukotriene-altering agent (e.g., *montelukast*) appears promising as another approach to antiinflammatory therapy for mild disease. Patient education should include initiation of periodic self-monitoring with a *peak flow meter*. Treatment of acute symptoms with as-needed use of a short-acting b_2-agonist continues as for mild intermittent disease; any requirement for daily or increased dosing should lead to consideration of therapy for moderate asthma.

Moderate Asthma. Frequent exacerbations require increasing the dose of *inhaled steroids* to at least *moderate* levels or continuing low doses and *adding an inhaled long-acting b_2-agonist* (e.g., salmeterol) or a bedtime dose of *theophylline*, especially if nocturnal symptoms are present. Although *montelukast* is not as effective for maintenance as are inhaled glucocorticoids, adding this antiinflammatory agent may allow reduction of the steroid dose. Patient education should stress *daily* monitoring of *peak flow* and increasing the dose of inhaled steroid at the first indication of a decline in peak flow. Treatment of acute symptoms with as-needed use of a *short-acting b_2-agonist* is the same as for mild persistent disease; continued requirements for daily or increased dosing should lead to consideration of therapy for severe asthma.

Severe Asthma. The foundation of therapy is *high-dose inhaled steroids*, supplemented during exacerbations by short courses of high-dose *systemic glucocorticosteroids* (e.g., oral prednisone). The prednisone program is rapidly tapered and discontinued after 5 to 10 days. Use of a *long-acting b_2-agonist* or *theophylline* can help control symptoms (particularly nocturnal exacerbations) and may reduce steroid requirements. Daily patient *monitoring of peak flow* and prompt initiation of maximal antiinflammatory therapy (e.g., high-dose prednisone) at the first sign of a marked decline in airway function are critical to avoiding severe exacerbations and emergency department visits. Use of a *short-acting inhaled b_2-agonist*, supplemented if necessary by inhaled *ipratropium*, can help ease the symptoms of a severe bronchospastic attack, but these drugs are no substitute for maximum antiinflammatory therapy. The role of montelukast in severe disease remains to be defined.

Refractory cases require consideration of exacerbating factors, such as exposure to offending allergens, gastroesophageal reflux, sleep apnea, and allergic bronchopulmonary aspergillosis (suggested by an eosinophil count >1,000/mL). *Immunotherapy* is indicated if a responsible allergen is identified, and a trial of proton pump inhibition can be helpful in persons with suspected reflux (see [Chapter 61]). The most common cause of refractory disease is *poor compliance* with the inhaled corticosteroid program and failure to monitor peak flows, which indicates a need for more patient education and counseling.

Treatment Modalities (In Order of Use in Stepped Care)

b_2-Agonist Bronchodilators. As noted above, bronchodilators have been relegated to a supporting role in the treatment of asthma. The inhaled semiselective b_2-agonists are the bronchodilators of choice; they produce prompt potent bronchodilation and little systemic adrenergic stimulation when used in moderation.

Preparations. Most preparations are available in aerosolized form dispensed from a *metered-dose inhaler* (MDI). A few are breath-actuated, but most require breath–hand coordination. The onset of action is very rapid, and systemic absorption occurs. Some preparations are available as *nebulized solutions*. Nebulized delivery offers few advantages over MDI delivery and costs more, but patients unable to use pressurized aerosols (e.g., the very young, the elderly) may benefit; doses delivered are higher, but the onset of action is slower than with MDIs and the equipment is not portable.

The *short-acting* preparations (e.g., *albuterol, pirbuterol, terbutaline, bitolterol*) have a rapid (2 to 5 minutes) onset of action that lasts 4 to 6 hours. Generic albuterol is well tolerated and among the least expensive. *Levalbuterol*, the L-isomer of albuterol, is available for delivery as a nebulized solution; it offers no particular advantages in safety or efficacy over racemic albuterol. Some of the short-acting inhaled agents are also available in longer-acting oral formulations; however, these formulations are not recommended because the onset of action is delayed, systemic adrenergic side effects can be considerable, and better-tolerated long-acting formulations are now available.

The inhaled *long-acting b_2-agonists* (e.g., *salmeterol*) provide up to 12 hours of bronchodilation with a minimum of systemic side effects, so that they are well suited for maintenance therapy. Because their onset of action is delayed, they do not obviate the need for a short-acting b_2-agonist when acute bronchospasm arises. At present, they are used only in conjunction with a program of corticosteroid therapy because concern persists (see below) regarding an increase in airway hyperresponsiveness and adverse outcomes when b_2-agonists are used on a regular basis without antiinflammatory therapy. The cost per dose is about two times that of the short-acting preparations.

The modern b_2-agonists have largely replaced the *nonselective b-agonists* (e.g., *isoproterenol, ephedrine, metaproterenol, isoetharine*), which have a very short duration of action and can cause severe adrenergic side effects (palpitations, nervousness, cardiac dysrhythmias).

Adverse Effects. When used in high doses, all semiselective b_2-agents can trigger systemic adrenergic side effects (e.g., *palpitations, tremor, tachycardia*). High doses may also cause *hypokalemia*. A worrisome retrospective report found that overuse of inhaled b_2-agonists was associated with *worsening asthma control* and *increased asthma mortality*, which raises a warning about sole reliance on these agents for asthma management. Explanations for the observed findings range from delay in starting needed antiinflammatory treatment to direct toxic effects, such as exacerbation of *bronchial hyperresponsiveness*. In persons with mild asthma, regular use of inhaled albuterol confers no clinical advantage over as-needed albuterol, but a small significant increase in bronchial hyperresponsiveness results—an increase that could conceivably be injurious to persons with more severe disease. Ongoing prospective study should help clarify the issue. Regular use of both short- and long-acting preparations may lead to *tolerance* to their bronchoprotective effect. Continuous use of salmeterol for prophylaxis shortens the duration of its protective effect.

Recommended Use. The use of *short-acting* inhaled preparations should be limited to providing prophylaxis for exercise- and cold-induced asthma and symptomatic relief of acute symptoms. These agents are to be taken only on an *as-needed basis*. Frequent bronchodilator use is an important sign of disease exacerbation and the need for additional antiinflammatory therapy. The regular use of a *long-acting* preparation may have a role in moderate and severe asthma, but only as an *adjunct* to steroid therapy, helping to sustain control and moderate steroid requirements. Acute attacks still require addition of a short-acting b_2-agonist.

Inhaled Glucocorticosteroids. The *first generation* of inhaled glucocorticoids (e.g., *beclomethasone, triamcinolone, flunisolide*) were developed in an effort to achieve the advantages of long-term steroid therapy without the systemic side effects. With regular use, many of the histologic features of asthma disappear, airway

hyperresponsiveness reverts to normal, and the number of exacerbations declines. These agents are topically active, bind to airway cell receptors, and inhibit transcription and translation of cytokines and protein mediators. Airway eosinophilia is reduced, but not entirely eliminated, which suggests that some degree of airway inflammation persists despite their use. The effect on lipoid inflammatory mediators is more variable, with leukotriene synthesis less consistently inhibited.

Systemic absorption of inhaled steroid from the lung is limited, but some of the inhaled dose invariably is swallowed. Effective first-pass hepatic metabolism of drug absorbed from the gastrointestinal tract limits systemic effects, but such effects, including adrenal suppression, can increase with the use of very high doses (see below). *Second-generation* formulations (e.g., *fluticasone, budesonide*) exhibit improved steroid-receptor binding in the lung and enhanced first-pass hepatic metabolism; however, any advantage in clinical outcomes remains to be determined.

Preparations. Most first-generation preparations are dispensed through *MDIs*, which require hand–breath coordination and a chlorofluorocarbon propellant. At equivalent doses, they demonstrate similar efficacy and differ predominantly in dose of steroid delivered per inhalation and cost per canister (see Table 48-1). In response to environmental concerns, the halogenated propellants are being phased out. To improve droplet delivery of drug to the lungs and reduce oropharyngeal deposition, a number of preparations come with a built-in *spacer*, which can also be purchased separately. For those who experience difficulty with hand–breath coordination, one of the *inhalation-triggered* dry-powder formulations (e.g., budesonide) may be worth considering (cost is also low). The risk for adverse systemic effects is greatest with preparations delivering the highest dose of inhaled steroid per puff, as fewer puffs are needed to exceed the safe daily limit.

Adverse Effects. When used at moderate doses, the inhaled corticosteroids are well tolerated and produce few adverse systemic effects. The principal localized complaints, *sore throat* and *hoarseness*, are consequences of oropharyngeal deposition of the inhaled steroid and subsequent *oropharyngeal candidiasis* and *vocal cord muscle weakness*. They can be minimized by better inhaler technique (facilitated by use of a spacer, as explained below), rinsing and gargling after MDI use, and use of nystatin mouthwash for established thrush. The risk for adverse systemic effects caused by currently available preparations of inhaled glucocorticoids becomes a concern with sustained use at high doses (750 to 850 μg/d). *Hypothalamic–pituitary–adrenal suppression, decreased bone density, growth retardation in children*, and *glaucoma, cataracts*, and *dermal thinning in the elderly* have all been described. The risks associated with long-term therapy at lower doses remain to be defined.

Use. The topically active, inhaled preparations are preferable to systemic steroids in most instances because systemic adverse effects are limited at the usual doses, so that the risk for systemic steroid–related complications is greatly reduced. Although highly effective, the oral and parenteral preparations of systemic glucocorticoids (e.g., prednisone, methylprednisolone, hydrocortisone) should be reserved for severe exacerbations and refractory disease and used for as short a period as possible (see below).

The original recommendations for inhaled steroids called for administration four times daily, but *twice-daily* regimens are nearly as effective and greatly facilitate compliance with maintenance therapy. Only during exacerbations might dosing four times daily be desirable. The onset of action is usually gradual, and it may take days for the patient to notice improvement—inadequately prepared patients may report that "the drug is not working." Full benefit may not be evident for several weeks. Response is generally dose-related.

The use of *high-dose* inhaled steroids can reduce the need for systemic steroids in many cases of severe asthma, especially when supplemented by b_2-agonists and other drugs. During severe acute exacerbations, a short course of high-dose systemic steroids is indicated because topical steroids may not penetrate obstructed airways, where need is greatest. Patients with extrinsic asthma may benefit from a topically active steroid also applied as a nasal spray during the ragweed season (see Chapter 222).

Oral Glucocorticosteroids. Systemic steroids remain the most effective treatment for asthma, especially the severe, acute exacerbations of this chronic inflammatory disorder. Limiting their use is the set of serious side effects associated with prolonged daily glucocorticosteroid intake (see Chapter 105). *Prednisone* is the most widely prescribed oral preparation; the cost is very low. Its half-life is 12 to 24 hours. Onset of action occurs clinically within 8 to 12 hours of intake.

Use and Adverse Effects. A *short-term course* (5 to 10 days) of high-dose prednisone (40 to 60 mg/d) begun at the earliest signs of an acute exacerbation can control an attack that does not respond promptly to maximum doses of inhaled steroids and bronchodilators. When combined with rapid tapering to full cessation within 5 to 10 days, a short course can obviate the need for emergency department treatment, reduce the risk for acute relapse, and avoid adrenal suppression.

Any *long-term* systemic steroid therapy should be confined to patients with chronic disabling symptoms refractory to maximal doses of all other forms of treatment. The adverse consequences of prolonged daily use of systemic glucocorticoids (osteoporotic fractures, adrenal suppression, skin changes, aseptic necrosis of bone, aggravation of diabetes mellitus) may outweigh the benefits in all but the most severe cases.

In most instances, regular use of high-dose inhaled steroids supplemented by bronchodilator therapy and short courses of systemic steroids can obviate the need for long-term systemic steroid use. If it proves difficult to withdraw oral steroid therapy entirely, one can try an *alternate-day regimen* supplemented by full doses of inhaled steroid; this results in less adrenal suppression and fewer steroid-related adverse effects than does daily systemic therapy (see Chapter 105). Refractory cases require investigation for exacerbating factors (see above).

Although always desirable, a switch from long-term systemic steroids to an inhaled steroid program must be planned carefully to avoid triggering an exacerbation of asthma or precipitating adrenal insufficiency. Slow tapering of the daily dose, use of alternate-day steroid programs, and initiation of full doses of inhaled steroids and adjunctive therapies are essential. Before any long-term program of systemic steroids is discontinued, a Cortrosyn stimulation test (which assays the level of adrenal responsiveness) should be considered to help determine the speed of tapering (see Chapter 105).

Cromolyn Sodium and Nedocromil. Cromolyn sodium and nedocromil prevent the degranulation of mast cells, so that they are useful as prophylactic agents for *exercise-* or *allergen-induced asthma* and as substitutes for inhaled steroids in mild persistent disease. They have no direct bronchodilator activity but can decrease airway hyperresponsiveness through their action on mast cells. They are not as effective as inhaled b_2-agonists for immediate use before exercise or exposure to cold air. Their regular use may avert the need for inhaled corticosteroids. A 4-week empiric trial is needed to assess efficacy; there is no way to predict response, and it may take weeks to emerge. Patients who fail a trial should be prescribed inhaled steroids, which are more effective. Because these drugs possess no direct bronchodilator activity, they should not be used to treat attacks.

Preparations and Use. Cromolyn is taken by the *inhaled* route. It is now available in an aqueous solution, so that the frequency of reactions to the often-irritating powdered formulation has been reduced. The dose schedule for patients with chronic asthma is one capsule four times daily. For prophylaxis of exercise-induced asthma, the patient inhales for several minutes before exercise or exposure to a known allergen. (Patients with exercise-induced asthma who cannot tolerate cromolyn can inhale a b_2-adrenergic aerosol a few times before engaging in activity). Cromolyn is expensive but is free of adverse side effects and should be considered a first-line drug in asthma prophylaxis. *Nedocromil* resembles cromolyn in action and effectiveness but is unrelated chemically. Use is similar to that of cromolyn. Side effects are minimal.

Leukotriene Modifiers. Appreciation of the role of inflammation in asthma has stimulated interest in inflammatory mediators and agents that inhibit them. The drugs of this class interfere with leukotriene activity, either by inhibition of synthesis (*zileuton*) or receptor antagonism (*montelukast* and *zafirlukast*). They are less efficacious than inhaled steroids, but they have proved useful for *prophylaxis* of mild exercise-induced asthma and for *control* of mild to moderate persistent disease. Their role in the treatment of more severe categories of persistent disease, especially in combination with inhaled steroids, remains to be determined; it is hoped they will have a steroid-sparing effect. Predictors of response have not been identified, so that a therapeutic trial is necessary. These drugs are especially effective in the treatment of aspirin-induced asthma. They are costly, and their long-term safety and efficacy, especially in persons with relatively severe disease requiring concurrent use of other drugs, has not been established. A vasculitis-like hypersensitivity reaction has been reported in association with leukotriene modifier therapy when concurrent steroid therapy is cut back.

Preparations. Of the available leukotriene modifiers, *montelukast* is the best tolerated and easiest to use. Its once-daily dosing schedule, reasonable efficacy (effective in two thirds of cases), and few adverse effects (it is the only drug in this class approved by the Food and Drug Administration for use in children under the age of 12) make it a practical though somewhat expensive choice for prophylaxis of exercise-induced asthma. It also shows promise for control of mild to moderate persistent asthma, allowing reductions in steroid and bronchodilator requirements. Drug absorption is not affected by food intake. The other agents in this class are of similar efficacy but more difficult to use. *Zileuton* requires qid dosing and can cause hepatocellular injury, necessitating close monitoring of transaminases. *Zafirlukast* has the disadvantages of reduced bioavailability when taken with food and reduced efficacy when taken with other asthma drugs (e.g., theophylline). It also impairs

warfarin metabolism, and transaminase monitoring is required.

Theophylline and Its Derivatives. The role of the methylxanthines *theophylline* and *aminophylline* (a derivative salt of theophylline) in asthma care has narrowed with the advent of faster, safer, more effective therapies (see above). Current use is limited to patients with moderate to severe asthma bothered by *nocturnal exacerbations* and to those with refractory, steroid-dependent disease. Although the methylxanthines became popular because they were the first oral active bronchodilators, their current usefulness as an adjunctive therapy may be a function of effects other than bronchodilation. They improve diaphragmatic function, myocardial contractility, and mucociliary transport and demonstrate such antiinflammatory effects as inhibition of anaphylactic mediator release and suppression of mast cell response. Their low cost and the availability of sustained-release preparations facilitate utilization.

Preparations. The preferred oral preparation is *aminophylline.* The half-life of oral theophylline or aminophylline averages 6 hours but can range from 4 to 8 hours; much individual variation is seen because of differences in clearance rates. Clearance occurs predominantly by hepatic biotransformation. Impairment of hepatic microsomal activity raises serum levels and prolongs duration of action. Generic *sustained-release formulations* provide therapeutic serum levels for 12 to 24 hours at low cost and in convenient once- or twice-daily dosing regimens.

A number of formulations previously used for acute bronchodilation are no longer recommended, including *theophylline elixir* (expensive, very short-acting, erratic absorption), aminophylline *suppositories* (erratic absorption, unpredictable serum levels), and *combination preparations* (inability to titrate theophylline dose, irrational combinations of agents).

Adverse Effects. *Adverse effects* are proportional to the serum level. The therapeutic index of these drugs is narrow (10 to 20 μg/mL), and monitoring of serum levels helps to ensure both safety and efficacy. Serum determinations are best obtained from blood drawn 4 to 6 hours after the last dose. The minor gastrointestinal side effects (*nausea, vomiting, reflux, diarrhea*) and the minor neurologic side effects (*agitation, tremor, insomnia*) are largely dose-related but can occur even at subtherapeutic serum levels. The gastrointestinal side effects are not affected by route of administration. Levels above 20 μg/mL are associated with a marked increase in risk for drug toxicity; at levels above 35 μg/mL, life-threatening *ventricular arrhythmias* can occur. *Seizures* refractory to standard anticonvulsant therapy have occurred without warning in patients with serum levels above 40 μg/mL.

Dosage and Use. When used for bronchodilation, methylxanthines were always prescribed in doses sufficient to achieve the "therapeutic range" (i.e., 10 to 20 μg/mL), which bordered on toxicity. Smaller doses of the drug (producing serum levels of 8 to 10 μg/mL) appear sufficient for reducing inhaled steroid requirements and improving nocturnal symptoms. Such supplementary *low-dose programs* are promising and may become the norm, providing a well-tolerated and inexpensive addition to current expensive treatment regimens.

The efficacy and safety of *IV methylxanthine* therapy for acute exacerbations of asthma requiring urgent or room-conducted care remains controversial. Failure in room-conducted studies to demonstrate additional bronchodilation beyond that achieved with *b*-agonists alone, and the association of such treatment with increased risks for cardiopulmonary toxicity, have blunted enthusiasm for its use. Nonetheless, some have found the need for hospital admission and assisted ventilation to be reduced.

Anticholinergic Therapy: Ipratropium. Ipratropium, a topically active muscarinic blocking agent similar to atropine, is available as an MDI preparation. It is particularly useful in chronic obstructive pulmonary disease, in which its bronchodilator effects rival those of the *b*-agonists (see [Chapter 47](#)). Its efficacy is considerably less in asthma, although it may add some marginal bronchodilation to that provided by b_2-agonist therapy in severe bronchospasm. Compared with b_2-agonists, it is longer-acting but slower to take effect. Unlike atropine, it is poorly absorbed, has little systemic effect, and can be used in patients with glaucoma and prostatism. However, care should be taken to avoid spray contact with the eyes in patients with narrow-angle glaucoma. It is the bronchdilator of choice for *b*-blocker–induced bronchospasm and appears useful in the elderly. A combination preparation with albuterol is heavily promoted but not approved by the Food and Drug Administration for the treatment of acute bronchospasm.

Other Agents. *Methotrexate* has been studied as a steroid-sparing agent for patients dependent on systemic steroid therapy. Although worth considering in refractory cases, this form of immunosuppressive therapy is not without its own serious toxic side effects (see [Chapter 88](#)).

Antibiotics have a limited role in prophylaxis. Although viral upper respiratory infections frequently precipitate attacks—making *influenza vaccination* a must—bacterial infections do not. Heavy sputum production has often been mistakenly attributed to infection when it was actually a manifestation of asthma. However, in cases in which bacterial infection is strongly suggested by sputum Gram's stain, prompt treatment with an appropriate antibiotic (see [Chapter 43](#)) is important pending confirmation by culture.

Allergen Avoidance and Immunotherapy. *Allergen identification* is worthwhile, especially in patients with seemingly refractory disease, with incapacitating seasonal disease, or in occupational settings (see [Chapter 39](#)). Although history is helpful in suggesting allergens, *skin testing* helps to confirm them and also will identify additional allergens that are likely to be clinically important. Avoidance of exposure and desensitization are too often overlooked as important components of the prophylactic management program.

Desensitization therapy (with intradermal injections of offending allergens; see [Chapter 222](#)) has been shown in controlled study to reduce the frequency and severity of asthmatic episodes when a *single offending allergen* can be identified. It can reduce or eliminate the need for systemic steroid therapy. Patients with refractory extrinsic asthma should be considered for allergen testing and desensitization, especially when a single, well-defined, unavoidable seasonal allergen is suspected. Use of immunotherapy for perennial allergic asthma in which the patient is sensitive to multiple allergens has not proved effective.

Avoidance of the offending agent(s) can be an important component of therapy and limit exacerbations even when desensitization is not feasible. Detailed patient education can be very helpful, especially when simple effective measures are recommended (e.g., use of air-conditioning during periods of air pollution, covering mattresses and pillows with impermeable sheets and pillowcases, elimination of wall-to-wall carpets and heavy draperies to limit exposure to dust mite allergen). Unfortunately, avoidance is not always feasible, and pharmacologic methods of prophylaxis may have to be used.

Monoclonal Anti-IgE Antibody. A small proportion of patients with severe asthma and no evidence of atopy often require systemic steroids for control of their disease. Evidence suggests that IgE antibody produced locally in the airway tissue of such patients may be pathophysiologically important. Initial studies of humanized monoclonal anti-IgE antibody to block the action of airway IgE are promising; such therapy may obviate the need for high-dose, long-term systemic corticosteroids.

Monitoring Therapy

Assessment of symptoms, signs, and expiratory flow rates (peak flow and FEV_1) is the basis of monitoring. The patient's subjective perceptions are remarkably accurate and useful for monitoring. *Estimates by patients* of daily changes in airway obstruction and the severity of their condition correlate better with measurements of peak expiratory flow than do the clinical assessments of their physicians.

Certain physical findings, such as the *ratio of inspiration to expiration*, help to judge the degree of bronchospasm semiquantitatively. However, wheezes and related physical findings are not sensitive indicators of airway obstruction. The absence of wheezes does not indicate resolution of bronchospasm (see below). *Pulsus paradoxus* and *sternocleidomastoid retraction* are signs of severe obstruction that suggest an FEV_1 of less than 1 L/s, but these findings are not inevitably present when expiratory flow rates are very low. Moreover, much variation is found between the degree of paradox and the severity of bronchospasm.

Spirometry provides additional sensitivity that helps to identify changes in airway function in the absence of symptoms and to categorize the severity of disease. If possible, the FEV_1 should be measured by the physician at each office visit and during exacerbations, and the *peak expiratory flow rate* measured by the patient regularly and during exacerbations. The FEV_1 is still prolonged at the time wheezes disappear. Even after the FEV_1 has returned to normal, measures of small-airway obstruction (e.g., *maximum midexpiratory flow rate*) continue to indicate bronchospasm. The clearing of wheezes signifies little more than partial resolution of large-airway bronchospasm; small-airway bronchoconstriction may still be prominent and slower to resolve. Failure to continue therapy beyond the resolution of audible wheezes and acute phase of bronchoconstriction is generally associated with a high rate of relapse.

Self-monitoring is made practical by use of a *hand-held peak expiratory flow meter*. In the NAEP guidelines, monitoring of peak flow both periodically and during

exacerbations is central to treatment decisions (see above).

Sputum and *blood eosinophil counts* correlate with the response to therapy in patients treated with steroids for an acute attack. Although blood eosinophilia is not an invariable feature of an acute exacerbation of asthma, it does decline with improvement of expiratory flow rate. The same holds true for sputum eosinophilia. The usefulness of the eosinophil count for predicting relapse and response to therapy is unsettled.

Arterial blood gases provide important information in severe cases, particularly adequacy of ventilation. A carbon dioxide pressure (P $_{CO_2}$) that is inappropriately high for the respiratory rate indicates ventilatory failure and an urgent need for hospitalization. However, because arterial blood gases are not readily available in most office settings, decisions usually must be made without them. *Chest radiography* rarely provides information of use in decision making.

Thus, some of the most easily obtained parameters (the patient's subjective assessment of severity, ratio of inspiration to expiration, pulsus paradoxus, sternocleidomastoid retraction, peak flow, and FEV_1) are among the more meaningful guides to clinical status and severity of illness.

The Seemingly Refractory Patient

Patient noncompliance is often the cause of "refractoriness." Common shortcomings include *improper inhaler technique, underutilization of antiinflammatory medication*, and *overdependence on bronchodilators*. Poor hand–breath coordination, the slow onset of action of inhaled steroids, fear of steroid side effects, and ignorance of the inflammatory nature of the illness contribute to such behavior. Other common patient mistakes include reliance on *nonprescription agents*, such as low-dose adrenergic inhalers, and *alternative medicine remedies* of no proven efficacy (e.g., acupuncture for asthma). Physician *inattention to allergen identification* is another common shortcoming; referral for allergen testing is indicated when the patient appears unresponsive to treatment.

Management of the Pregnant Patient

Fetal morbidity and mortality are increased if asthma is uncontrolled during pregnancy. Most asthma drugs are safe to use during both during pregnancy and breast-feeding, although in some instances data are lacking because of the difficulty in performing controlled studies. Epinephrine increases the risk for fetal malformations, and the safety of the b_2-agonists and cromolyn remains to be established; until safety is proven, they should be avoided if possible. The use of inhaled steroids at moderate doses appears to be without serious consequence, and even systemic steroids can be prescribed if necessary. Theophylline is safe, as is penicillin. Erythromycin is a reasonable alternative in penicillin-allergic patients; tetracycline is contraindicated because it damages fetal liver, bone, and teeth.

PATIENT EDUCATION

Patients need to be made partners in the management of their asthma. Successful outcomes depend on good compliance and proper use of medication. Instruction in *preventive measures* is always appreciated by patients. The bedroom environment deserves particular attention. Covering the mattress and pillows with impermeable materials limits exposure to dust mite allergen, a potential trigger of asthma and its exacerbations. Wall-to-wall carpets are another source of such allergens and should be avoided. Because asthma is a condition characterized by periodic exacerbations, every patient who is capable of understanding and carrying out a medication program should be given instructions for initial self-treatment of an attack, along with strong advice to call the physician promptly if relief does not come quickly. Patients need to know that excessive delay may lead to refractory bronchospasm. Home use of a *hand-held flow meter* has helped encourage patient participation in monitoring and adjusting treatment in timely fashion.

Addressing patient concerns and providing written information facilitates *compliance*. Many worry about becoming "dependent" on medication or "immune" to it. These fears need to be addressed openly. A medication booklet that lists prescribing information, side effects, and indications for use alongside a picture of the medication can be helpful to patient and family. Often, patients mistakenly stop the wrong medication or cease therapy altogether because they are fearful or unfamiliar with the side effects of their medications.

Patients in whom bronchospasm is triggered by air pollution, pollens, or exercise need an *activity prescription*. Staying indoors, avoiding physical exertion, and using air-conditioning on particularly bad days are helpful measures. Those with exercise-induced asthma need not restrict themselves so long as prophylactic measures suffice; however, very cold, dry days may be difficult.

Patients with asthma caused by occupational exposure or household factors need careful *counseling* when such difficult alternatives as leaving a job, giving up a favorite pet, or moving to a new location are being considered. Often, less extreme measures are adequate (see above). A number of patients with allergic asthma request advice about desensitization treatment. Allergen testing and consideration of a trial of such therapy are reasonable if episodes are frequent and incapacitating and a single allergen can be identified (see above and Chapter 222).

Patients receiving steroids deserve an extra measure of instruction, particularly when switching over from systemic to aerosol therapy. Writing out the tapering schedule and emphasizing the importance of taking systemic steroids at the time of an exacerbation or major stress will help minimize the risk for adrenal insufficiency.

The *pregnant patient* with asthma will be reluctant to take medication. Detailed counseling about which medications can be used with safety and the importance of asthma control to the health of the fetus is needed to ensure compliance and alleviate concern.

Inhaler Technique. With the growing importance of MDI therapy, proper inhalation technique is essential. The delivery of drug to distal airways is facilitated by *increased duration of breath holding* and by *prolongation and moderation of inspiratory flow*. Rapid inspiration deposits drug in the upper airway; very deep inspiration is no better than moderate inspiration. During periods of respiratory distress, a greater number of inhales may be needed to deliver an adequate dose to the distal airways. Thus, patients need to be instructed to increase the number of inhales during a period of respiratory distress if benefit is not immediately forthcoming; however, they should also be reminded that rapid, deep inhales are neither necessary nor desirable. Extreme care is warranted when the b_2-agonist dose is increased because systemic absorption will occur when drug is deposited in the proximal airway.

Correct MDI use involves hand–breath coordination (i.e., coordinating inspiration with actuation of the MDI), a skill that takes some practice to master. Two recommended approaches are (a) placing the inhaler between closed lips, actuating the inhaler, breathing in, and holding the breath, and (b) holding the mouthpiece 3 to 4 cm from open lips, releasing the medication at the beginning of a full 5-second inspiration, and holding the breath for 10 seconds. The latter technique is a bit more difficult but preferred because less of a jet effect is created to deposit drug on the retropharynx; twice the dose is delivered to the lower respiratory tract if the inspiration is moderate, prolonged, and accompanied by breath holding.

Many patients make the mistake of inhaling first, then actuating the canister, holding their breath for 2 or 3 seconds more, and exhaling before taking the first inhale. Others inhale through the nose. Because many patients cannot perform aerosol inhalation correctly after a demonstration, they need to practice under observation. Moreover, about half forget how to do it when tested on follow-up. Repeated checks of technique are important.

Use of a Spacer. More than 40% of patients cannot master such techniques and need to use an inhalation chamber, often referred to as a "spacer." Commercially available spacers are aerosol-holding chambers that not only eliminate the need for hand–breath coordination but also cut down on oropharyngeal deposition of steroid. They improve delivery substantially, minimize adverse topical effects of inhaled steroids, and improve overall control. They should be considered for persons who cannot master MDI technique and for those who demonstrate inadequate disease control. Their principal disadvantage of most spacers is their bulky size, although some inhalers come with spacers built in.

Breath-Actuated Systems. A few b_2-agonists and inhaled steroid preparations are now available in *breath-actuated formulations*. These are triggered by inhalation and do not require as much hand–breath coordination as do MDIs.

INDICATIONS FOR ADMISSION AND REFERRAL

Admission. One of the most difficult determinations is predicting the need for hospitalization at the time of initial presentation. Ability to make such predictions is

particularly important for the care of patients with severe attacks who visit the office or emergency department. Some have argued that the response to maximum nonsteroidal therapy is a good predictor of immediate outcome and need for admission. Most studies provide little evidence that any one parameter is predictive, although one group noted that patients who sat bolt upright on admission to the emergency department had a strong likelihood of requiring admission. Another group developed an index of multiple clinical parameters selected by multivariate discriminant analysis to predict the need for hospitalization. A pulse rate of more than 120/min, respiratory rate of more than 30/min, pulsus paradoxus of more than 18 mm Hg, peak expiratory flow rate of less than 120 L/min, moderate to severe dyspnea, accessory muscle use, and wheezing were the presenting clinical parameters used in the index. Although in the investigators' setting the index was capable of distinguishing between those who required admission and those who did not (sensitivity, 95%; specificity, 97%), it did not function nearly as well when applied prospectively by other investigators in their emergency department settings.

Without more definitive means of prediction, clinical status and response to therapy remain the most helpful guidelines for decision making. Consideration of hospital care is indicated for patients with an acute attack who manifest any one of the following:

1. Subjective report of severe difficulty breathing
2. Failure to respond fully and promptly to inhaled b_2-agonist therapy followed promptly by full doses of prednisone
3. Use of accessory muscles of respiration (sternocleidomastoid retraction)
4. Pulsus paradoxus of more than 10 mm Hg
5. FEV_1 of less than 1.0 L/s; peak flow reduced by more than 50% and declining
6. Arterial PCO_2 inappropriately high for respiratory rate
7. Underlying cardiac condition
8. Inadequate home situation or a history of poor compliance

Referral. In certain instances, timely referral can be most helpful. Referral for patient *teaching* and *measurement of air flow* is essential if one's practice does not have the time, materials, equipment, or expertise available. *Identification of allergens* and *irritants* is another indication for referral and must be accomplished if the patient is to be advised regarding avoidance of precipitants, even if desensitization is not indicated. *Failure to respond* to treatment, particularly if frequent severe exacerbations necessitate the use of systemic steroids, is yet another indication for referral.

THERAPEUTIC RECOMMENDATIONS

Mild Intermittent Asthma

- Prescribe use as needed of an *inhaled semiselective b_2-agonist* (e.g., 2 to 3 puffs of *albuterol*, repeated in 20 minutes if necessary) for an episode of bronchospasm and for a few minutes before exercise or exposure to cold as prophylaxis for exercise- and cold-induced asthma. Avoid regular use.
- If an alternative to albuterol is desired for prophylaxis, consider a trial of *cromolyn* or *nedocromil* (2 puffs inhaled a few minutes before activity or exposure to cold).
- If exercise is going to be very prolonged or prolonged prophylactic protection against unexpected exercise is desired, prescribe use as needed of a *long-acting b_2-agonist* (e.g., 1 to 3 puffs of salmeterol twice daily taken at least half an hour before exercise) or a *leukotriene receptor antagonist* (e.g., 10 mg of *montelukast* every morning). Avoid regular use of salmeterol because it may decrease the duration of protection.
- Teach patient self-management program, including proper inhaler technique, importance of as-needed use only, and avoidance of environmental precipitants.
- Consider advancing to treatment of mild persistent asthma if more than twice-weekly use of b_2-agonist therapy is required.

Mild Persistent Asthma

- Add daily *antiinflammatory* therapy; begin *low-dose* inhaled glucocorticosteroids (e.g., 2 to 4 puffs of *beclomethasone* twice daily); if it is desired to avoid corticosteroids, begin a 4-week trial of a *mast cell stabilizer* (e.g., 2 puffs of *cromolyn* or *nedocromil* two to four times daily) or consider *montelukast* (10 mg every morning).
- Teach the patient how to perform periodic self-monitoring with a *peak flow meter* and how to make a prompt adjustment in the steroid dose with any decline in air flow.
- Continue treatment of acute symptoms with as-needed use of a *short-acting b_2-agonist*. Any requirement for *daily* or *increased* dosing should lead to consideration of therapy for moderate asthma.

Moderate Persistent Asthma

- Advance antiinflammatory program to *intermediate-dose* inhaled *corticosteroids* (e.g., 4 to 8 puffs of *beclomethasone* twice daily).
- If *nocturnal symptoms* are a problem or it is desired to limit steroid exposure, continue low-dose inhaled steroid therapy and add either a *long-acting b_2-agonist* (e.g., 1 to 2 puffs of *salmeterol* every 12 hours) or a methylxanthine (e.g., 300 mg of *extended-release theophylline* daily at bedtime) to the program. Never use a long-acting bronchodilator in the absence of corticosteroid therapy.
- Consider *montelukast* (10 mg every morning) as another alternative for limiting steroid dose in persons with mild to moderate disease.
- Continue treatment of acute symptoms with as-needed use of a *short-acting b_2-agonist*. Any requirement for *daily* or *increased* dosing should lead to consideration of therapy for severe asthma.
- Emphasize the need for *daily* monitoring of *peak flow* and increasing the dose of inhaled steroid at the first sign of a decline in peak flow.
- Continue as-needed use of a *short-acting b_2-agonist* for treatment of acute symptoms; continued requirements for daily or increased dosing should lead to consideration of therapy for severe asthma.

Severe Persistent Asthma

- Advance the antiinflammatory program to *high-dose* inhaled *corticosteroids* (e.g., 4 to 6 puffs of *beclomethasone* four times daily) and supplement with a long-acting b_2-agonist (e.g., 2 puffs of salmeterol every 12 hours) or sustained-release theophylline (300 mg every 12 hours, with regular monitoring of the serum theophylline level).
- For acute severe exacerbations, supplement inhaled steroids with a short course of high-dose *systemic glucocorticosteroids* (e.g., prednisone started at 40 to 60 mg/d and tapered to full cessation within 5 to 10 days).
- Emphasize to the patient the importance of regular daily *monitoring of peak flow* and prompt initiation of high-dose prednisone at the first sign of markedly declining airway function. Have the patient fill a prednisone prescription and keep it for prompt initiation of therapy. Inform the patient that any delay in initiating steroid therapy and overreliance on short-acting bronchodilators can be dangerous.
- Continue as-needed use of a *short-acting b_2-agonist* for treatment of acute symptoms and consider adding a trial of inhaled *ipratropium* (e.g., 2 puffs as needed) if b_2-agonist therapy alone does not suffice for an acute attack. Increase the number of puffs of short-acting bronchdilator and monitor the patient carefully if the exacerbation is marked (e.g., peak flow <60% of predicted). A short course of systemic steroids should be considered and started promptly if improvement is not rapid.
- Consider any persistent requirements for daily or increased dosing of bronchodilator therapy as indications to add daily systemic steroid therapy (e.g., 10 to 20 mg of prednisone every morning).
- Make repeated attempts to taper systemic steroids to the lowest dose sufficient to prevent attacks and, if possible, discontinue systemic steroids; if discontinuation of systemic steroids is not possible, then consider switching to alternate-day therapy (e.g., 10 to 20 mg every other day). To facilitate tapering and maintain control, continue inhaled corticosteroid therapy at full doses in conjunction with long-acting bronchodilator program.
- Taper systemic steroids slowly if the patient has been taking prednisone long enough to cause hypothalamic–pituitary–adrenal suppression (see Chapter 105). At times of stress and severe flares, be sure inhaled steroid therapy is at maximum doses and consider resuming full doses of systemic steroid therapy (e.g., 40 to 60 mg of prednisone per day) until episode passes.
- In *refractory cases*, check for and treat any exacerbating factors, such as exposure to an offending allergen, gastroesophageal reflux, sleep apnea, and allergic bronchopulmonary aspergillosis (suggested by an eosinophil count >1,000/mL). *Immunotherapy* is indicated if a single responsible allergen is identified. Check for *poor compliance* with the inhaled corticosteroid program and failure to monitor peak flows, which indicate the need for more patient education and

counseling.

For All Patients

- Before treating for asthma, always briefly consider other causes of bronchospasm and wheezing.
- Identify offending allergens and irritants; consider skin testing, especially if a single allergen is suspected (e.g., seasonal asthma), and desensitization if a single allergen is discovered; design an avoidance program for those with multiple allergens; emphasize smoking cessation for those who continue to smoke.
- Encourage active patient participation in management by providing parameters (such as changes in peak flow or symptoms) for self-initiated adjustments in treatment. Be sure the patient is fully informed about medications, their side effects, and proper use.
- Teach proper use of the *hand-held peak flow meter, MDI*, and *spacer*. Demonstrate and check inhaler and peak flow meter technique. Consider breath-activated inhalers for persons who cannot use MDIs.
- Provide written instructions for carrying out the treatment programs for maintenance and exacerbation, with emphasis on what to do when. Keep it simple and customized to the patient's capacity for compliance. Directly elicit and address any patient concerns.
- Remind patients to avoid overreliance on short-acting bronchodilators for disease control and never to use antianxiety agents or sedatives in the setting of an exacerbation.
- Remember that a severe exacerbation (peak flow <60% of predicted) can occur with any category of asthma and that prompt initiation of a short course of prednisone (40 to 60 mg/d with rapid tapering to cessation in 5 to 10 days) should be considered if a prompt response to bronchodilators and full doses of inhaled steroids does not occur.
- Administer *trivalent influenza vaccine* each fall at least 6 weeks before the start of the flu season. Also administer *pneumococcal vaccine* (see Chapter 6).
- Arrange prompt emergency department care if signs of severe airway obstruction are present (e.g., peak flow reduced by 50%, pulsus paradoxus, FEV_1 <1 L/s, use of accessory muscles of respiration).
- Consider referral for patients who require systemic steroids frequently or persistently.

CHAPTER 49 MANAGEMENT OF TUBERCULOSIS

BENJAMIN DAVIS AND HARVEY B. SIMON

The primary care physician most commonly encounters tuberculosis (TB) as a positive tuberculin skin test result in the absence of active infection. An estimated 7% of the U.S. population may fall into this category. Alternatively, the primary care clinician sees active TB, which is becoming increasingly common among HIV-positive persons and other high-risk populations (see Chapter 38). Through the years, diagnosis and treatment have shifted from the sanitarium and specialist to the community and primary physician.

The rapid diagnosis and treatment of TB are impaired by several factors, including inadequate sensitivity of skin testing and sputum smears, a wide variety of clinical presentations, the several weeks required to obtain confirmatory cultures and antibiotic sensitivities, long treatment regimens (with associated adherence problems), and the emergence of drug-resistant strains. In addition, many clinicians have little experience with the disease and often do not suspect its presence. Even patients admitted to university hospitals may experience a delay in diagnosis, with some cases recognized only at autopsy. In addition, the management of TB has undergone such tremendous changes that studies have demonstrated suboptimal management by many general physicians in the United States. Clearly, the diagnosis and treatment of TB pose major challenges for the primary physician.

PATHOPHYSIOLOGY AND EPIDEMIOLOGY

Virtually all cases are acquired through *person-to-person aerosol* transmission of a nonmotile, acid-fast, gram-positive rod. People with active pulmonary infection shed infecteddroplets, which are then aerosolized into the environment. Because most infectious patients discharge relatively few organisms, casual contacts are at low risk for infection, and most secondary cases occur among household members, schoolmates, or other close contacts of the index case. TB is more common in immigrants and population groups in which crowding, poverty (especially homelessness), or a high risk for HIV infection is commonplace (see Chapter 38). Among HIV-infected patients, the risk for disease after infection is increased 1,000-fold. Serious outbreaks (with attack rates of 10%) have been reported among patients in hospital wards with a large concentration of AIDS patients.

Most persons harboring the tubercle bacillus mount an immune response sufficient to prevent progression from *primary infection* to clinical illness; they manifest a positive skin test result. About 5% of infected persons fail to contain the primary infection and progress to *active primary disease* within 2 years of initial infection. The proportion of infected persons who progress is much higher among AIDS patients. In the past, primary infection occurred almost entirely in childhood; however, as the epidemiology of tuberculosis has changed (see Chapter 38), primary tuberculosis is now also seen in adults, particularly among elderly nursing home residents and patients on AIDS wards. *Nosocomial tuberculosis* may be developing into an important problem. A worrisome characteristic of some nosocomial outbreaks has been the emergence of organisms *resistant* to one or more antituberculous drugs.

Another 5% of infected patients (again, a higher proportion of AIDS patients) experience *reactivation of latent endogenous infection*, most often within 2 to 4 years of the initial infection or at times of lowered host resistance. However, reactivation can occur many decades after initial infection, as reported among elderly nursing home residents. More than one fifth of patients with reactivated disease have histories of inadequately treated clinical TB. In many instances, a discrete insult to host defenses, such as steroid therapy, alcoholism, malnutrition, neoplastic disease, HIV infection, or gastrectomy, can be implicated, but at times it is impossible to identify the reason for reactivation.

Until the advent of polymerase chain reaction (PCR) technology and development of the techniques of molecular epidemiology, the vast majority of active TB cases in the United States were thought to represent reactivation of latent disease. Several recent studies, however, have suggested that in large metropolitan centers such as San Francisco and New York City, between 35% and 40% of active tuberculosis cases represent *newly acquired infection*. Although the AIDS epidemic accounts for some of this change in epidemiology, it is clear that clinical disease develops shortly after infection in more immunologically "normal" persons than was previously thought.

CLINICAL PRESENTATION AND COURSE

Primary Infection. As noted above, more than 90% of patients are entirely asymptomatic at the time of primary infection and can be identified only through conversion of the tuberculin skin test from negative to positive. The majority of these patients have normal findings on chest radiography. Among the 10% who progress directly to symptomatic disease, four broad syndromes can be identified: (a) *Atypical pneumonia* is the most common, characterized by fever and nonproductive cough. Chest x-ray films may show unilateral lower lobe patchy parenchymal infiltrates or paratracheal or hilar adenopathy. Although such patients should receive full antituberculous chemotherapy when the disease is diagnosed (see below), it usually resolves even without treatment. (b) *Tuberculous pleurisy* and effusion are accompanied by fever, cough, pleuritic chest pain, and occasionally dyspnea. Chest x-ray films reveal unilateral pleural effusions, often without identifiable parenchymal lesions. The tuberculin test result is almost always strongly positive. Diagnosis depends on examination and culture of the pleural fluid or on percutaneous needle biopsy of the pleura because sputum cultures are positive for organisms in only 30% of such cases. (c) *Direct progression* from primary disease to upper lobe involvement is another presentation. (d) Early *systemic dissemination*, which used to be seen exclusively in children, now occurs in HIV-infected patients.

Reactivation (Postprimary) Tuberculosis. Notwithstanding our greater understanding of primary disease, this is still the most common clinical form of TB. Symptoms usually begin insidiously and progress during a period of many weeks or months before diagnosis. Constitutional symptoms are often prominent, including *anorexia, weight loss*, and *night sweats*. Most patients have *low-grade fever*, but higher temperatures and even chills may be seen occasionally when the disease progresses more rapidly. In addition, most patients present with pulmonary symptoms, including *cough* and *sputum production*. Dyspnea is relatively uncommon in the absence of underlying chronic lung disease. A frequent complaint is *hemoptysis*, often in the form of bright red streaks of blood caused by bronchial irritation. Although physical examination findings are usually nondiagnostic, chest x-ray films are highly suggestive of the diagnosis. Typical features include *infiltration* in the *posterior apical* pulmonary segments, which may be unilateral or bilateral and progresses to frank *cavitation*. Apical lordotic views and chest tomography may be helpful in documenting cavitary disease. Occasionally, postprimary TB may involve the lower lung fields, and in rare instances the chest radiographic appearance may be normal. The tuberculin skin test result is positive in about 80% of patients with reactivation tuberculosis; patients with advanced disease are often malnourished and thus anergic.

Extrapulmonary Tuberculosis. Approximately 20% of all newly recognized cases of TB in the United States are extrapulmonary. Although the frequency of pulmonary TB is constant, the incidence of extrapulmonary disease is increasing, largely among HIV-positive patients (see below). Although the clinical features of extrapulmonary TB vary widely, certain generalizations are possible. Past history is not a reliable guide to the diagnosis. Only 25% of patients have a past history of TB; of these, virtually all have been inadequately treated. A long latent period between the first episode of infection and the extrapulmonary presentation is typical. Approximately 50% of patients with extrapulmonary disease have entirely normal chest radiographic findings; most of the others have stigmata of old, inactive pulmonary disease, and a minority have coexisting active pulmonary infection. Although extrapulmonary disease can involve all organ systems, either singly or in various combinations, the most commonly affected areas are the genitourinary tract, musculoskeletal system, and lymph nodes.

The most common type of extrapulmonary TB is infection of an individual organ system. The patient is most often afebrileand can be entirely free of constitutional complaints. The illness typically pursues an indolent course characterized by local organ dysfunction and eventual destruction rather than by progressive general decline. In fact, the clinical presentation in these persons more often suggests neoplastic disease than infection. The tuberculin skin test result is almost always positive. Clinical syndromes in this category include genitourinary tuberculosis, tuberculous arthritis and osteomyelitis, tuberculous lymphadenitis, and many others.

HIV-positive patients with TB may experience extrapulmonary disease and dissemination early on. When CD4-cell counts are well preserved (see Chapter 13), tuberculous infection usually causes pulmonary disease that resembles TB in HIV-negative persons. However, in more severely immunocompromised HIV patients,

TB is often disseminated at presentation. A high incidence of tuberculous *meningitis* has been reported among HIV-positive patients, often in conjunction with *diffuse lymphadenopathy*. The occurrence of pulmonary or extrapulmonary TB in patients with HIV infection fulfills the criteria for the diagnosis of AIDS.

In HIV-infected patients with disseminated disease, the result of the purified protein derivative (PPD) skin test is often negative. Chest radiographic findings are normal in more than 10% of patients. When infiltrates do occur, they are often nonspecific and involve the lower lobes. Despite these atypical features, the diagnosis can usually be established, if suspected, without much difficulty by visualizing or culturing the causative organism from the sputum or extrapulmonary sites.

Atypical Mycobacterial Infection. Clinical infection with *atypical mycobacteria* is not seen often in primary care practice. Representative syndromes caused by these organisms include cervical adenitis in children (scrofula), pulmonary infection, and cutaneous disease (swimming pool granuloma). Disseminated disease occasionally takes place in immunosuppressed persons. For example, *Mycobacterium avium-intracellulare* has been a major cause of disseminated infection in patients with AIDS. Unlike tuberculous infection in HIV-positive patients, which can be disseminated in the early stages of illness, *M. avium-intracellulare* infection does not cause disseminated disease until late.

DIAGNOSIS

The tuberculin *skin test* is the most sensitive test for the diagnosis of infection with *Mycobacterium tuberculosis* (see Chapter 38); it is far more sensitive than chest radiography. A positive tuberculin test result does not by itself prove the presence of active disease but does indicate that infection has occurred. Negative tuberculin reactions have been documented in 20% of patients with TB, particularly those with overwhelming or advanced disease, malnutrition, and debility. In HIV-positive patients, especially those with low CD4-cell counts, the rate of false-negative skin test results has been as high as 50%. When active pulmonary disease is present, the diagnosis of pulmonary TB can usually be confirmed by examination of the *sputum*, with precautions taken to *avoid spread the of organisms during efforts to obtain sputum*. If patients are not able to produce sputum spontaneously, attempts should be made to *induce sputum* with the aid of hydration, pulmonary physiotherapy, intermittent positive pressure breathing (IPPB), and mucolytic agents. *Bronchoscopy* or *bronchoalveolar lavage* may be necessary for obtaining appropriate specimens. Although *cultures* are necessary for a positive diagnosis and are more sensitive than smears, sputum specimens should be examined microscopically either by the traditional *Ziehl-Neelsen (acid-fast) stain*, or by the newer Truant *fluorescent stain*. Sputum or bronchoscopic washings should be examined both directly and after concentration by centrifugation and digestion. Carefully collected individual specimens are preferred to a 24-hour pool of sputum and saliva. Cultures of first morning fasting *gastric aspirates* may also be helpful in children. Because gastric acid is toxic to mycobacteria, the collection bottles should contain a buffer such as sodium bicarbonate. Smears of gastric juice are misleading because of the potential presence of saprophytic mycobacteria, and they should not be performed.

Tissue biopsy is often required for the diagnosis of tuberculous pleurisy or extrapulmonary disease because sputum and gastric samples are usually negative for organisms in these situations.

PRINCIPLES OF TREATMENT

Prophylaxis in Uninfected Persons. In many parts of the world where tuberculosis is common, bacille Calmette-Guérin (BCG) vaccine is used for the prevention of primary infection. It is intended only for prophylaxis and should not be given to patients with positive skin test results (see Chapter 38). Because the incidence of tuberculosis is relatively low in the United States, BCG vaccination is not recommended in this country. All close contacts of patients with active pulmonary tuberculosis should be considered for *isoniazid* (INH) chemoprophylaxis, particularly if they are children, adolescents, or immunocompromised (see Chapter 38).

Prophylaxis in Tuberculin Converters and Persons with Latent Disease. Prevention of active TB can be achieved with INH (see Chapter 38 for detailed guidelines). Patients with a positive skin test result should be evaluated to exclude active infection. One needs to check for cough, fever, sputum production, pleuritic chest pain, lymphadenopathy, meningeal irritation, pleural effusion, pulmonary consolidation, and enlargement of the liver or spleen. Chest radiography is essential, and the results of complete blood cell count, differential, urinalysis, and liver function tests (particularly measurement of alkaline phosphatase) may provide clues of active disease (e.g., "sterile" pyuria or isolated elevation of alkaline phosphatase). If no active infection is identified, the patient should be reassured, and the potential risks and benefits of INH therapy should be explained so the patient can participate in therapeutic decisions.

Treatment of Patients with Active Tuberculosis. Antituberculous drugs are the cornerstone of therapy. Because the patient will not be contagious shortly after starting therapy, most treatment can be administered on an outpatient basis after a brief period in the hospital. The chemotherapy of tuberculosis is different from other antimicrobial programs and proceeds according to a unique set of principles:

- Multidrug regimens and completion of a full course of therapy are necessary to prevent the emergence of drug-resistant organisms.
- Single daily dosing is preferred.
- Prolonged chemotherapy is necessary. Nearly all patients can be cured with regimens lasting 6 months. However, HIV-infected persons may require longer treatment. When INH and rifampin cannot be used simultaneously because of patient intolerance or drug resistance, older, more prolonged regimens of 18 to 24 months are necessary.
- Directly observed therapy (DOT) given twice or thrice weekly should be considered for all new patients.
- No matter what regimen is chosen, it is important to follow patients closely to ensure compliance and monitor for drug efficacy and toxicity.
- Because chemotherapy will control the organisms, surgery is reserved for the treatment of complications, such as restrictive pericardial scarring.
- Elaborate programs of rest and diet have no place in the modern treatment of tuberculosis.
- Prolonged surveillance beyond 1 year after completion of a full course of therapy is generally not necessary because of the efficacy of current chemotherapeutic regimens; however, immunosuppressed patients and those with drug-resistant organisms require more prolonged follow-up.

As little as 2 weeks of multidrug therapy will greatly decrease the infectiousness of patients with tuberculosis, although a few mycobacteria may still be present on sputum smears or cultures. The decision of whether or not to hospitalize patients with newly diagnosed TB should take into account the clinical status of the patient in addition to the health and ages of other people living at home. Certainly, the presence at home of children (especially infants), pregnant women, or persons infected with HIV or having debilitating medical conditions should prompt hospitalization until the index patient can be reliably considered noninfectious. Patients with extrapulmonary tuberculosis are much less infectious and can sometimes be managed entirely as outpatients.

Ensuring Adherence. Poor adherence is the single most important cause of treatment failure and the emergence of multidrug-resistant strains. Conversion to negative cultures takes four times longer in nonadherent patients; their risk for acquiring drug-resistant disease is five times greater, and the treatment time needed to achieve cure is nearly twice as long. However, adherence is a notoriously difficult thing to predict in an individual patient. Probably the most reliable predictors of poor adherence are prior poor adherence, adolescence, and heavy alcohol or IV drug use. Socioeconomic status, race, and ethnicity should not be used to predict adherence.

DOT coupled with a free supply of the necessary drugs appears to be one of the most successful adherence strategies for persons with active tuberculosis. The wide use of DOT has been a cornerstone of public health measures for tuberculosis control in the 1990s and has undeniably contributed to the reversal of the rising incidence in active disease seen in the 1980s. *DOT should be considered initially for all patients with newly diagnosed TB.*

CASE REPORTING AND PATIENT EDUCATION

All cases of tuberculosis should be reported promptly to public health authorities, so that contacts can be investigated and appropriate control measures instituted. However, it must be remembered that, particularly in elderly patients, the diagnosis of tuberculosis still carries a social stigma and dire prognostic implications. Reassurance and education are therefore of great importance. It should be stressed that tuberculosis occurs in all social and economic classes, that modern chemotherapy is truly curative, and that prolonged periods of hospitalization and isolation are no longer necessary.

Patients who are candidates for INH prophylaxis should understand the risks and benefits of INH therapy. If INH therapy is recommended and accepted, the patient should be instructed to discontinue the medication and report to the physician if adverse effects are noted, including skin rash, fever, fatigue, anorexia, abdominal distress, jaundice, and peripheral neuropathic symptoms. The importance of full compliance with the drug regimen, be it for prophylaxis or treatment of active disease, must be stressed.

THERAPEUTIC RECOMMENDATIONS

Prophylaxis

- For more information, see Chapter 38.
- In the decision to use INH for prophylaxis, the risk for drug-induced hepatotoxicity (see next section, Antituberculous Chemotherapeutic Agents) must be weighed against the benefit of preventing active disease. The older the patient, the greater the risk for hepatitis, although the benefit usually outweighs risk, especially in populations with a high incidence of infection and active disease (see Chapter 38 for detailed guidelines).
- Prompt diagnosis and institution of an effective, individualized treatment program are essential to preventing the spread of disease and emergence of resistant organisms. Of particular importance is the early recognition of TB in HIV-infected patients. A high index of suspicion and an awareness of the potentially atypical presentations of TB in these patients (e.g., disseminated disease, meningitis) are essential.

Active Disease

- Patients with active pulmonary or extrapulmonary tuberculosis should be treated for 2 months with INH, rifampin, and pyrazinamide, followed INH and rifampin for 4 months, for a total duration of treatment of 6 months.
- Because nearly all centers in the United States currently report greater than 4% resistance to one of the drugs mentioned above, and because of the now-recognized importance of newly acquired infection, ethambutol (or streptomycin) should be included in the initial regimen until the results of drug susceptibility tests are known, at which time it can be stopped if the presence of a sensitive organism is confirmed.
- The above treatment regimen applies to patients with or without HIV infection. However, because relapse rates are higher in HIV-infected patients, careful clinical follow-up should be the rule. Many authorities advocate continuing INH and rifampin for 6 months following sputum conversion.
- If INH and rifampin cannot be administered simultaneously because of patient intolerance or drug resistance, multiple drug therapy should be continued for 18 to 24 months. Such patients should be referred to an infectious disease specialist or to the local public health authority for optimal management. For patients relapsing after a previous course of antituberculouschemotherapy, or for patients in whom more widespread drug resistance is suspected, the initial therapy may involve six or more drugs and should be coordinated by an infectious disease specialist or public health authority.
- DOT should be considered initially for all patients in whom active TB is diagnosed. Twice- and thrice-weekly regimens have established efficacy when given as part of DOT.
- For use in *pregnancy*, INH, rifampin, and ethambutol all appear to be safe.
- After completion of therapy, all patients should be followed for 1 year, with monitoring for evidence of recurrence. Longer follow-up is appropriate for those with drug-resistant organisms, HIV-positivity, or suspected poor compliance.
- *Hospitalization* should be considered in the *initial stages of active pulmonary disease* to minimize the risk for spread. Chemotherapy for 2 weeks usually suffices to render the patient noninfectious.

Antituberculous Chemotherapeutic Agents

Isoniazid. Introduced into clinical use in the early 1950s, INH remains the single most important antituberculous drug. Of importance is the excellent tissue penetration of this small, water-soluble molecule. The distribution of INH includes the central nervous system, tuberculous abscesses, and intracellular sites. The major metabolism of INH is by hepatic acetylation. Although metabolites are excreted by the kidneys, it is not necessary to modify INH doses except in cases of advanced renal failure. INH is available both orally and parenterally. The usual dose is 5 mg/kg of body weight, not to exceed 300 mg/d for an adult.

The major adverse effects of INH include the following:

- *Neurotoxicity*, ranging from peripheral neuropathy (which can be prevented by administration of 50 mg of pyridoxine daily) to much less common manifestations, including encephalopathy, seizures, optic neuritis, and personality changes.
- *Hypersensitivity* reactions, including fever, rash, and rheumatic syndromes with or without the presence of antinuclear antibodies.
- *Hepatocellular injury*, including serious clinical hepatitis in fewer than 2% of cases, but a transient, clinically insignificant rise in transaminase levels in 10% to 20%. The risk for clinically significant hepatitis increases with age.

The U.S. Public Health Service does not recommend routine *transaminase* (aspartate aminotransferase and alanine aminotransferase) determinations in persons who are reliable and able to comply with directions for reporting symptoms of hepatitis. If transaminases are elevated before therapy is begun, however, it is prudent to monitor them at monthly intervals.

In symptomatic patients with an elevated transaminase, INH should be discontinued and liver function should be monitored. In asymptomatic persons with a mild elevation (up to 2.5 times normal), the drug can be continued, but the patient should be monitored weekly. If the transaminase level fails to return to normal in 3 to 4 weeks, it seems prudent to discontinue the INH. On the other hand, even if a patient is asymptomatic, a single, more substantial transaminase elevation may be grounds to discontinue the agent. Again, it must be emphasized that these are "rules of thumb" rather than precise guidelines. INH treatment may be resumed cautiously in patients for whom it was stopped, with careful monitoring.

Rifampin is a major antituberculous drug and rivals INH in efficacy. Rifampin is a large, fat-soluble molecule that achieves excellent tissue penetration, including the central nervous system. The drug is excreted by the liver; modification of dosage is not required in renal failure but may be necessary in hepatic insufficiency. It is available in both oral and parenteral formulations. The average adult dose is 600 mg/d taken once daily. Patients should be cautioned to expect *orange discoloration of urine, sweat, tears*, and *saliva*, which is of no clinical significance.

Toxicities include *hypersensitivity* reactions (fever, rash, eosinophilia), *hematologic* toxicities (thrombocytopenia, leukopenia, hemolytic anemia), and *hepatitis* (including elevated transaminases in up to 10%). Drug interactions occur; rifampin increases the metabolism of warfarin, quinidine, oral contraceptives, and methadone. Rifampin should never be used in high-dose intermittent therapy because toxic reactions (including hemolytic anemia, thrombocytopenia, and hepatic failure) occur frequently. However, intermittent therapy in doses of 600 mg given twice weekly appears to be well tolerated.

Pyrazinamide, a derivative of nicotinic acid, was introduced in 1952 but was not widely used until its incorporation into short-course regimens in the 1980s. Like INH and rifampin, it is bactericidal, a major asset in short-course therapy. The drug is well absorbed from the gastrointestinal tract and is widely distributed in body tissues and fluids, including the cerebrospinal fluid. It is excreted by mixed hepatic and renal mechanisms. Major toxicities are hepatic dysfunction, hyperuricemia, and hypersensitivity. The usual dose is 15 to 30 mg/kg daily (maximum, 2 g).

Ethambutol was introduced clinically in the United States in 1967 and represented a major advance in antituberculous chemotherapy. Although ethambutol penetrates tissues well—including the central nervous system when the meninges are inflamed—it is not bactericidal; it is only bacteriostatic. The drug is excreted by the kidneys. Dose modification in renal failure should be based on serum ethambutol levels (available through the manufacturer), and patients with renal failure who require the drug should be monitored. The major toxicities of ethambutol include hypersensitivity reactions, such as fever and rash, and optic neuritis, which is dose-related and usually manifested first by a loss of color vision. Less common side effects include neuritis, gastrointestinal intolerance, headache, and hyperuricemia. The usual dose is 15 mg/kg daily; 25 mg/kg may be given daily for the first 2 months. Color vision and visual acuity should be monitored periodically because of a small risk for retinal injury; for this reason, the drug is usually not administered to young children.

Streptomycin, the first effective antituberculous drug, remains useful. Like other aminoglycosides, streptomycin has only a fair tissue distribution, being inactive at an alkaline pH in an anaerobic milieu and penetrating the cerebrospinal fluid very poorly. It must be given parenterally. Streptomycin is excreted by the kidneys, and the dosage should be reduced in patients with renal failure. Major toxicities include hypersensitivity reactions and *toxicity of the eighth nerve*, especially the vestibular division, which results in vertigo. The dose of streptomycin is 15 mg/kg, up to 1 g daily.

"Second-line" Antituberculous Drugs tend to be both less effective and more toxic than the standard agents, but occasionallythey are of critical importance in patients with drug-resistant tuberculosis and in those who cannot tolerate the standard therapies. Three of these agents are administered orally, including *paraaminosalicylic acid* (PAS), *ethionamide*, and *cycloserine*. For many years, PAS was considered a first-line drug, but because of its relatively weak tuberculostatic action and the very high incidence of gastrointestinal intolerance associated with its use, it has been relegated to a secondary role. Two other drugs available

parenterally, kanamycin and capreomycin, are pharmacologically similar to streptomycin.

Newer Drugs. With the emergence of new multidrug-resistant strains has come an accelerated search for new antituberculous agents. Several fluoroquinolone antibiotics have some activity against *M. tuberculosis*, including *ciprofloxacin*. Their effectiveness has not clearly been demonstrated.

CHAPTER 50 MANAGEMENT OF THE COMMON COLD

WILLIAM A. KORMOS

The term "common cold" describes a self-limited catarrhal illness caused by a variety of respiratory viruses. It is indeed a common problem, with adults averaging two to four colds per year and almost 7 days lost from work per person per year. Although most patients treat their symptoms at home, physicians are still frequently consulted for upper respiratory infections. The primary task for the physician is to distinguish the common cold from bacterial infections, allergic conditions, and epidemic diseases such as influenza. Once the common cold is diagnosed, reassurance about the self-limited nature of the disease and patient education about its predominantly viral cause is the next step. However, upper respiratory tract infections continue to be a great source of inappropriate use of antibiotics. A recent survey demonstrated that physicians prescribe antibiotics to half of patients labeled with "colds." Instead, physicians should be knowledgeable about symptomatic therapies, including over-the-counter remedies. A targeted treatment plan aimed at the predominant symptoms is not only more effective but also more responsible.

PATHOPHYSIOLOGY AND CLINICAL PRESENTATION

The oropharynx and nasopharynx are lined by a stratified squamous epithelium and are normally teeming with a varied microbial flora. In addition, many potentially pathogenic bacteria can temporarily reside on these epithelial surfaces as "colonizers" without causing true infection. With a few exceptions, such as herpes simplex virus and the Epstein-Barr virus, viruses are not usually long-term members of the normal flora of the respiratory tract.

Numerous host defenses protect the upper airway from infection. The first of these defenses are mechanical; particulate matter is expelled by the cough and sneeze reflexes, entrapped by viscous mucous secretions, and propelled outward by ciliary action. In addition, local immunologic defenses attempt to deal with organisms that have breached the mechanical barriers. These defenses include lymphoid tissue, respiratory secretions that contain immunoglobulin A antibodies, and a rich vasculature capable of rapidly delivering phagocytic leukocytes. Once in the nasal cavity, viruses gain access to the upper airway by binding to ICAM-1 (an intercellular adhesion molecule). Experimental trials are being conducted in which soluble ICAM-1 is used to block this step in the initiation of infection.

Mechanisms of transmission include *airborne transmission* of virus-laden respiratory secretions via small aerosolized particles that remain suspended or large particles that travel only a few feet. However, the most efficient means of transmission is *direct mucous membrane contact* with virus, usually on contaminated hands. Self-inoculation of viruses surviving on the hands is accomplished by touching one's nose or eyes. Children remain an important reservoir of these viruses. The timeless motherly warning that "you'll catch cold if you get wet or damp" has not been borne out by experimental studies, which have demonstrated equal susceptibility in chilled and nonchilled hosts. However, evidence from prospective controlled studies suggests that *psychological stress*, especially chronic life stresses and poor social supports, can increase the risk for infection.

The common cold is caused by viral agents, mostly from five major families of viruses. *Rhinoviruses* are the most common viral agent associated with upper respiratory tract illness. Because there are more than 110 antigenic serotypes, cross-immunity does not exist, and reinfection with another serotype right after a recent cold is common. Coronavirus, parainfluenza virus, coxsackievirus, and respiratory syncytial virus account for the rest of the etiologic agents. *Influenza A* and *influenza B* produce a more severe syndrome that overlaps with the common cold. Influenza infection typically occurs in the winter months (December to March) in the northern hemisphere. The clinical syndrome consists of fever and diffuse myalgia, often accompanied by a nonproductive cough and headache. Lack of fever significantly decreases the probability of influenza. Patients with underlying cardiopulmonary disease and the elderly are at higher risk for development of a secondary bacterial pneumonia following influenza infection.

Incubation periods for viral upper respiratory infections range from 1 to 5 days; virus shedding lasts up to 3 weeks. Typical symptoms include coryza, pharyngitis, laryngitis, headache, malaise, and fever, in various combinations. Experimental evidence suggests that these symptoms are more the results of the body's response to the infection (through mediators like bradykinin, prostaglandin, interleukin, and histamine) than the actual viral infection itself. Ear and sinus discomfort also are often present, frequently caused by mucosal edema that impairs drainage (see Chapter 218 and Chapter 219).

Whether known as the common cold, nasopharyngitis, or upper respiratory infection, these problems generally resolve spontaneously. Common viral upper respiratory infections rarely progress to pneumonia; most colds resolve spontaneously within 1 week, although symptoms may linger up to 2 weeks in one fourth of patients.

DIAGNOSIS

The diagnosis of the "common cold" remains a clinical one, based on the typical presentation. Patients should be examined for localized bacterial infection, such as otitis media, sinusitis, or streptococcal pharyngitis (see Chapter 218, Chapter 219, and Chapter 220). If the patient presents with symptoms typical of influenza, further diagnostic testing can be considered with *rapid testing*, in which antibodies to common influenza antigens are usually used. The sensitivity of these tests appears to be high, and is even higher if nasopharyngeal washings rather than a swab are sent. Although not widely in use at present, these tests may become more important as new treatments for influenza become available (see below). On the other hand, identification of the specific virus causing the "common cold" is neither practical nor important.

PRINCIPLES OF MANAGEMENT

Prevention

The best things one can do to avoid "catching" a cold are to avoid aerosol exposure, wash hands, and keep hands away from mucous membranes (conjunctivae, nasal and oral mucosae). Gargling with "antiseptic" mouthwash is of no benefit. Initial studies on the use of inhaled a $_2$-interferon have shown promising results for the prevention of rhinovirus infection, but such approaches remain experimental. The enthusiasm surrounding the use of high-dose vitamin C (ascorbic acid) for prophylaxis has waned as controlled studies have failed to demonstrate efficacy. Similarly, zinc lozenges have proved no better than placebo in controlled trials.

Symptomatic Relief

Therapeutic efforts are directed toward relieving nasal congestion, sneezing, rhinorrhea, headache, and grippelike symptoms and preventing complications such as otitis, sinusitis, and lower respiratory tract infection. Targeted therapy aimed at the most bothersome symptoms is preferred to all-inclusive cold remedies, which often contain irrational mixtures or subtherapeutic doses of active ingredients. Sympathomimetics remain the mainstay of decongestant therapy. Data suggesting a cholinergic pathophysiology for rhinorrhea and sneezing have stimulated interest in new forms of anticholinergic therapy.

Decongestants can be helpful, not only for providing symptomatic relief but also for preventing sinus and eustachian tube obstruction that can result in sinusitis and otitis media, respectively.

a-Adrenergic Agents are the most commonly used decongestants. They work by causing generalized vasoconstriction, thereby reducing the formation of secretions. Because they produce systemic vasoconstriction, sympathomimetics may raise blood pressure when used in doses sufficient to alleviate nasal congestion. No oral adrenergic agent provides selective local vasoconstriction; *sympathomimetic nasal sprays* (e.g., Afrin) are more effective for this purpose but may be associated with rebound congestion after as little as 3 days of continuous use, leading to difficulty discontinuing use and an increased risk of chronic abuse. According to most authorities, sympathomimetic nasal sprays are good for very short-term therapy, whereas oral preparations are better when treatment is to continue for longer than 3

to 4 days.

Anticholinergic Agents have been used for years in the treatment of the common cold, mostly in the form of over-the-counter *sedating first-generation antihistamines*, which exert an atropine-like drying effect. It is this effect, not antihistaminic activity, that probably accounts for the symptomatic usefulness of anticholinergics in patients bothered by profuse rhinorrhea and excessive sneezing. However, their marked drying effect can exacerbate symptoms of congestion and cause upper airway obstruction by impairing the flow of mucus. In addition, they cause drowsiness, a side effect that may impair daytime functioning, although it can provide some nighttime rest. These agents can also worsen symptomatic benign prostatic hypertrophy and glaucoma and should be avoided by patients with these conditions. Use of a prescription *second-generation, nonsedating antihistamine* is irrational and has *no place* in management of the common cold because these agents have little anticholinergic activity and cold symptoms have no allergic pathophysiology. Nonetheless, antihistamines continue to be widely consumed for use in colds, both in prescription form (which is extremely expensive and wasteful) and in over-the-counter preparations, usually in combination with a sympathomimetic and other substances (see below).

Ipratropium, a topically active anticholinergic agent now available in a nasal spray preparation, is being heavily promoted for relief of nasal symptoms of the common cold. In a placebo-controlled, double-blind, randomized trial, the nasal spray preparation provided a significant reduction in subjective and objective measures of rhinorrhea and sneezing in comparison with saline placebo spray and with no treatment. Of note, significant benefit was also found with use of the saline control spray in comparison with no treatment. Global ratings by patients for overall effectiveness followed a similar pattern. Observed side effects included increased nasal dryness and blood-tinged mucus in approximately 10% to 15% of subjects. No cases of sinusitis or marked nasal obstruction were reported, which suggests that short-term use of the spray (up to 5 days) might be reasonably well tolerated. The nasal spray is expensive.

Analgesics are useful for relief of the headache, fever, and achiness that often accompany a cold. *Aspirin* and *acetaminophen* have similar analgesic and antipyretic effects and are key ingredients in the combination cold remedies. However, both have been found capable of delaying the immune response to experimental rhinovirus infection, although neither prolongs viral shedding. Nonprescription doses of *ibuprofen* showed similar effects, but prescription doses of *naproxen* did not alter viral shedding or antibody response in one trial. All remain clinically useful for symptomatic relief of the headache, myalgias, and fever that may accompany a cold. Salicylate derivatives such as salicylamide are sometimes used, although they are much less effective than aspirin. Of all the analgesics, plain aspirin is by far the least costly; the other agents can be expensive.

Expectorants and Heated Humidification. Expectorants are included in many preparations in the belief that they stimulate the flow of mucus. There is no evidence to support this view, although these agents are widely prescribed and requested by patients. More important is adequate *hydration*, which helps loosen secretions and prevent upper airway obstruction and the complications that may ensue. *Warm fluids* (including tea and, yes, chicken soup) can increase the rate of mucous flow, providing some symptomatic relief, as can *inhaled steam* (another of grandmother's remedies) or use of a dilute saline nasal spray.

Research suggesting that increasing the nasal mucosal temperature to 37°C could limit viral replication and decrease nasal congestion led to a renewed interest in the inhalation of warm, humidified air. A double-blinded study of steam inhalation through an *active device* showed *no significant benefit* over placebo therapy, although both were associated with considerable subjective improvement. An expensive heated nebulizer device (the Viralizer) has been heavily promoted as a means of promptly and completely relieving cold symptoms. Controlled study has failed to confirm such excessive claims.
