Worsening ophthalmopathy is a concern and is more common with radioiodine therapy than with other forms of antithyroid treatment for Graves' disease. Risk is exacerbated by *cigarette smoking.* As noted earlier, up to 20% of patients with Graves' disease and eye involvement predating treatment for hyperthyroidism experience an exacerbation after treatment for hyperthyroidism. Correction of hyperthyroidism does not appear to cause ophthalmopathy *de novo,* but treatment-induced hypothyroidism (which is common in patients treated with radioiodine) appears to increase the risk for worsening eye problems.The mechanism is unclear; a treatment-induced outpouring of antibody-stimulating antigen is hypothesized.

Prophylactic treatment with oral *prednisone* for 3 months (started at 40 mg/d a few days after radioiodine therapy and continued for 1 month before taper to full cessation over 8 weeks) prevents ophthalmopathy in persons with little or none before treatment. Although steroids are tapered after the first month, the incidence of steroid side effects (see Chapter 105) is high. Cyclosporine has also been tried. It is less effective than prednisone but has proved helpful in combination for refractory cases. At present, avoidance of hypothyroidism appears to be the best mode of prevention. The mode of therapy may also be germane (see also Chapter 204).

Risks for cancer and *birth defects* have been long-standing concerns. The gonadal radiation dose from iodine 131 therapy is small, the equivalent of that from a barium enema or an IV pyelogram. To address the question of cancer risk, cohort studies have followed tens of thousands of patients for decades. Recent analyses indicate that the risk for overall cancer mortality is not increased, but the rate of thyroid cancer deaths is increased fourfold in comparison with that of patients who received other forms of therapy. Although this increase in relative risk is statistically significant, the absolute risk remains very small. Interestingly, more than a year after treatment, a slight increase in total cancer mortality risk was noted for patients treated with antithyroid medications. More study is needed to define these comparative risks. Radioiodine therapy is also associated with increased risks for cardiovascular disease, stroke, and osteoporotic fracture. Whether this is a consequence of the therapy or the underlying thyroid status of these patients remains to be clarified.

Surgery represents the most direct ablative approach to hyperthyroidism. The objective is to reduce the thyroid mass sufficiently to cure the hypermetabolic state without inducing a hypothyroid condition. Unfortunately, the incidence of permanent hypothyroidism is substantial, and smaller but perceptible risks for hypoparathyroidism and laryngeal paralysis exist. Moreover, hyperthyroidism may recur despite subtotal thyroidectomy in Graves' disease. Prior preparation of the patient with antithyroid drugs is required to avoid precipitating thyroid storm. Surgery is particularly useful for relieving esophageal obstruction; cosmesis and pregnancy are other indications. It is also a choice when antithyroid drugs fail or produce complications, or when patients are noncompliant or refuse radioiodine. Young patients with moderate to severe disease do particularly well. However, treatment with iodine 131 has largely replaced surgery because it is less expensive and associated with less morbidity.

Iodides are sometimes useful as supplemental agents because they can block peripheral conversion of T_4 to T_3 and inhibit hormone release. *Potassium iodide* was the earliest of the iodides to be employed. The *organic iodide radiographic contrast agents* (e.g., ipodate, iopanoate) have supplanted the inorganic iodides. However, control is sometimes problematic. Paradoxical increases in hormone release can occur. Thus, iodides are best utilized for preoperative control in patients who require a second drug to counter the hyperthyroidism and in those for whom b-blockers and other antithyroid medications are contraindicated.

Treatment of Osteoporosis. Bone-preserving therapy should be considered for hyperthyroid women found to be osteoporotic, especially if they are menopausal (see Chapter 164).

Choice of Therapy

Graves' Disease. There is little consensus among thyroidologists regarding the best treatment for Graves' disease, except in the case of *elderly patients,* for whom *radioactive* iodine is considered the treatment of choice. Surveys of opinion regarding the treatment of *middle-aged* and *younger patients* reveals marked diversity of opinion, split between *antithyroid drugs* and radioiodine, with surgery deemed best reserved for those who are not candidates for either. An initial trial of antithyroid drug therapy represents a reasonable starting point for treatment, supplemented by b-blocker therapy to help establish a euthyroid state and control adrenergic symptoms. When such therapy fails to achieve control, or the patient is unable to tolerate it or experiences a relapse after it has been completed, radioiodine can be considered. Despite the absence of evidence for long-term genetic risk, concern persists about giving radioiodine to patients in their reproductive years.

Contributing to the diversity of opinion is dissatisfaction with available therapies. None appears capable of definitively halting the underlying immunopathologic process, which remains poorly understood. Adding *thyroid replacement therapy* to antithyroid drug therapy decreases the frequency of recurrence of Graves' disease and reduces the production of antibodies to TSH receptors.

Treatment of ophthalmopathy also remains a challenge. Etiologic therapy awaits a better understanding of the underlying disease mechanisms. Although ophthalmopathy may worsen with treatment of the hyperthyroidism, especially if hypothyroidism is induced, no evidence has been found that scaling back treatment prevents an exacerbation. However, radioiodine appears to be the modality most likely to worsen ophthalmopathy, perhaps because it is the most likely to induce hypothyroidism. This has led some to recommend thyroxine supplementation to prevent hypothyroidism. Moderately high doses of glucocorticoids given at the time of antithyroid treatment can reduce the risk for ophthalmopathy, but such prophylactic therapy is not recommended for routine use because of the high incidence of adverse side effects, the inability to predict who will experience an exacerbation, and the low incidence (7%) of severe ophthalmopathy. However, patients with moderate to marked preexisting ophthalmopathy may be reasonable candidates for such prophylactic treatment. Good eye care is also a priority.

With a host of alternative therapies available, each with its own advantages and disadvantages, it is important to individualize treatment according to the patient's needs, capabilities, and clinical status. For now, one must settle for treating the hyperthyroidism; etiologic therapy is awaited.

Toxic Nodule. Radioiodine is the treatment of choice for elderly patients with this condition. Because the rest of the gland is suppressed by the hyperfunctioning nodule, the incidence of posttreatment hypothyroidism is far less than that seen with treatment of Graves' disease. The optimal radioiodine dose remains a subject of debate. A relatively low dose of iodine 131 (5 to 15 mCi) appears to provide excellent results with minimaladverse effects (75% of patients euthyroid by 2 months, >90% within 6 months, posttreatment hypothyroidism very rare). Surgical removal may be preferable in young patients.

Hyperthyroidism in Pregnant and Nursing Patients. The choice is between antithyroid drugs and surgery; radioiodine is contraindicated because it crosses the placenta and concentrates in the fetal thyroid. Antithyroid drug therapy is considered safer than surgery, with surgery reserved for refractory cases and patients who refuse to take their medication. Among the *antithyroid agents, PTU* is preferred; methimazole has been associated with aplasia cutis in the fetus. The risk that drug will cross the placenta and induce hypothyroidism in the fetus is small and not strictly dose-related, but precipitation of hypothyroidism in the mother can compromise the fetus and should be avoided. Pregnant women with Graves' disease may transfer large amounts of TSab to the fetus and induce fetal thyrotoxicosis, even after thyroid ablation. Testing the newborn for thyrotoxicosis is essential in this setting. Evidence that treatment of pregnant thyrotoxic patients leads to impaired intellectual development in the offspring has not been found. The optimal antithyroid drug regimen for the fetal thyroid status appears to be one that maintains maternal levels of free T_4 near the upper limit of normal.

Breast-feeding mothers can transfer antithyroid medication in milk, but the amount is small, especially of PTU, and not likely to induce significant hypothyroidism. However, a discussion of potential risks and the need for careful monitoring is important.

The short-term use of *b-blocking agents, iodides*, or both provides prompt, effective, and safe control of thyrotoxic symptoms. Symptoms improve within 2 to 7 days. Longer-term use of these agents is more problematic. b-Blocking drugs have been linked to retarded intrauterine growth, small placenta, and postnatal bradycardia and hypoglycemia. Nevertheless, the complication rate is low, and use during pregnancy is generally safe. Extended use of iodides is riskier, with large, obstructing fetal goiters reported.

Surgery is usually reserved for the patient who has failed or is a poor candidate for medical treatment. Operative mortality, although low, still exceeds that associated with drug therapy. Before subtotal thyroidectomy, preoperative medical therapy is indicated to attain control and prevent thyroid storm.

Thyroiditis. As noted above, hyperthyroidism associated with thyroiditis can be managed symptomatically with *b-blocking agents* because spontaneous resolution is the rule. Aspirin and occasionally corticosteroids are indicated in subacute thyroiditis to control inflammatory symptoms.

Monitoring Therapy

Monitoring treatment requires attention to the clinical status and indices of thyroid function. Clinical status is assessed by taking note of any changes in weight, degree of heat intolerance, tremulousness, anxiousness, appetite, level of energy, resting heart rate, ophthalmopathy, skin texture, or skin temperature. The *TSH* level provides the best measure of the treatment end point (normalization of TSH) and the earliest evidence of overtreatment and development of hypothyroidism. The amount of circulating thyroid hormone can be assessed by monitoring changes in the serum concentration of *free T_4* (or total T_3 in the case of T_3 toxicosis), but assessment is needed only when the TSH level is abnormal.

In patients with Graves' disease, monitoring the serum level of *antibodies to TSH receptors* also helps predict the clinical course. Relapse is a strong possibility if TSab remains elevated and is less likely, although not ruled out, when it is reduced or absent.

For patients taking antithyroid drugs, routine monitoring of the *leukocyte count* should be considered, especially for those taking PTU or more than 30 mg of methimazole per day. Risk is greatest during the first 4 months of therapy.

PATIENT EDUCATION

Patients with hyperthyroidism are often relieved to know that their "nervousness" is caused by an underlying medical illness rather than an emotional problem and that it will improve with therapy. Patients who are taking antithyroid agents need to be instructed about prompt reporting of symptoms suggestive of agranulocytosis (e.g., fever, chills), especially during the first 4 months of therapy. Those with prominent exophthalmos should be warned to see the physician at the first sign of diplopia or visual impairment. Hyperthyroid mothers taking antithyroid drugs and eager to breast-feed their infants need not be prohibited from breast-feeding so long as one takes the time to explain the potential risks and the importance of careful monitoring. Patients treated with radioiodine should be told to watch for symptoms of hypothyroidism.

INDICATIONS FOR REFERRAL AND ADMISSION

Patients who are candidates for therapy with iodine 131 should undergo a thyroid scan and be seen by the endocrinologist or radiation therapist for calculation of the dose of iodine 131 to be administered. Consultation with an endocrinologist is also indicated in the management of the pregnant or lactating hyperthyroid patient and the patient with severe ophthalmopathy of Graves' disease. Visual impairment caused by severe ophthalmopathy may require hospital admission for very high-dose systemic steroid therapy or surgical decompression. Referral for consideration of surgical therapy is also indicated when the patient's swallowing is obstructed and when the patient is pregnant, desires cosmetic improvement, or fails antithyroid drug therapy. Prompt hospital admission is needed if heart failure, rapid atrial fibrillation, or angina develops.

THERAPEUTIC RECOMMENDATIONS

- For prompt control of adrenergic symptoms of hyperthyroidism, regardless of underlying cause, start treatment immediately with a b- *blocking agent* (e.g., 80 mg of propranolol per day, 50 mg of atenolol per day). Increase dose daily until symptoms are controlled. Use with extreme caution in patients who have preexisting heart failure unrelated to thyroid disease.
- For *nonpregnant young* and *middle-aged* patients with *Graves' disease*, start *methimazole* (20 to 30 mg/d) in addition to the b-blocker program. Continue both methimazole and b-blockade for 4 to 8 weeks, and then taper the b-blocker as the antithyroid agent takes effect. Adjust the antithyroid drug dose according to the clinical status and thyroid indices (TSH, free T $_4$). Use the lowest possible dose that maintains biochemical and biologic control. Monitor closely to avoid precipitating hypothyroidism. Monitor leukocyte count if more than 30 mg of methimazole is being taken per day or if the patient is elderly.
- If a response is obtained, continue antithyroid therapy for 12 to 24 months. One can measure TSab at 12 months. If TSab is absent and the patient appears to be in remission clinically and biochemically, then try discontinuing therapy. If relapse occurs, then consider resumption of antithyroid therapy for 12 more months or radioiodine therapy.
- For the *pregnant patient* with *Graves' disease*, consider antithyroid drug therapy, but obtain endocrinologic consultation before initiating treatment. *PTU* is preferred (starting dose is 100 mg three times daily) and can also be given to the patient who is eager to breast-feed. Risks of such therapy should be fully explained and understood by the patient. Careful monitoring of thyroid status in both mother and baby is essential. Maintain the pregnant patient's free T $_4$ levels near the upper limit of normal; monitor TSH closely.
- For all patients taking antithyroid medication, consider *monitoring* the *leukocyte count* every 2 to 4 weeks during the first 4 months of therapy, then every 4 to 6 months. Stop therapy if the neutrophil count falls below 1,500/mL. The risk for agranulocytosis and the need for close monitoring are greatest in elderly patients and those taking PTU or more than 30 mg of methimazole per day.
- For patients with Graves' disease who have severe symptomatic ophthalmopathy, obtain a prompt endocrinologic consultation. Options include very high-dose systemic glucocorticoids (120 to 150 mg of prednisone per day), local steroid injection, surgical decompression, and radiation therapy.
- For patients with Graves' disease who have mild to moderate ophthalmopathy, minimize the risk for worsening eye disease by avoiding posttreatment hypothyroidism. The routine use of systemic daily steroid therapy for prophylaxis of posttreatment exacerbation is not recommended but may be considered for patients who begin radioiodine treatment with moderately severe eye changes already established (20 to 40 mg of prednisone per day for the first month, followed by taper to full cessation during the next 8 weeks). For periorbital edema, advise elevating the head of the bed and prescribe a mild diuretic (e.g., 50 mg of hydrochlorothiazide per day). Prescribe methylcellulose drops to prevent corneal drying (see also Chapter 204).
- Consider *therapy with iodine 131* for patients with a *solitary toxic nodule, elderly patients with Graves' disease*, and other patients with Graves' disease who fail or cannot be maintained on therapy with antithyroid drugs (relapse, agranulocytosis). Continue b-blockade for the 2- to 3-month period that it takes for the radioiodine to exert its full effect on the gland. Between 3 and 6 months after onset of treatment and at 3- to 6-month intervals thereafter, monitor TSH for evidence of hypothyroidism; correct promptly by starting thyroid replacement therapy before hypothyroidism develops.
- Refer for consideration of *surgery* any patient who has a *neck obstruction* or a *cosmetic concern* or who is *poorly compliant* in taking medication. Surgery should also be considered when antithyroid drug therapy has failed or is contraindicated. Young patients do particularly well. If surgery is contemplated, continue antithyroid or b-blocking therapy up to the moment of surgery. Monitor for postoperative hyperthyroidism.
- Treat patients with *transient hyperthyroidism* associated with thyroiditis symptomatically with *b-blockade* until the condition resolves on its own.
- Screen and treat hyperthyroid women for *osteoporosis* (see Chapter 144 and Chapter 164); they are at increased risk for hip fracture.

CHAPTER 104 APPROACH TO THE PATIENT WITH HYPOTHYROIDISM

The development of accurate and relatively inexpensive diagnostic techniques and the availability of low-cost, high-quality levothyroxine preparations have greatly facilitated the diagnosis and management of hypothyroidism. Hashimoto's thyroiditis accounts for most of the cases of hypothyroidism seen in the United States. Other causes of thyroid injury include idiopathic thyroid atrophy, previous radioactive iodine (iodine 131) therapy, and subtotal thyroidectomy. Women are more frequently affected than men. The prevalence of hypothyroidism increases with age. As much as 5% of the elderly population manifests evidence of hypothyroidism, most of it resulting from thyroiditis. Less common causes include neck irradiation, iodide administration, and the use of lithium or paraaminosalicylic acid. Pituitary insufficiency can result in secondary hypothyroidism. Rarely, hypothalamic disease is the source of difficulty. Assessment for hypothyroidism includes an evaluation of the patient taking long-term thyroid hormone replacement therapy for unclear reasons. The primary physician should be able to determine when replacement therapy is indicated and to prescribe it with safety and precision.

PATHOPHYSIOLOGY, CLINICAL PRESENTATION, AND COURSE

Pathophysiology

The basic mechanisms of hypothyroidism can be divided into those that impair thyroid function (primary hypothyroidism) and those that principally involve hypothalamic–pituitary function (secondary hypothyroidism). In primary disease, the hypothalamus responds with an increased output of thyrotropin-releasing hormone (TRH), which triggers pituitary thyrotropin (TSH) secretion. This in turn stimulates thyroid gland enlargement, goiter formation, and the preferential synthesis of triiodothyronine (T_3) over thyroxine (T_4). In secondary hypothyroidism, the TSH response is inadequate, the gland is normal or reduced in size, and both T_4 synthesis and T_3 synthesis are equally reduced.

Primary Hypothyroidism may occur as a result of blockade of thyroid TSH receptors, impairment of thyroxine production, or inhibition of thyroxine release. In *Hashimoto's thyroiditis*, the most common form of hypothyroidism, *immune-mediated injury* may damage all three components of glandular function. The precipitants of excessive antibody production remain ill-defined, but TSH receptors and microsomal enzymes (e.g., peroxidase) are among the targeted antigens. In fact, antimicrosomal antibodies serve as a convenient laboratory marker for the condition (see below). Pathologically, a lymphocytic infiltrate and glandular enlargement are noted; frank nodularity may develop (see Chapter 95). Antibodies directed against glandular antigens can impair the response to TSH and the synthesis and release of hormone. Although most patients with Hashimoto's thyroiditis remain euthyroid, a fraction experience transient hyperthyroidism because of the premature release of thyroid hormone (see Chapter 103). If hormone synthesis is sufficiently compromised, hypothyroidism may ensue and can be permanent. Most patients with Hashimoto's thyroiditis have mild disease and remain euthyroid, although a modest goiter may develop.

Postpartum thyroiditis is believed to be a common variant of Hashimoto's thyroiditis (see Chapter 103), affecting up to 5% of women postpartum. Antibody production peaks 3 to 4 months after delivery and then declines. A period of transient hyperthyroidism may be followed by hypothyroidism, but most patients return to euthyroid status. The symptoms of mild hyperthyroidism may be mistakenly attributed to "tension" and are followed by fatigue and depression resulting from the onset of hypothyroidism. The symptoms resolve spontaneously within 2 to 3 months but tend to recur with subsequent pregnancies.

Radiation-induced hypothyroidism is another leading cause of thyroid injury in the United States. It is a common and permanent consequence of iodine 131 therapy and also of external neck irradiation that exceeds 2,500 rads (used to treat lymphoma and head and neck cancers). Onset is within 3 to 6 months of treatment.

Subacute thyroiditis following a viral upper respiratory infection is a more transient form of thyroid injury. In this condition, the gland is very tender and enlarged, sometimes asymmetrically. A brief period of hyperthyroidism may precede glandular hypofunction, but spontaneous remission and restoration of normal thyroid function are the rule. Pathologically, a granulomatous giant cell infiltrate and a marked reduction in iodine uptake characterize the condition. The clinical course ranges from weeks to a few months.

Subtotal thyroidectomy produces transient hypothyroidism in most patients and permanent hypothyroidism in about half within the first year after surgery. *Drugs* with antithyroid activity, such as *lithium*, can induce some evidence of hypothyroidism in about a fifth of cases, but only 5% become clinically hypothyroid. *Iodide excess* impairs thyroxine synthesis and release, especially in patients with preexisting thyroid disease; *iodide deficiency* inhibits hormone synthesis. Drugs that have an antithyroid effect produce a rapid but reversible form of hypothyroidism.

Secondary Hypothyroidism occurs most commonly as a result of injury to thyrotropes by a functioning or nonfunctioning pituitary adenoma. Many other forms of sellar or suprasellar disease can produce the same net result, which is inadequate production of TSH leading to an atrophic thyroid gland and hypothyroidism. Other hormone-producing cells of the pituitary may also be involved and cause a host of associated endocrinopathies (see Chapter 100 and Chapter 101). Primary hypothyroidism can sometimes mimic secondary disease by causing the pituitary to enlarge; however, the pituitary shrinks in response to exogenous thyroid hormone in primary disease, but not in secondary disease.

Clinical Presentation

Subclinical Hypothyroidism. Along with the ability to detect early disease (see below) comes the designation of subclinical hypothyroidism, defined as an asymptomatic elevation in serum TSH concentration (ranging from 6 to 14 mU/L, depending on the specificity desired) accompanied by thyroid hormone levels within normal limits. The general population prevalence averages 7% for women and 2.5% for men. In about 20% of patients with a TSH concentration above 6 mU/L, clinically symptomatic hypothyroidism develops within a period of 5 years; the incidence of clinical disease rises to almost 100% for those with a TSH level above 14 mU/L. Patients with high titers of antithyroid antibodies are at greatest risk for becoming overtly hypothyroid, which suggests that Hashimoto's thyroiditis plays an important role. The meaning of an isolated TSH between 6 and 10 mU/L remains unclear, although some evidence has been found of an increased risk for coronary artery disease resulting from lipid abnormalities.

Clinical Hypothyroidism. The overt symptomatic manifestations of hypothyroidism reflect the decreases in metabolic rate and sensitivity to catecholamines that result from insufficient circulating thyroid hormone. Early symptoms are gradual in onset and may occur before serum free thyroxine levels fall below normal limits, although the TSH level rises as soon as circulating levels of thyroid hormone are sensed to be inappropriately low. The patient typically complains of *fatigue*, moderately *dry skin, heavy menstrual periods*, a slight *weight gain*, or *cold intolerance*. These symptoms are followed during the next few months by the development of very dry skin, coarse hair, hoarseness, continued weight gain (although appetite is minimal), and slightly *impaired mental activity* (e.g., minor diminution in psychomotor activity, visual–perceptual skills, or memory). Later, depression may become evident.

In late stages, hydrophilic mucopolysaccharide accumulates subcutaneously, producing the *myxedematous changes* that characterize the severe form of the disease. The skin becomes doughy, the face puffy, the tongue large, the expression dull, and mentation slow, even lethargic. *Muscle weakness, arthralgias, diminished hearing*, and *carpal tunnel syndrome* are also found. Daytime sleepiness in severely myxedematous patients suggests that obstructive sleep apnea may be occurring. *Dementia* may ensue and be only partially responsive to thyroid replacement therapy.

On examination, a *goiter* may be evident. If Hashimoto's disease is the cause, the goitrous gland may feel rubbery, nontender, and even nodular. In the case of subacute thyroiditis, it will be very tender and enlarged, although not always symmetrically. Diffuse enlargement also occurs with hereditary defects in thyroxine synthesis or the use of iodides, paraaminosalicylic acid, or lithium. An atrophic gland is characteristic of secondary hypothyroidism. The heart may show signs of dilatation or an effusion. Bowel sounds are diminished, and the relaxation phase of the deep tendon *reflexes* is slowed or "hung up."

In *secondary hypothyroidism*, signs of accompanying ovarian and adrenal insufficiency (e.g., loss of axillary and pubic hair, amenorrhea, postural hypotension) may

be seen as a consequence of concurrent loss of luteinizing hormone (LH), follicle-stimulating hormone (FSH), and adrenocorticotropic hormone (ACTH) production. Myxedematous changes tend to be less marked than with primary hypothyroidism, and the gland is smaller.

Laboratory Manifestations

As noted earlier, in primary hypothyroidism, *TSH elevation* may precede clinical manifestations. The earliest development is an increase in TRH, followed by the TSH response. At this stage, thyroid hormone levels may still be reported as "within normal limits," although in reality, they are reduced from baseline. Only later does free thyroxine fall to overtly abnormal levels. *Hypercholesterolemia*—an increase in low-density lipoprotein (LDL) cholesterol and a reduction in high-density lipoprotein (HDL) cholesterol—is often noted. Hypothyroidism is associated with a number of *anemic states*. The most common is a mild normochromic normocytic anemia. In addition, a microcytic anemia may ensue from iron deficiency secondary to heavy menstrual bleeding. Also, a macrocytic picture that clears on administration of exogenous thyroid hormone is sometimes encountered. A true megaloblastic anemia resulting from *vitamin B_{12}* deficiency occurs in about 10% of hypothyroid patients with a macrocytic smear; the relation between hypothyroidism and pernicious anemia is unresolved, but an autoimmune mechanism is postulated.

In severe cases of myxedema, dilutional hyponatremia occurs as a result of inadequate renal blood flow. A warning of impending myxedema coma is a rise in arterial carbon dioxide tension ($PaCO_2$), which takes place as the respiratory drive weakens.

DIFFERENTIAL DIAGNOSIS

The causes of hypothyroidism can be categorized according to whether they impair the thyroid gland (primary hypothyroidism) or the hypothalamic–pituitary axis (secondary hypothyroidism) (Table 104.1). Primary disease is far more prevalent than secondary disease. Hashimoto's thyroiditis and postirradiation disease are the leading causes in the United States.

Primary Hypothyroidism
  Hashimoto's thyroiditis
  Postpartum disease (transient)
  Postirradiation disease
  Subtotal thyroidectomy
  Subacute thyroiditis (transient)
  Antithyroid drugs (lithium, PAS, PTU, methimazole, iodide
    excess)
  Iodide deficiency
  Infiltrative disease (hemochromatosis, amyloidosis, scleroderma)
  Biosynthetic defect, hereditary
Secondary Hypothyroidism
  Pituitary macroadenoma
  Empty sella syndrome
  Infarction
  Infiltrative disease (e.g., sarcoidosis)
  Surgery or radiation-induced injury

PAS, para-aminosalicylic acid; PTU, propylthiouracil.

Table 104.1. Differential Diagnosis of Hypothyroidism

WORKUP

Screening for Hypothyroidism

The test of choice to screen for hypothyroidism is a *serum TSH determination*, the most sensitive and cost-effective of available tests. Modern TSH assays provide a very sensitive means of detecting hypothyroidism, often long before the patient becomes overtly symptomatic. Measurement of *thyroid hormone levels* is indicated if the TSH is elevated, but not for screening, because the test sensitivity is lower and the cost is no less.

Despite the ease and effectiveness of detection, considerable controversy remains regarding the value of adding a TSH determination to the periodic health examination. The frequency of hypothyroidism is low in men, and the impact of treatment on asymptomatic patients is unclear. Although screening for hypothyroidism has been calculated to be as cost-effective as many other generally accepted preventive medical practices ($9,000 to $23,000 per quality-adjusted life-year), such calculations are based on benefits noted in observational studies of symptomatic patients; no randomized trials have evaluated the treatment of asymptomatic patients detected by screening. Nonetheless, patients in subgroups with an increased prevalence of hypothyroidism might be reasonable candidates for screening, and for them a TSH determination should at least be considered. These include women over the age of 50 years (especially if hyperlipidemic) and patients with goiter, Hashimoto's thyroiditis (presence of antithyroid antibodies), recent radioiodine or external neck irradiation, or recent thyroid surgery. In addition, the prevalence of hypothyroidism is high among patients with mental dysfunction admitted to geriatric units and among women older than age 40 with such nonspecific complaints as fatigue.

Diagnosis of Hypothyroidism

Although the history (cold intolerance, skin changes, unexplained weight gain, hoarseness, fatigue, heavy periods) andphysical findings (dry skin, coarse hair, goiter, "hung-up" reflexes) often suggest the diagnosis, confirmation and the detection of early disease require laboratory study.

The diagnosis of *primary hypothyroidism* is readily achieved by demonstrating an *increased TSH level* and a *low free T_4 level* (or *free T_4 index*). The TSH is the more sensitive indicator of primary hypothyroidism and the test of choice. The designation of "*subclinical hypothyroidism*" is given to the asymptomatic patient with a modest elevation in TSH (6 to 10 mU/L) and a free T_4 index remaining within normal limits. However, the range of normal for the free T_4 index is wide. A single free T_4 determination may not detect the patient who has a modest yet physiologically important decline in hormone level because the serum concentrations may remain within normal limits. Moreover, antithyroid antibodies can interfere with the commonly used immunoassays and produce falsely high or low readings, depending on the type of assay used. Nevertheless, the free thyroxine level is a better measure of thyroid function than the *total* T_4, which is affected by changes in thyroid-binding globulin that are independent of thyroid function.

Often, measurement of *total T_3* is routinely ordered as part of a battery of thyroid function tests. The assay is expensive to perform, and the results correlate poorly with thyroid status, affected by such events as a fall in peripheral conversion of T_4 to T_3, which is common in the elderly and in nonthyroidal illness. Determinations of serum *cholesterol* and *thyroglobulin* and of *radioactive iodine uptake* are also insensitive tests that contribute little to the diagnostic evaluation.

Secondary hypothyroidism should be suspected when the TSH level is inappropriately low in the setting of overt hypothyroidism. Concurrent amenorrhea, galactorrhea, postural hypotension, or visual field deficits also suggest pituitary– hypothalamic disease. Imaging of the sellar region is indicated. *Computed tomography* (CT) is best for detecting small lesions within the sella; *magnetic resonance imaging* (MRI) is best for imaging the suprasellar region (see Chapter 100). *TRH stimulation* is sometimes used to confirm secondary hypothyroidism, but the test often fails to distinguish among its causes.

Patients who are taking a thyroid preparation but in whom hypothyroidism has not been documented can be evaluated by stopping replacement therapy. Abrupt cessation of exogenous thyroid hormone therapy is not dangerous so long as the patient has no prior history of severe hypothyroidism. Prompt and adequate (although submaximal) responses of the pituitary and thyroid gland occur when hormone intake is halted. However, because it takes about 5 weeks for full functioning of the hypothalamic—pituitary–thyroid axis to return, testing for hypothyroidism should be delayed until then to avoid a false-positive diagnosis of hypothyroidism.

Identifying the Underlying Cause

History should be checked for possible etiologic factors, such as exposure to iodine 131, neck irradiation, recent viral infection, use of medications with antithyroid activity (lithium, excess iodide), residence in an area of iodide deficiency, subtotal thyroidectomy, pituitary surgery or irradiation, and recent pregnancy.

Physical Examination should include a careful look at the thyroid gland for size, consistency, and nodularity. An exquisitely tender gland suggests subacute thyroiditis. A nontender, diffusely enlarged gland is seen in early Hashimoto's disease, iodide deficiency, and congenital biosynthetic defects, and after childbirth. A rubbery, multinodular goiter suggests more advanced Hashimoto's thyroiditis. When secondary hypothyroidism is suspected clinically, the blood pressure should be checked for postural hypotension and the visual fields for deficits.

Laboratory Investigation is relatively limited. The *TSH* level (to differentiate primary from secondary disease) and *antimicrosomal antibody* titer (presence of antibodies strongly suggestive of Hashimoto's thyroiditis) are the most useful. In patients with a sellar mass lesion, determination of the serum levels of LH, FSH, ACTH, and prolactin may be indicated (see Chapter 100 and Chapter 101). A *lipid profile* (see Chapter 15) should be obtained in all hypothyroid patients because it is likely to be abnormal and require attention. Those with suspected Hashimoto's disease should also have a *complete blood cell count* and a serum *vitamin B_{12}* determination.

PRINCIPLES OF MANAGEMENT

The availability of high-quality, inexpensive preparations of levothyroxine make restoration of the euthyroid state readily achievable. The issues are when to initiate therapy, how best to do so, how best to monitor the patient, and how long to continue treatment.

Subclinical Hypothyroidism

The need for replacement therapy in subclinical hypothyroidism is a matter of debate. Favoring therapy is the opportunity to correct secondary lipid abnormalities (elevated LDL cholesterol, reduced HDLs) and decrease the size of the gland if it is enlarged. Also, some persons are actually symptomatic, although the relation of symptoms to thyroid disease is not appreciated until treatment is instituted and the patient reports feeling considerably better. This is especially true for patients with neuropsychiatric symptoms. Against treatment is the lack of evidence from prospective, controlled trials that treatment is beneficial, safe, and cost-effective. No evidence has been found that early treatment affects the natural history of the underlying cause. Lipid and symptom responses to replacement therapy in patients with only modest elevations in TSH (e.g., <10 mU/L) appear modest at best. Moreover, osteoporosis or atrial fibrillation can be induced with excessive treatment, which can easily occur in patients with minimally elevated TSH levels.

Given these present uncertainties, a reasonable approach would be to follow expectantly truly asymptomatic persons with mild elevations in TSH (<10m U/L) and to consider treating those with more substantial increases in TSH (i.e., >10 mU/L). Those who are to be managed expectantly should undergo an annual assessment that includes a TSH determination, and they should be treated if they are becoming symptomatic or the TSH increases substantially.

Clinical Hypothyroidism

For patients who are clinically hypothyroid, replacement therapy is indicated. Treatment of mild to moderate disease is best instituted gradually because hypothyroid patients are very sensitive to the effects of thyroid hormone. (An excessive rate of replacement may cause tremor, nervousness, and palpitations.) Adequate replacement should result in resolution of fatigue, loss of excess weight, and reversal of autonomic symptoms. The first signs of response are a modest loss of weight, increase in the pulse rate, and resolution of constipation. Myxedematous skin changes, pleural and pericardial effusions, and elevated creatine phosphokinase levels also normalize, but this requires more time. Most patients feel better within 2 weeks, and clinical resolution is usually complete by 3 months. Therapy for primary hypothyroidism is continued indefinitely, except in patients with transient disease, such as those with postpartum or subacute thyroiditis.

Replacement Program. Levothyroxine remains the preparation of choice for most patients (see below). A replacement dose of 100 to 125 µg/d usually suffices. The elderly tend to have a 20% lower daily requirement because of decreased T_4 clearance. Current levothyroxine replacement doses are lower than those previously cited because contemporary levothyroxine preparations are more potent.

The *starting dose* and rate of adjustment depend on age, height, weight, presence of chronic disease (especially coronary artery disease), severity and duration of symptoms, and pretreatment TSH level. Young, otherwise healthy patients can be started on a nearly full dose of levothyroxine (100 µg/d). The dose can be adjusted in 25- to 50-µg increments until a euthyroid state is achieved. In patients older than age 50 (who are at increased risk for silent coronary disease) and those with known heart disease, more cautious replacement is indicated to avoid precipitating angina, arrhythmias (atrial fibrillation, sinus tachycardia), and even heart failure. In this setting, it is best to initiate therapy with 25 to 50 µg/d and increase it in 25-µg steps. If angina or other cardiac symptoms occur, the dosage of thyroid hormone should be reduced. Some advocate the concurrent administration of a b- *blocking agent* (e.g., propranolol) to protect the heart from the increase in myocardial oxygen demand associated with thyroxine therapy.

The onset of effect is usually gradual, becoming evident in 2 to 4 weeks. One should allow 4 to 6 weeks between dose adjustments because it can take that long for a given dose to become fully effective.

Preoperative management has been a subject of concern. Coronary patients found to be mildly to moderately hypothyroid can safely undergo urgent surgery (including bypass procedures) without prior replacement. The rate of complications is no greater than that for nonhypothyroid patients, and the cardiac risks are less than when replacement therapy is initiated preoperatively. However, careful preoperative planning of anesthesia is essential because the clearance of anesthetics is reduced.

Replacement Preparations. The replacement preparation of choice for most patients continues to be *levothyroxine* (L-T_4), based on uniform bioavailability, cost, safety, and ease of monitoring therapy (see below). The half-life is about 24 hours, which allows for convenient once-daily administration. Some of the drug is converted peripherally to T_3, so that it is usually unnecessary to use the more expensive preparations containing mixtures of T_4 and T_3. Patients who continue to be bothered by *neuropsychiatric symptoms* clearly referable to their hypothyroidism may benefit from a trial of *mixed therapy*, in which 12.5 µg *of triiodothyronine* is substituted for 50 µg of levothyroxine. However, *antidepressant therapy* (see Chapter 227) should be considered for patients with major depression if thyroid hormone replacement is not helping. The exclusive use of exogenous T_3 is considered inadvisable for replacement purposes, especially in older patients, because it causes rapid increases in metabolic rate and oxygen demand and can precipitate angina. Moreover, its short half-life produces wide swings in T_3 levels and makes frequent administration necessary. For these reasons, it is best to switch patients from desiccated thyroid hormone or T_3 preparations to levothyroxine.

Levothyroxine has its own shortcomings. In the early 1980s, variations in the biologic activity and hormonal content of some commercial preparations were reported. Quality control efforts mandated by the Food and Drug Administration have eliminated most of this variability. Although pharmacokinetic differences are found between different preparations, those that have been thoroughly tested appear relatively interchangeable. Nonetheless, it is probably best, if possible, to stay with a particular levothyroxine preparation as long as it appears to provide adequate replacement and a consistent performance. Using a brand name preparation has no particular advantage. The absorption of levothyroxine is impaired by simultaneous ingestion of ferrous sulfate, which binds to it. Because T_3 is the pertinent feedback hormone and derives from conversion of T_4, the amount of thyroxine necessary to normalize the TSH level may produce serum free thyroxine levels in the high-normal to slightly elevated range.

Monitoring and Adjusting Replacement Therapy is best accomplished by measuring the serum *TSH* with the sensitive TSH assay, the results of which closely correlate with physiologic measures of thyroid hormone effect. However, reliance on the TSH determination can lead to erroneous conclusions during the initial 6 to 12 months of therapy because it can take that long for the TSH level to normalize despite adequate replacement doses. *Free T_4* levels may also correlate poorly with the physiologic status during this initial period of therapy. For these reasons, objective monitoring is difficult during the start-up phase of treatment, so that reliance on symptoms and signs is necessary.

The role of *symptoms* and *signs* in monitoring therapy is the subject of debate. Most studies suggest that the correlation between test results and clinical findings is poor, but more data are needed. For now, TSH testing appears to be the preferred method of monitoring, supplemented by correlation with the clinical state during periods when the TSH changes may lag behind the changes in the physiologic state (e.g., during initiation of therapy). Thus, if the patient becomes clinically euthyroid during the early phase of replacement therapy but the TSH level is still elevated, it is best to leave the dose unchanged and repeat the TSH determination in 4 to 8 weeks. If the TSH falls but remains elevated and the patient continues to be clinically hypothyroid, then an increase in the thyroxine dosage is warranted. If the TSH level of the hypothyroid patient shows no change, then poor compliance is the most likely explanation and no dose adjustment is warranted. If TSH is undetectable,

then the replacement dose is excessive.

When an excessive dose is suggested by a very low or absent TSH, measurement of the *free T$_4$* (or *free T$_4$ index*, which is an excellent proxy for the free T$_4$) can help determine just how excessive the current dose is.

Once a stable replacement dosage has been achieved, twice-yearly TSH determinations are probably sufficient. Any upward adjustments in dosage should be made in small increments and followed by repeated TSH testing in 6 to 8 weeks.

Secondary Hypothyroidism

Treatment and monitoring must take into account the lack of TSH response and any coexisting adrenal or ovarian hypofunction. Because thyroid replacement and the resultant rise in metabolic rate can precipitate an addisonian crisis, adrenal function should be assessed with an ACTH stimulation test before replacement therapy is prescribed in any patient suspected of having secondary hypothyroidism. Patients with an inadequate ACTH response would be candidates for treatment with cortisone acetate before levothyroxine replacement.

MANAGEMENT RECOMMENDATIONS

Screening and Diagnosis

- Consider TSH screening for women over the age of 50 years (especially if hyperlipidemic or with complaints of fatigue); persons with Hashimoto's thyroiditis, recent radioiodine or external neck irradiation, or recent thyroid surgery; and patients with mental dysfunction admitted to geriatric units.
- Stop any exogenous thyroid or antithyroid medication if the reason for its use is unclear; recheck the TSH level 4 to 6 weeks after treatment is stopped.
- Confirm the diagnosis of hypothyroidism with TSH and free T$_4$ or free T$_4$ index determinations.
- If the patient appears clinically and biochemically hypothyroid but the TSH is not appropriately elevated, test for pituitary insufficiency.

Primary Hypothyroidism

- If possible, stop all drugs with a potential antithyroid effect (e.g., iodides, para-aminosalicylic acid, lithium).
- Begin replacement with a once-daily morning dose of levothyroxine. Initiate therapy with 50 to 100 µg/d in young, otherwise healthy patients and with 25 to 50 µg/d in older patients; the size of the dose is a function of patient age and weight, severity and duration of hypothyroidism, and the presence of underlying heart disease. Particular caution is indicated in the presence of underlying coronary disease; small starting doses are required for these patients.
- Monitor initial therapy by TSH determination and clinical state. The goal is normalization of the TSH, but be aware that the TSH level may initially require several months to normalize despite adequate thyroid hormone replacement. If the patient is clinically euthyroid but the TSH is still elevated, continue the same dose and repeat the TSH determination in 4 to 8 weeks. A check of the free T$_4$ (or free T$_4$ index) may be of use if TSH is low or absent. Also monitor for side effects (e.g., tremor, angina, arrhythmias).
- Increase the dose in increments of 25 to 50 µg; the lower increment is appropriate for elderly patients and those with heart disease.
- Allow 4 to 6 weeks for a new dose to take full effect before considering another increase in dose.
- Patients who continue to be bothered by *neuropsychiatric symptoms* clearly referable to their hypothyroidism may benefit from a trial of *mixed therapy*, in which 12.5 µg of *triiodothyronine* is substituted for 50 µg of levothyroxine. However, patients with major depression should be considered for *antidepressant* therapy (see Chapter 227) if thyroid hormone replacement is not helping.
- The average levothyroxine replacement dose for most adults is 100 to 125 µg/d; for the elderly, the average dose is 20% less.
- Avoid excessive doses of replacement therapy (TSH <0.5 mU/L) because of the risk for inducing osteoporosis.
- Once the proper dose has been achieved, monitor therapy every 6 to 12 months with a TSH determination.
- Levothyroxine is the thyroid replacement preparation of choice; select and stay with a particular manufacturer's preparation. The use of desiccated thyroid and the sole use of T$_3$ preparations is not recommended.
- Patients with mild to moderate hypothyroidism and underlying coronary disease need not receive replacement therapy before urgent surgery. However, careful planning of anesthesia is necessary.

Secondary Hypothyroidism

- Perform an ACTH stimulation test to assess adrenal reserve. If it is low, give cortisone acetate *before* prescribing thyroid replacement.
- Replace thyroid hormone as for primary hypothyroidism.
- Monitor therapy by following clinical signs and free T$_4$.

PATIENT EDUCATION

Euthyroid patients who are inappropriately placed on exogenous thyroid hormone for the treatment of fatigue or obesity are often reluctant to give up the medication. Documenting that their thyroid status is perfectly normal is an essential first step in taking them off the medication successfully. Often, they will agree to a request from the physician to halt thyroid hormone for 5 weeks and have their TSH and free T$_4$ measured. Usually, patients note little change in how they feel, and this helps to convince them that exogenous hormone is unnecessary.

Hypothyroid patients need to be warned of the danger of increasing their medication too rapidly or taking more than is prescribed. Unfortunately, some patients adjust their dosages on the basis of other symptoms that they mistakenly attribute to hypothyroidism, such as symptoms of depression. All patients should be instructed to measure and record their weight regularly and report any unexplained change of 5 lb or more.

It is imperative that the patient and family be instructed about the signs of worsening hypothyroidism. Hypothyroid patients have been known to stop taking their thyroid medication. The importance of continuing therapy indefinitely must be emphasized to patients and the persons close to them.

CHAPTER 105 GLUCOCORTICOID THERAPY

The therapeutic potency of glucocorticoids has led to their widespread use. Although benefits can be substantial, adverse effects are numerous, including serious metabolic derangements and suppression of the hypothalamic–pituitary–adrenal (HPA) axis. To maximize the therapeutic response and minimize the risks, a number of questions must be addressed before steroid therapy is initiated: (a) Is the underlying disorder of such severity that the benefits of therapy outweigh the risks? (b) Will prolonged treatment be required, or will a brief, limited course suffice? (c) Have alternative, less morbid therapies been maximally utilized? (d) Does the patient have any underlying condition that will worsen on steroid therapy or predispose to drug-induced complications? (e) Can a less suppressive regimen (e.g., alternate-day therapy) be utilized?

The primary physician must decide when and how to institute steroid therapy, whether to use daily or alternate-day treatment, and how to withdraw long-term glucocorticoid treatment safely.

ADVERSE EFFECTS

Most adverse effects of glucocorticoids are a function of degree of systemic absorption, dosage, and duration of use. A few are irreversible; fortunately, most resolve within several months of termination of therapy.

Suppression of the Hypothalamic–Pituitary–Adrenal Axis. Suppression compromises the physiologic response to major stress (e.g., surgery, injury), putting the patient at risk for hypotension and hypoglycemia. Symptoms and signs include *light-headedness, nausea, postural hypotension*, and *hypoglycemia*. Risk correlates with *dose* and *duration* of therapy, but it is hard to predict HPA responsiveness accurately on the basis of dose and duration alone. Other factors are believed to be operative also. Even the so-called "physiologic dose" of 7.5 mg of prednisone that supposedly corresponds to daily endogenous glucocorticoid synthesis is suppressive in some patients. Moreover, individual patients vary widely. Some experience clinically important HPA suppression with the use of as little as 5 mg of prednisone taken daily for a few weeks, whereas others manifest no measurable HPA suppression despite the use of much higher daily doses.

Scheduling of the *dose* has some effect on the degree of HPA suppression. *Daily* physiologic doses of glucocorticoids (e.g., 5 to 7.5 mg of prednisone) given in the morning do not cause suppression of any consequence, but if the same doses are given at night, normal diurnal cortisol secretion is inhibited. Doses just above the physiologic range are suppressive after about a month of use. *Alternate-day* therapy, in which short- or intermediate-acting preparations are taken at 8 a.m. every other day, does not induce clinically significant HPA suppression, nor does a *cyclic* program of 5 days of daily therapy followed by 2 to 4 weeks off therapy. However, cycles of 2 weeks on and 2 weeks off do lead to HPA suppression. A single daily pharmacologic dose of glucocorticoid produces less HPA suppression than does the same dose divided and taken at intervals during the course of the day.

Recovery from HPA suppression can take up to 12 months. Hypothalamic–pituitary function returns first, reappearing 2 to 5 months after cessation of suppressive therapy, and is manifested by appropriate plasma adrenocorticotropic hormone (ACTH) levels that demonstrate a normal diurnal pattern. Signs of adrenal recovery become evident at 6 to 9 months, with a return of the baseline serum cortisol level to normal. Maximal adrenal response to ACTH may not reappear until 9 to 12 months after cessation of therapy. There is no proven method for accelerating the restoration of normal HPA function once it has been inhibited. The administration of ACTH does not seem to speed adrenal recovery.

Like predicting the onset of HPA suppression, estimating how long clinically important hyporesponsiveness will persist is also difficult. Again, individual variation is great, and the degree of suppression cannot be reliably estimated by the basal serum cortisol concentration. In the setting of such uncertainty, *testing of the HPA axis* becomes an important adjunct to clinical decision making. Of the available stimulation tests (insulin-induced hypoglycemia, corticotropin, metyrapone, corticotropin-releasing hormone), the *corticotropin (ACTH) test* is the most widely used; results correlate well with cortisol levels measured during the stress of surgery. A blood sample is drawn to measure the serum cortisol, after which a one-ampule (250-µg) bolus of synthetic ACTH (*cosyntropin*) is injected IV. Additional samples of blood are drawn at 30 and 60 minutes for cortisol determinations. The test produces a few false-positive results in comparison with insulin-induced hypoglycemia (the "gold standard" for testing HPA function), but it is safer and more convenient to perform. False-negatives may occur if central suppression, but not yet adrenal suppression, has developed. A low-dose (1 µg) cosyntropin test may be helpful in identifying central suppression when a standard-dose test result is suspected to be a false-negative. Some argue that the corticotropin-releasing hormone (CRH) test combines the sensitivity and specificity of insulin-induced hypoglycemia with the convenience of corticotropin testing, but few direct comparisons have been made. The test can be performed in the outpatient setting, but CRH is very expensive. The basal cortisol level has shown little correlation with the results of stimulation testing and is not a substitute for such testing.

Although HPA suppression is important to detect, it is not the only factor determining the ability of corticosteroid-exposed patients to respond appropriately to stress. Some patients manifest a hypotensive response to stress despite a normally responding HPA axis, and patients with a blunted HPA response may manifest no signs of clinical adrenal insufficiency. More work is needed to elucidate the mechanisms governing stress response in steroid-treated patients.

Metabolic and Endocrinologic Side Effects. A *negative nitrogen balance* (the result of inhibition of protein synthesis and enhancement of protein catabolism) is believed to be partially responsible for reduced muscle mass, weakness, thinning of the skin, and striae formation. *Fat redistribution* accounts for the characteristic truncal obesity and cushingoid appearance. Both fat redistribution and negative nitrogen balance are minimized by using alternate-day therapy or giving no more than a physiologic dose each morning, but not by using ACTH or daily pharmacologic glucocorticoid doses. Acne is seen, more often with ACTH than with glucocorticoid use, because of stimulation of adrenal androgen production.

Glucose intolerance is common. Mechanisms include increases in peripheral insulin resistance, gluconeogenesis, glucagon secretion, and substrate availability. Usually, the glucose intolerance is mild, does not lead to ketosis, and resolves when therapy is stopped. When carbohydrate intolerance develops, the effect appears to be dose-related.

Hypertension and *fluid retention* with peripheral edema are more common when agents with mineralocorticoid effects are used, and they are not dependent on any prior elevation of blood pressure (Table 105.1). Again, dosage and duration of therapy are important factors. *Electrolyte derangements* are common, especially hypokalemia.

DURATION OF ACTION	GLUCOCORTICOID POTENCY[a]	EQUIVALENT GLUCOCORTICOID DOSE (mg)	MINERALOCORTICOID ACTIVITY
Short-Acting			
Cortisol (hydrocortisone)	1	20	Yes[b]
Cortisone	0.8	25	Yes[b]
Prednisone	4	5	No
Prednisolone	4	5	No
Methylprednisolone	5	4	No
Intermediate-Acting			
Triamcinolone	5	4	No
Long-Acting			
Betamethasone	25	0.60	No
Dexamethasone	30	0.75	No

[a] The values given for glucocorticoid potency are relative. Cortisol is arbitrarily assigned a value of 1.

[b] Mineralocorticoid effects are dose-related. At dosages close to or within the basal physiologic range for glucocorticoid activity, no such effect may be detectable.

Adapted from Axelrod L. Glucocorticoid therapy. Medicine (Baltimore) 1976;55:39, with permission.

Table 105.1. Commonly Used Glucocorticoids

Enhanced Susceptibility to Infection results from the antiinflammatory and immunosuppressive actions of corticosteroids. Bacterial infections are common. Candidiasis and aspergillosis sometimes develop. Herpes zoster, varicella, vaccinia, and cytomegalovirus infection are the principal viral infections encountered in patients on steroids. Reactivation of tuberculosis is a well-recognized risk (see Chapter 49).

Osteoporosis develops when steroids are used for prolonged periods. The exact incidence of clinically significant loss is unknown, but estimates are in the 50% range, making this underappreciated consequence one of major importance. The precise relation between dosage, duration of use, and risk for osteoporosis remains unclear, although some evidence suggests that alternate-day therapy minimizes the chance of serious osteoporosis. Even as little as 5 mg of prednisone per day overtime can result in bone loss. Patients with a predisposition to osteoporosis, such as menopausal women and immobilized persons, appear to be among the most susceptible. The *axial skeleton* is affected more than the limbs, and vertebral compression fractures may result. *Aseptic necrosis of the femoral head* and other bones is a well-recognized and serious, but relatively rare, skeletal complication. Sometimes it may be a manifestation of the underlying illness for which corticosteroids are being given, such as rheumatoid arthritis or systemic lupus. However, the risk is markedly increased with an increase in steroid dose and prolonged therapy.

Gastrointestinal Effects. Gastritis, peptic ulceration, and gastrointestinal bleeding have all been attributed to steroid use. Multiple randomized, controlled trials have produced conflicting results, as have major metaanalyses examining pooled data from such trials (see Chapter 68). Hotly debated is the degree to which ulcer risk is a function of dosage and duration of exposure. The risk appears small until dosages in excess of the equivalent of 30 mg of prednisone per day are reached and continued for more than a month. Even then, the increase in rate of peptic ulceration is in the range of only 1% to 2%. Most peptic ulceration is caused by the concurrent use of nonsteroidal antiinflammatory agents. Antacids and food do not interfere with absorption of oral steroid preparations.

Acute pancreatitis is noted with increased frequency in patients taking corticosteroids. *Panniculitis* is unique to iatrogenic Cushing's syndrome.

Myopathy may result from the prolonged intake of large doses. Proximal muscle wasting and weakness of the lower extremities are characteristic. Patients have difficulty climbing stairs. The average time of onset is 5 months into treatment. Muscle enzymes are normal. The complication is reversible, and exercise may help minimize it.

Psychological and Behavioral Changes are particularly common in the elderly. The reported incidence ranges from 25% to 40%, mostly among patients receiving high doses. Increased appetite, mild euphoria, and changes in sleep patterns are rather common at the beginning of treatment. Psychoses, which are not predictably related to dosage or duration of therapy, can occur; they slowly respond to reduction or cessation of steroid use. Some clinicians argue that the patient's premorbid personality plays a role; others deny this. Steroid therapy can exacerbate previous psychiatric disease.

Cataracts of the posterior subcapsular type are reported in 10% to 35% of cases and are predominantly dose- and duration-dependent. A few require removal; most do not.

Adverse Effects of Inhaled Glucocorticoids. The inhaled topically active steroid preparations used for asthma are usually well tolerated and not associated with significant adverse effects, even when used daily for months at a time. However, the growing appreciation of the need for long-term therapy with inhaled steroids and the development of increasingly potent preparations (e.g., fluticasone) have raised concerns about the potential for systemic effects. Metaanalytic study finds that the risk for HPA suppression is greatest when the dosage of most inhaled steroids exceeds 1.5 mg/d (>0.75 mg/d for fluticasone). Fluticasone demonstrates greater biologic activity and confers a greater risk on a milligram per milligram basis in comparison with beclomethasone, budesonide, and triamcinolone. Similar relationships and dose thresholds have been noted in regard to the risks for osteoporosis and posterior subcapsular cataracts. A lesser risk for ocular hypertension and glaucoma has been observed, but no evidence of permanent growth retardation in children. Skin bruising parallels HPA suppression.

PRINCIPLES OF THERAPY

The challenge of glucocorticoid use is to obtain maximal therapeutic benefit with a minimum of adverse effects. In most instances, steroids do not cure disease or alter its natural history; rather, they suppress or alter the inflammatory and immunologic responses and, in doing so, reduce symptoms. Therefore, one must carefully weigh the perceived therapeutic benefit against the potential risks. The risk is negligible for a short-term course of therapy (7 to 14 days), even with high doses, which can be very effective in selected situations (e.g., acute asthma, contact dermatitis). Appetite stimulation and restlessnessare the principal side effects. No long-term consequences have been noted. The decision to initiate more prolonged steroid therapy requires additional consideration of the risks involved (see above).

Selection of Agent. Corticosteroid preparations differ principally in duration of action and degree of mineralocorticoid activity (Table 105.1). *Short-acting agents* are less likely to cause HPA suppression, especially when prescribed for morning use in low doses as part of an alternate-day program (see below). Long-acting agents are preferred for situations in which a high-dose steroid effect must be sustained (e.g., increased intracranial pressure). Mineralocorticoid activity is desirable in adrenal insufficiency but not in situations of excessive inflammation or immunoreactivity. Regardless of the agent selected, it is essential to continue maximal nonsteroidal therapy, insofar as it reduces steroid requirements.

Prednisone is the most widely prescribed of the glucocorticoids. Its short half-life, low cost, and negligible mineralocorticoid effect make it useful for most immunosuppressive and antiinflammatory indications. *Prednisolone* is the active hepatic metabolite of prednisone and is useful in the setting of liver failure. *Dexamethasone* is the long-acting glucocorticoid of choice, being about seven times more potent on a weight basis than prednisone and having a half-life of 24 hours. This potency makes the agent useful for suppressive testing of the HPA axis. *Hydrocortisone* (cortisol) is the naturally occurring glucocorticoid. It has one fourth the glucocorticoid potency of prednisone but exerts some mineralocorticoid effect when used in pharmacologic doses, which makes it useful for parenteral supplementation in a patient believed to have adrenal suppression. *Florinef (9-a-fluorohydrocortisone)*, a potent mineralocorticoid with virtually no glucocorticoid effect, is used primarily for replacement in adrenal cortical insufficiency.

Theoretically, the use of *ACTh* would appear attractive because it might avoid adrenal suppression, but it also induces undesirable mineralocorticoid and androgenic responses. Moreover, it must be given parenterally, and there is no way to know how much glucocorticoid effect is obtained from a given dose. These disadvantages limit its usefulness, although it is given preferentially by many neurologists for exacerbations of multiple sclerosis (see Chapter 172).

Selection of Dosing Schedule: Alternate-day versus Daily. Most conditions that require prolonged corticosteroid treatment, such as asthma (see Chapter 48), sarcoidosis (see Chapter 51), inflammatory bowel disease (see Chapter 73), and nephrotic syndrome (see Chapter 142), can be well controlled with *alternate-day therapy*, although it is often necessary to begin with a program of daily steroids when the disease is very active and symptoms are severe. Important advantages of alternate-day treatment are avoidance of significant HPA suppression and minimization of cushingoid side effects without a substantial loss of antiinflammatory activity. It appears that the antiinflammatory effects of glucocorticoids persist longer (up to 3 days) than the undesirable metabolic effects. Other adverse effects that are reduced or eliminated by an alternate-day schedule include inhibition of delayed hypersensitivity, susceptibility to infection, negative nitrogen balance, fluid retention, hypertension, and psychological and behavioral disturbances.

Alternate-day therapy by itself will not prevent HPA suppression if a long-acting steroid preparation is used (e.g., dexamethasone). Moreover, therapy must really be given on alternate days, with the total dose taken first thing in the morning every other day. Intermittent therapy or doses taken throughout the day every other day do not preserve HPA responsiveness.

Daily steroid therapy is indicated during acute exacerbations of disease and in the limited number of conditions that are controlled only by daily glucocorticoid administration, such as temporal arteritis (see Chapter 161) and pemphigus vulgaris. When daily therapy is necessary, HPA suppression can be minimized by having the patient take the entire daily dose first thing in the morning and by prescribing a short-acting glucocorticoid at the lowest possible dose. Daily single-dose regimens may be as effective or nearly as effective as divided-dose regimens in controlling underlying illness. However, manifestations of Cushing's syndrome are not prevented, as they are with alternate-day therapy.

Switching from a Daily to an Alternate-day Schedule. Most patients who experience a remission on daily therapy are candidates for a trial of alternate-day steroids (see above for exceptions). Switching makes it possible for the patient to transfer to a less morbid program without a diminution in disease control. In switching, the *same total steroid dose* is continued, whereas in tapering, it is gradually reduced. Switching is carried out by gradually increasing the dose on the first day and decreasing it on the second day until a double dose is taken every other day, with no drug taken on the in-between days.

How fast the changeover can be made varies, depending on the activity of the underlying disease, duration of therapy, degree of HPA suppression, and

cooperativeness of the patient. A rough guideline for switching to alternate-day therapy is to make changes in increments of 10 mg of prednisone (or its equivalent) when the daily prednisone dose is greater than 40 mg, and in 5-mg increments when the daily dose is between 20 and 40 mg. For daily doses smaller than 20 mg, the changes should be made in increments of 2.5 mg. The interval between changes ranges from 1 day to several weeks and is determined empirically, based on the clinical response. It is important to keep in mind that most patients who have been on a daily steroid program for more than 2 to 4 weeks probably have some degree of HPA suppression.

Tapering and Withdrawing Therapy. The abrupt withdrawal of steroid therapy after a patient has been on daily doses of prednisone greater than 20 to 30 mg for more than a month can precipitate adrenal insufficiency, a flare-up of the underlying illness, or a withdrawal syndrome. There is no way to speed HPA recovery, nor are specific schedules available for reducing the daily dose. One must monitor disease activity and decrease the dose empirically by small amounts, watching for flare-up of disease or signs of adrenal insufficiency, such as postural hypotension, weakness, and gastrointestinal distress.

One empirical approach to reducing the dose toward physiologic levels is to make changes in decrements of 10 mg of prednisone or its equivalent every 1 to 3 weeks, so long as the daily dose is above 40 mg. Below 40 mg, the decrement is 5 mg. Once a physiologic dose of prednisone is reached (5 to 7.5 mg/d), the patient can be switched to 1-mg prednisone tablets or the equivalent dose of hydrocortisone, so that further reductions in dose can be made in smaller steps than is possible when 5-mg prednisone tablets are used. Weekly or biweekly reductions can then be carried out in steps of 1 mg of prednisone at a time, as permitted by disease activity.

During the tapering process, a *steroid withdrawal syndrome* develops in some patients, characterized by depression, myalgias, arthralgias, anorexia, headaches, nausea, and lethargy. Studies have failed to show a relationship between these symptoms and low cortisol or 17-hydroxycorticosteroid levels. In most instances, symptoms are reported when levels are normal, or even elevated, but falling rapidly. HPA responsiveness has also been found to be normal in many of these patients. The mechanisms responsible for this syndrome are unknown but seem to be linked to the rapidity with which the dose is tapered.

Identification and Treatment of Steroid-induced Adrenal Suppression. At times of anticipated stress (e.g., impending surgery), it is important to know how responsive the HPA axis is and whether or not supplementary steroid therapy will be needed. As noted earlier, it is very difficult to predict the onset and duration of HPA suppression, so that testing of the HPA axis is a useful adjunct for deciding who will need supplementation. In the office setting, the administration of *cosyntropin* (250 μg of synthetic ACTH) is a convenient, safe, and effective means of testing for suppression (see above). If the serum cortisol level at 60 minutes is above 18 μg/dL or an increase from baseline of at least 10 μg/dL is noted, then adrenal responsiveness is sufficient to sustain the patient through a stress equivalent to general anesthesia. Testing can be carried out in similar fashion by administering 100 μg of CRH as an IV bolus; CRH testing is more expensive, but it is more sensitive and helpful when pituitary dysfunction is a concern. Alternatively, a low-dose ACTH test (with 1 μg of synthetic ACTH) may help detect central disease.

If the patient cannot mount an adequate cortisol response, or testing is impractical because of urgency or unavailability of agents or assays, corticosteroid supplementation should be administered for acute stress. *Hydrocortisone* is usually prescribed because it provides both glucocorticoid and mineralocorticoid effects. Depending on the severity of the stress, one administers 100 to 400 mg of hydrocortisone per day in divided doses. The lower end of the dose range is appropriate for the stress of gastroenteritis, influenza, or dental extraction. During major stress, such as trauma or surgery, the patient should be given 100 mg of hydrocortisone parenterally every 6 to 8 hours. A prepackaged syringe containing 4 mg of *dexamethasone* phosphate can be prescribed for the patient or family to carry for parenteral use in an emergency should medical care be unavailable and the patient become unconscious or so ill that steroids cannot be taken by mouth. The need to continue supplementation is based on the duration of the stress and the underlying state of the HPA axis.

Prophylaxis and Treatment of Osteoporosis. Patients requiring long-term daily steroid therapy are at high risk for osteoporotic fracture, and prophylaxis and treatment should be considered for them. Even modest doses of prednisone (e.g., 7.5 mg/d) are associated with a risk for significant bone loss when used on a daily basis for a prolonged period. Vertebral compression fractures are of particular concern, as trabecular bone seems most affected. Bone density should be measured (see Chapter 144), especially if the patient is menopausal. If osteoporosis is not particularly severe and the woman is menopausal, then standard *estrogen* replacement therapy should be considered in conjunction with *vitamin D* and *calcium* supplementation (see Chapter 164). If the patient has severe osteoporosis, is at high risk (e.g., prolonged high-dose therapy, inactivity), or has a history of vertebral compression fracture, then the bisphosphonate *alendronate* appears to offer the best prophylaxis. For most patients, a 5-mg dose of alendronate taken once daily with a large glass of water on arising in the morning is safe and effective. Postmenopausal patients not taking estrogen replacement therapy obtain better protection with 10 mg of alendronate per day. Careful instruction on the proper administration of alendronate is essential to its safe use (see Chapter 164).

Minimizing Risk of Inhaled Corticosteroids. The single most important means of reducing the risk for systemic effects is to keep the daily dose as low as possible (i.e., <1.5 mg/d for beclomethasone, flunisolide, budesonide, triamcinolone; <0.8 mg/d for fluticasone). The ways to accomplish this without compromising asthma control include concurrent use of a long-acting b-agonist (e.g., salmeterol) or leukotriene inhibitor (e.g., montelukast), and immunotherapy (see Chapter 48).

PATIENT EDUCATION

Steroids should be given with caution to patients whose reliability or intelligence is in question because of the risk of HPA suppression and adrenocortical insufficiency. Patients on alternate-day therapy must be instructed about the importance of keeping to the alternate-day schedule and taking their medication around 8 a.m. so as to minimize the risk for suppression. Patients on a suppressive dose of steroid should be informed about the need for steroid supplementation when stress or illness occurs and should wear an identification bracelet stating that they take a corticosteroid. Patients must understand the need to contact the physician and increase the steroid dose when they are subjected to physiologic stress.

Many patients are reluctant to discontinue long-term steroid therapy because they fear recrudescence of the underlying illness or experience malaise as the drug is tapered. A detailed review of the side effects of prolonged therapy is necessary so that the rationale for reducing the dose and the desirability of eventually discontinuing corticosteroid therapy are understood and appreciated. Any change in dosage and schedule should be written out. When prolonged daily high-dose therapy is required, the psychological impact of adverse effects (e.g., cushingoid features) can be lessened by informing the patient that they are likely to occur but are at least partially reversible.

THERAPEUTIC RECOMMENDATIONS

- Prescribe glucocorticoids only when maximal doses of other forms of therapy have proved insufficient and when the risks of steroid use are outweighed by the therapeutic benefit expected.
- To minimize the steroid dose required, always try to *add steroid therapy* to the ongoing treatment program rather than replace it.
- In the setting of active *autoimmune* or *inflammatory* disease, initiate a full-strength program of daily glucocorticoid therapy with *prednisone* (40 to 60 mg/d, or prednisolone in cases of hepatocellular failure). When replacement therapy for adrenal cortical insufficiency is needed, use *hydrocortisone* (see below). The long-acting *dexamethasone* is reserved for testing the HPA axis and for the rare situation in which very high-dose, sustained-action therapy is required (e.g., increased intracranial pressure). All glucocorticoids can be taken with food; absorption is not impaired.
- To *minimize the risk for HPA suppression*, avoid prescribing long-acting preparations, give the entire glucocorticoid dose in the morning or, better yet, on alternate days, and continue for the shortest possible time.
- Try initiating therapy on an *alternate-day* basis when symptoms are not severe and the condition is not one with an absolute requirement for daily treatment (i.e., temporal arteritis, pemphigus vulgaris, severe inflammatory bowel disease).
- Once control is achieved, *taper* to the lowest dose that maintains control and terminate if possible. Tapering is carried out empirically; the patient is monitored for disease activity and evidence of adrenal insufficiency (postural hypotension, gastrointestinal upset, fatigue, muscle weakness, hypoglycemia).
- For very brief courses of corticosteroid therapy (<7 to 14 days), taper rapidly over 7 to 10 days to full cessation provided that disease activity remains quiescent. When longer courses of therapy are required, taper more slowly, reducing the dose in 10-mg decrements when the daily dose is above 40 mg and in 5-mg steps when it is below 40 mg. The *rate of tapering* is determined by disease activity and the appearance of symptoms of steroid withdrawal or adrenal insufficiency. Once the dosage has been reduced to 5 mg of prednisone every other day, therapy can be stopped or switched to 5-mg hydrocortisone or 1-mg prednisone tablets and reduced in decrements of 2.5 mg of hydrocortisone or 1 mg of prednisone.
- If tapering is unsuccessful or prolonged therapy is deemed necessary, then ascertain and maintain the lowest effective dose and try *switching to an alternate-day regimen* if it is not already being utilized.
- When switching to alternate-day therapy, begin by modestly reducing the second day's dose and adding that amount to the first day's dose. In this manner, the same total dose is maintained. If the daily dose is above 40 mg, reduce the dose on the alternate day by the equivalent of 10 mg of prednisone, and by 5 mg if the daily dose is below 40 mg. Below 20 mg, the increment is 2.5 mg. The interval between changes in dose is determined empirically, based on the clinical status of the patient. The end point of switching is attained when the previous entire 2-day dose is being given once every other day.

- If withdrawal symptoms are a problem on alternate-day therapy, a small morning dose of hydrocortisone (10 to 20 mg) given on the off day may help alleviate symptoms without prolonging HPA suppression.
- When HPA responsiveness is in question, perform a *cosyntropin stimulation test*. Administer 250 µg parenterally and measure serum cortisol immediately before and 30 and 60 minutes after administration.
- Because 9 to 12 months of HPA suppression may begin after as little as 2 to 4 weeks of 20 to 30 mg of prednisone daily, advise patients taking daily pharmacologic doses to supplement their steroid intake when under stress or experiencing an acute illness. In the setting of injury, surgery, or an inability to take oral medication, prescribe parenteral hydrocortisone or its equivalent. The total daily stress dose is 100 to 400 mg of hydrocortisone, given in divided doses every 6 to 8 hours. Provide a prepackaged syringe containing 4 mg of dexamethasone for IM emergency use.
- To prevent or treat *steroid-induced osteoporosis*, begin by measuring the vertebral bone density. If the patient is markedly osteoporotic, prescribe 5 mg of *alendronate* per day; if the patient is postmenopausal, prescribe a dose of 10 mg/d. Instruct the patient regarding the proper intake of alendronate to the minimize risk for esophageal irritation (see Chapter 164). Alternatively, consider estrogen replacement therapy in conjunction with calcium and vitamin D supplementation for menopausal women taking corticosteroids if the degree of osteoporosis is not severe and the risk for steroid-induced disease is not great (see Chapter 164).

PART 8 GYNECOLOGIC PROBLEMS

CHAPTER 106 SCREENING FOR BREAST CANCER

ALBERT G. MULLEY, JR.

INTRODUCTION

Breast cancer is among the most feared illnesses that afflict women, especially in North America and northern Europe where incidence rates are five to six times higher than in Asia and Africa. More than 150,000 women develop breast cancer each year in the United States, accounting for more than one in four cancer diagnoses among women. Of these, 50,000 eventually die of the disease, accounting for one in five female cancer deaths. The lifetime probability that an American woman will develop breast cancer is approximately 12%. The morbidity and mortality associated with this disease, coupled with the importance of the breasts to many women's self-image, make breast cancer a topic of intense interest.

Breast cancer is one of only a few conditions for which benefits of screening have been well documented in randomized controlled trials, but there is controversy about which women should be screened and how often. Advances in molecular biology, including identification of breast cancer susceptibility genes, have improved our ability to estimate risk and predict behavior of breast cancer for some women, but the clinical introduction of these techniques poses new challenges. These and other controversies and advances are heralded by the media, increasing public awareness and expectations. The primary care provider deals with breast cancer screening and diagnosis or associated fears on a daily basis. Knowledge of various recommendations is insufficient. Primary care providers must understand the benefits and harms of breast cancer screening and other modes of prevention and communicate these effectively to patients.

EPIDEMIOLOGY AND RISK FACTORS

The epidemiology of breast cancer has been studied extensively. Furthermore, analysis of familial patterns and identification of breast cancer susceptibility genes have refined our understanding of risk associated with age and family history.

Age. Risk of breast cancer increases with age. The median age at the time of diagnosis is about 55 years; 45% of cases occur after age 65. However, breast cancer is not uncommon in women younger than 40 in whom approximately 20% of cases occur. When breast cancer does occur earlier in life, it is more likely to be associated with a susceptibility gene. For example, before age 40, about 5% of non-Jewish women with breast cancer and about 25% of Jewish women with breast cancer can be expected to have *BRCA1* mutations.

Family History. Overall, a family history of breast cancer, whether among maternal or paternal relatives, increases the risk approximately two- to threefold. For women who have a family history, specific risk depends heavily on the age at onset of cancer for combinations of first-degree and second-degree relatives. For example, if one first-degree or second-degree relative had cancer diagnosed at or after age 50, the cumulative breast cancer risk by age 80 is approximately 10%, not significantly different than risk for the general population. If a first-degree relative had cancer before age 50, cumulative risk may be as high as 20%. With a history of early onset in two first-degree relatives, the probability that the family is affected by a dominant breast cancer susceptibility gene is substantial, and cumulative cancer risk by age 80 approaches 50%.

Susceptibility genes account for about 5% to 10% of all breast cancers. In addition to family clustering and early age at onset of disease, family history of bilateral or multifocal breast cancer and ovarian cancer suggest inherited cancer predisposition. *BRCA1*, which accounts for about half of all inherited breast cancer, confers a cumulative breast cancer risk of approximately 85% and an ovarian cancer risk of 50%. Women with *BRCA2* mutations face approximately the same risk of breast cancer but a significantly lower (10% to 20%) risk of ovarian cancer. Many members of families affected by breast cancer susceptibility genes have indicated a preference not to be tested. Also, the response to learning about susceptibility is varied. Some women choose to have prophylactic surgery (bilateral mastectomies and/or oophorectomies); others do not. Prophylactic surgery reduces risk by about 90%.

Reproductive History. Generally, there is an inverse relationship between breast cancer risk and parity, but maternal age at the time of first full-term pregnancy may be the most important factor related to reproductive history. In a woman with high parity, whose first birth occurs before the age of 20, the risk of breast cancer is half that of a nulliparous woman and one third that of the woman with one or two births after the age of 30. It has been suggested that childbirth transiently increases risk of breast cancer but reduces risk in later years. Either spontaneous or induced abortion may increase risk slightly, but the association is weak and could be due to reporting bias. Lactation appears to reduce slightly the risk of premenopausal cancer.

Menstrual History. Both late menarche and early natural menopause reduce breast cancer risk. Women who experienced menarche after age 16 have half the risk of those who experienced it earlier. Women in whom menopause occurred before age 45 have half the risk of those in whom menopause occurred after age 55. Women with early surgical menopause seem to be similarly protected.

History of Benign Breast Disease. The relative risk of breast cancer is two- to threefold greater in women who have a history of benign breast disease. Some have estimated higher relative risks and others have questioned whether or not benign breast disease confers any additional risk. Most women with benign breast disease worrisome enough to prompt biopsy have nonproliferative changes and are not at increased risk for eventual breast malignancy. Risk is concentrated among those women who have proliferative changes, especially those with atypical hyperplasia, on biopsy. Women with proliferative disease without atypical hyperplasia account for one in four breast biopsies and have a twofold increase in risk. Those with atypical hyperplasia have a fivefold increase in risk but account for only 1 in 25 biopsies.

History of Previous Malignancy. Approximately 10% of women who survive 10 years after the diagnosis of breast cancer will have a second primary malignancy, usually in the contralateral breast. Increasing popularity of breast-sparing surgery for minimal breast cancer will increase the incidence of second breast cancers; about 10% to 20% of women who choose breast-sparing surgery followed by radiation experience ipsilateral in-breast recurrences during the 10-year period after treatment of the initial tumor. Women with a history of endometrial carcinoma have slightly increased risk of breast cancer.

Diet, Drugs, and Other Factors. Breast cancer incidence varies fivefold among different countries and is positively associated with national dietary intake of fat. Diets high in fat have produced increased rates of mammary tumors in laboratory animals. Data from case-control studies have suggested a positive association, but prospective studies, including a recent overview of studies involving more than 300,000 women and nearly 5,000 cases, have found no evidence of a positive association between dietary fat and breast cancer. Low levels of vitamin A have also been linked to increases in risk. Obesity has been associated with minor increases in risk.

The role of drugs is controversial. Evidence for increased risk after oral contraceptive use is equivocal; risk may be slightly increased (relative risks in the range of 1.1 to 1.2) for younger women and for long-time users. Breast cancer risk from postmenopausal estrogen and combined estrogen-progestin hormone replacement therapy is also uncertain. A recent case-control study found no association, but a 16-year cohort analysis of the Nurses' Health Study found increased relative risk among women currently using hormones (1.32 for estrogen alone and 1.41 for estrogen plus progestin), as compared with postmenopausal women who had never used hormones. Women who were former but not current users had no greater risk than women who never used hormones.

Several studies have demonstrated an association between daily moderate alcohol consumption and modest increase in breast cancer risk.

A study suggesting that women who had undergone breast augmentation had lower cancer risk received substantial media attention. However, the analysis was found to be faulty, and a subsequent analysis showed no difference in risk after breast implants.

NATURAL HISTORY OF BREAST CANCER AND EFFECTIVENESS OF EARLY THERAPY

Little can be said with certainty about the natural history of breast cancer. The few observational studies of untreated invasive breast cancer have shown widely variable tumor doubling times ranging from less than a week to more than 6 months.

Younger women tend to have faster growing tumors than older women. The average time for development of an invasive tumor that can be detected by mammography for women aged 35 to 49 is 15 months. The average time that a tumor is detectable by mammography before a clinical diagnosis is made is thought to be approximately 3 years. Again, however, progression is likely to be faster among younger women.

There is even greater uncertainty about the natural history of noninvasive breast cancer. Dramatic increases in the incidence of ductal carcinoma *in situ* (DCIS) in recent years are attributable to mammographic screening. DCIS incidence rates increased approximately 4% annually during the decade ending in 1983 and approximately 18% annually for the subsequent decade. More than 25,000 new cases of DCIS are now diagnosed among American women each year. Many of these lesions appear to be slow growing, and evidence suggests that 50% or more of untreated women with DCIS would not develop invasive disease.

Therapy for early-stage breast cancer is highly effective (see Chapter 122). DCIS does not affect survival during the first 1 to 9 years after diagnosis and treatment. Women with small invasive cancers (e.g., 1 cm) and negative axillary nodes can expect a disease-free survival of 90% to 95% during the 5 to 10 years after either mastectomy or breast-conserving surgery followed by radiation. Cumulative recurrence risk rises sharply with increase in tumor size and/or metastasis to axillary lymph nodes.

Attention to breast cancer screening has dramatically increased the proportion of breast cancers that are in earlier stages of development at the time of diagnosis. Alone, this stage shift is inadequate evidence for screening benefit (see Chapter 3). But breast cancer screening, particularly mammographic screening, has been shown to decrease breast cancer morbidity and mortality for some women. Controversy remains about which women should be screened and how often.

SCREENING METHODS

Mammography

Mammography has become the cornerstone of breast cancer screening programs. Clinical trials have demonstrated that screening mammography can reduce breast cancer mortality by 25% to 30% for women aged 50 years or older. These same trials have reported no statistically significant reduction in breast cancer mortality in women aged 40 to 49 after 7 to 10 years of follow-up. The few studies that have longer follow-up for women in this age group do show a nonsignificant trend toward mortality reduction. An overview of nine randomized trials and four case-control studies estimated the relative risk for breast cancer mortality for women aged 50 to 74 to be 0.74 (95% confidence interval, 0.66 to 0.83). For women aged 40 to 49, the relative risk estimate was 0.93, but the 95% confidence interval (0.76 to 1.13) included 1.

The sensitivity of initial screening mammography increases with age as fat replaces more dense and radiopaque breast tissue. After age 50, the sensitivity approaches 95%. For women aged 30 to 39 and 40 to 49, sensitivity is approximately 75% and 85%, respectively. Specificity is approximately 95% and does not vary significantly with age. However, false-positive results, including interpretations that request follow-up examination of some kind, are not at all uncommon and are a source of considerable anxiety. In one large retrospective cohort study, false-positive results, defined broadly, occurred in 6.5% of mammograms; cumulative incidence after 10 mammograms was estimated to be 50%. Cumulative incidence of false-positive mammograms leading to biopsy approached 20%.

It is important to note that as many as 50% of breast cancers detected after abnormal mammography in women under age 50 are DCIS; in older women, DCIS accounts for only one in five cancers detected by mammography.

Physical Examination

A physical examination by the patient's clinician can detect cancers that are not detected by mammography. Much of the benefit evident in the Health Insurance Plan study was derived from the physical examination rather than from mammography; only 44% of cancers in women aged 50 to 59 and 19% of those in women aged 40 to 49 were found on mammography alone. In the younger age group, 58% of cancers were found by physical examination alone. In the Canadian trial, in which women aged 50 to 59 were randomized to clinical examination and mammography or clinical examination alone, clinical examination alone was as effective as the combination. However, in a recent meta-analysis of trials and case-control studies, no difference was found in mortality reduction between studies that offered both examination and mammography and those that offered mammography alone. Nevertheless, physical examination and mammography should be viewed as complementary procedures; a substantial proportion of cancers, particularly among younger women, will be missed by physicians who rely too heavily on mammography and thereby neglect careful systematic inspection and palpation of the breasts.

Breast Self-Examination

Breast self-examination has both supporters and detractors. Surveys have disclosed that many women perform breast self-examination but that most do not perform the procedure monthly and do not spend sufficient time to do it correctly. Age, education, marital status, having been instructed by a health professional, regular professional breast examinations, and a family history of breast cancer have all been shown to influence breast self-examination behavior.

Some question the effectiveness of self-examination in the early detection of disease. A randomized trial of an intensive self-examination educational intervention among more than 250,000 factory workers in Shanghai found no difference in breast cancer mortality after 10 years of follow-up. The intervention did not appear to advance the time of diagnosis of breast cancer. However, it did increase the risk of biopsy for benign disease, thereby underscoring the potential psychological morbidity associated with self-examination. Women who are both well informed and highly motivated should not be discouraged from practicing breast self-examination. Seven to 10 days after menses is the best time for premenopausal women who choose to practice self-examination; postmenopausal women can pick a regular calendar date, such as the first of each month.

Updated: 10/8/02

PATIENT EDUCATION

Many women are frightened by what they learn about breast cancer from the popular media. This is especially true for women with a family history of breast cancer, whose fears may have been heightened by the identification of breast cancer susceptibility genes. With regard to screening and prevention, fear is more an obstacle than a motivator for many patients. The primary care provider now has greater responsibility to provide accurate information about genetic predisposition and other risk factors.

One reason that breast cancer fears may be exaggerated is frequent reference to lifetime cumulative incidence rates such as the often-cited one in eight or one in nine figures for the general population. Often, younger women do not appreciate the effect of age on breast cancer incidence and dramatically overestimate their chances of being diagnosed or dying of breast cancer in the near future. For example, a 30-year-old woman may have a 12% chance of developing breast cancer during the remainder of her lifetime, but the probability that she will develop cancer in the next 10 years is less than 5 in 1,000 and the probability that she will die of breast cancer in the same period is 1 in 1,000. For a 40-year-old woman, the comparable 10-year incidence and mortality figures are 15 in 1,000 and 2 in 1,000, respectively.

The debate about which women should receive routine mammography can best be summarized for patients by asking them to consider the likely outcomes of initial screening mammograms for women younger than 50 years and those 50 and older, as presented in Table 106-1.

	≤ 50 YEARS OLD	≥ 50 YEARS OLD
No. woman screened	1,000	1,000
No. abnormal reports	53	71
No. diagnostic procedures	102	132
No. biopsies	13	25
No. invasive cancers	1	7.5
No. dectal carcinoma *in situ*	1	2.5

Table 106-1. Estimated Outcomes of First-Screening Mammography Stratified by Age

Alternatively, the discussion can focus on the mortality reduction benefits of mammography. For example, the probability of dying in the next 15 to 20 years of breast cancer that develops in the next 10 years is reduced approximately from 0.8% to 0.7% for the 40-year-old woman, from 1.3% to 1.1% for the 50-year-old woman, from 2.0% to 1.4% for the 60-year-old woman, and from 2.5% to 1.7% for the woman who is 70 years or older.

CONCLUSIONS AND RECOMMENDATIONS

- Breast cancer is common. Although risk factors allow identification of subgroups at particularly high risk, women without risk factors are nonetheless at substantial risk and should be educated about breast cancer and the benefits and harms of screening.
- Testing and counseling related to breast cancer susceptibility genes and family history must be conducted with utmost care. The implications of inherited breast cancer, including limitations of available prevention strategies, should be discussed before referral for testing.
- Breast cancer mortality is reduced 25% to 30% by mammographic screening among women aged 50 to 74; regular mammograms should be performed in this age group at 1- to 2-year intervals.
- Among women younger than 50 years, a modest benefit (approximately 10% mortality reduction) seems likely based on trial results, but mammography has not been proven to be beneficial. Furthermore, younger women face a higher likelihood of mammographic detection of DCIS and the subsequent difficult therapeutic decisions leading to potentially unnecessary surgery. Women in this age group should be engaged in a dialogue about their wishes regarding mammography. Ideally, this should include quantitative estimates of the benefits and harms of screening. When regular mammography is performed for women younger than 50 years, a shorter screening interval (e.g., every year) may be more appropriate.

CHAPTER 107 SCREENING FOR CERVICAL CANCER

In the United States, the annual incidence of invasive cervical cancer exceeds 15,000 cases and annual mortality is approximately 5,000. For an American woman, the lifetime probability of developing invasive cervical cancer is about 0.7%. The incidence of carcinoma in situ is more than three times that of invasive disease. There is a very long asymptomatic period during which cytologic detection of cervical neoplasia is possible. Early therapy is often curative. Appropriately, the Papanicolaou (Pap) smear is one of the most widely used cancer screening tests.

EPIDEMIOLOGY AND RISK FACTORS

Age and sexual activity are the principal risk factors for cervical cancer. The age-specific prevalence rates for carcinoma in situ follow a bimodal distribution with the dominant first peak of about 6 per 1,000 women occurring in the 30-to-45 age group. A second peak of about 5 per 1,000 occurs among women older than age 60. The highest carcinoma *in situ* incidence rates are in the 25-to-29 age group. The prevalence of invasive carcinoma is highest in older age groups, rising precipitously after age 50. A breakdown in host barriers at the time of menopause has been proposed as an explanation for the decreased *in situ* and increased invasive prevalence rates observed in these patients.

Many factors have been associated with cervical neoplasia. Most are related to sexual activity. First intercourse at a *young age* (i.e., before age 18) and *multiple sexual partners* (four or more) are the factors most consistently associated with high risk. Increasing parity, poor personal hygiene, a history of venereal disease, an uncircumcised partner, and a high number of sexual partners of the husband or regular sexual partner have also been linked to cervical cancer. The extremely low risk of cervical neoplasia in women who have never had intercourse and the consistent association with variables that define sexual exposure has sparked several hypotheses about cervical cancer as a venereal disease. An association between herpes simplex type 2 virus and cervical cancer has been described, but more recent findings do not suggest a causal link. The strongest evidence points to *human papillomavirus* (HPV), particularly types 16 and 18, as potential venereally transmitted oncogenic agents. It is now thought that the combination of exposure to such agents and the presence of susceptible cervical epithelium leads to cervical neoplasia. Observations that normal immature squamous epithelium in the transformation zone of the cervix is particularly sensitive to viral infections may explain some of the long-observed epidemiologic correlates of cervical cancer. Immature squamous cells are present in the developing transformation zone after menarche and during remodeling of the transformation zone after pregnancy. Women who are sexually active early in life and who have multiple pregnancies may be more likely to come in contact with oncogenic agents when their cervical epithelium is susceptible to infection. This theory would also explain the two- to fourfold increase in risk of dysplasia and carcinoma *in situ* in women exposed *in utero* to diethylstilbestrol. Persistent susceptibility to oncogenic agents may stem from immature metaplastic squamous cells that arise in the areas of cervical and vaginal adenosis frequently found in women exposed to diethylstilbestrol (see Chapter 110).

Other factors have been associated with cervical neoplasia, but it is difficult to control for sexual exposure. The incidence of cervical cancer is decreased in Jewish women and increased in African-Americans, native Americans, and Hispanics. *Socioeconomic status* may be the most important predictor, inasmuch as the racial and ethnic disparities are reduced or eliminated when socioeconomic factors are controlled. Smoking has been identified as a potentially important independent risk factor for cervical cancer in a number of studies that controlled for both sexual activity and socioeconomic status. Although the issue remains controversial, the weight of current evidence supports the association. One theory holds that smoking may make women more susceptible to the oncogenic effects of viruses. Evidence suggests that use of oral contraceptives confers a modest increase in cervical cancer risk. Women infected with HIV are at increased risk of HPV infection, and the prevalence of cervical dysplasia ranges from 10% to 60% depending on the severity of immunosuppression.

The most compelling risk information comes from the Pap smear itself, in that the risk of carcinoma is 100 times greater in women with dysplasia than in those with a normal cervix.

NATURAL HISTORY OF CERVICAL CANCER AND EFFECTIVENESS OF THERAPY

Cervical cancer classically presents with *intermenstrual bleeding* prompted by coitus or douching. Symptoms invariably occur late in the course of the disease. Epidemiologic evidence indicates that the natural history of cervical neoplasia should be viewed as a progression from mild dysplasia, through carcinoma *in situ*, to invasive carcinoma. Only some mildly dysplastic lesions progress to carcinoma. It is not clear that carcinoma *in situ* invariably becomes invasive, but epidemiologic data suggest that progression occurs in most cases. Both of these premalignant lesions, which are referred to together as cervical intraepithelial neoplasia, are reliably detected by cytologic techniques.

The mean duration of the detectable asymptomatic period, as estimated from incidence and prevalence rates, is very long. The mean duration of carcinoma *in situ* varies with age but averages about 10 years. The duration of asymptomatic invasive carcinoma is 5 years for all age groups. It should be emphasized that these are estimated means; the proportion of cervical cancers that become invasive early in their development is not known.

There is no doubt that the earlier the clinical stage of the tumor when detected and treated the better the prognosis. Survival for carcinoma *in situ* treated with hysterectomy is essentially 100%. However, the uncertainty about the natural course of carcinoma *in situ* must be kept in mind. Relative 5-year survival rates for localized and regional invasive carcinoma are about 80% and 40%, respectively. The 5-year experience of one screening program demonstrated that 86% of cases detected by cytologic screening were limited to regional invasion, whereas only 44% of those presenting symptomatically were in this early stage.

SCREENING METHODS AND DIAGNOSTIC TESTS

There are three techniques of cell collection for Pap staining and cytologic screening of the cervix. The easiest and least effective is aspiration from the vaginal pool. More sensitive, but requiring visualization of the cervix with a vaginal speculum, are *endocervical swabbing and cervical scraping*. The sensitivity of the vaginal aspirate technique has been reported in a range from 62% to 92% in the presence of invasive carcinoma and from 31% to 70% in the presence of carcinoma *in situ*. The range of reported sensitivities for swabbing is 82% to 92% and that for scraping, 86% to 100%. There is no consistent difference in detection rates between invasive carcinoma and carcinoma *in situ* with the swabbing and scraping techniques. Current recommendations suggest that two cell smears should be taken for each test: one from the endocervical canal, with either a saline-moistened cotton swab or a cytologic brush designed specifically for the purpose, and one scraped with a spatula from the os of the cervix, which contains the squamous-columnar junction or transformation zone. Smears should be interpreted by an experienced cytopathologist. Use of the endocervical brush is more likely to collect endocervical cells than use of a cotton swab, but it is not known whether this increases the detection rate for abnormal smears or affects clinical outcomes.

Recent reports indicate that sensitivity in actual practice may be substantially lower because of poor cell collection technique or faulty interpretation. To roughly estimate the practical false-negative rate resulting from the combination of these potential errors, investigators have defined a smear as falsely negative if a woman subsequently developed a confirmed lesion within a defined follow-up period. In one such study, 17% of women developed such lesions within 2 years of a negative smear. These findings have prompted recommendations that the screening interval should be kept short between the first and second smear for women regularly screened. There have also been developments in automated interpretation of smears, both to enrich samples for rescreening and as a strategy to improve the efficiency of screening without a loss in sensitivity.

The *specificity* of cytologic diagnosis is very high. In a 2-year period, 151 of 25,000 cytologic examinations of the cervix performed at the Massachusetts General Hospital were read as positive. Eighty percent of these women had cervical cancer. Clearly, more than 99% without disease had negative smears. This high specificity limits the costs associated with false-positive results.

The *frequency* of cervical cancer screening has been controversial. Because of the usually long duration of the asymptomatic detectable period of cervical intraepithelial neoplasia, which is easily controlled and cured when detected, the American Cancer Society and others have moved away from earlier recommendations of annual Pap smears. Generally, smears are now recommended every 3 years after two successive negative smears 1 year apart at ages 20 and

21 or younger if the patient is sexually active. The purpose of the short first interval is to improve sensitivity of the first screening effort. Though women who are at high risk because of early age at first intercourse, multiple sexual partners, or other risk factors may be tested more frequently, the clinician should be mindful that the decision about test frequency depends more on the duration of the asymptomatic detectable disease rather than a woman's individual risk.

Some recommendations for more frequent screening among young women reflect concern about evidence that a greater proportion of carcinoma *in situ* among younger women may be rapidly progressive. For example, in 1982 the Canadian Task Force recommended that women who have had sexual intercourse should be screened annually between ages 18 and 35. Pap smears every 5 years are recommended for women ages 35 to 60. Screening is not recommended for women who have never had intercourse. Subsequent findings, however, do not support the hypothesis that there is an increased frequency of lesions that move rapidly from carcinoma *in situ* to invasion.

Screening is recommended until age 65. Screening after age 65 is not cost effective in women who have been undergoing regular screening and have had normal smears. However, those who have not been screened previously should be (cervical cancer screening is now a Medicare benefit).

Cytologic smears are not read as simply positive or negative. The original Papanicolaou system included five classes ranging from normal (class I) to suggestive of invasive cancer (class V). Subsequently, a World Health Organization committee recommended classifying specimens as "normal," "atypical," "dysplasia" (mild, moderate, or severe), "carcinoma *in situ*," "invasive cervical cancer," and "adenocarcinoma." In 1988, a committee of the National Cancer Institute recommended the Bethesda System, which replaces the older class II "atypical" category with the designation "reactive and reparative change." This term is used to describe cellular changes in response to inflammation and other nonneoplastic processes. The Bethesda System also introduced the term "squamous intraepithelial lesion," which includes two grades. Low-grade squamous intraepithelial lesions are consistent with HPV infection and mild dysplasia and correspond to the old class III mild dysplasia category. High-grade lesions include the moderate and severe dysplasia and carcinoma *in situ* designations. Women whose smears show high-grade squamous intraepithelial lesions (i.e., moderate to severe dysplasia) or carcinoma *in situ* and those with smears suggestive of invasive cancer should be referred to a gynecologist experienced in the use of the colposcope. Colposcopic examination will allow the gynecologist to select sites for biopsy and determine the limits of the lesion. This will allow informed choice between conservative measures such as electrocautery and cryotherapy, which are used increasingly frequently, and more traditional measures such as conization and hysterectomy. Such decisions will be based not only on the size, location, and histology of the lesion but also on the patient's age, parity, and reliability for follow-up.

Because of the association between HPV infection and cervical cancer, some have advocated HPV testing as primary screening for cervical cancer. However, there is wide variation in prevalence rates of HPV positivity in different populations. Among younger women, where reactivity is often transient, it appears to be more a marker for sexual activity than for cancer risk. Among older less sexually active women, the persistence of HPV is an indication of increased risk. Results of screening studies, most of which have been conducted among high-risk women, have been mixed. Current evidence does not support HPV testing for primary screening.

CONCLUSIONS AND RECOMMENDATIONS

- The high prevalence, long mean duration of asymptomatic detectable disease, and availability of a highly specific screening test make cervical cancer screening an important task for all primary care providers.
- Known risk factors, including early sexual activity and high number of sexual partners, allow selection of high-risk patients and populations.
- Because of the long duration of preinvasive detectable disease in women of reproductive age, annual screening in the absence of specific risk factors may be unnecessary. Two screens with a short interval (e.g., 1 year) may be used to reduce the number of false-negative prevalence cases. The interval between subsequent screens can be lengthened for low-risk individuals. The presence of a risk factor, particularly in the menopausal or postmenopausal patient, may be an indication for more frequent (i.e., yearly) screening.
- Annual Pap smears after two negative smears 6 months apart is the recommended strategy for women who are infected with HIV. However, benefits for women with only 1 to 2 years of life expectancy due to late-stage HIV infection are modest.
- A cytologic smear positive for cancer or a high-grade squamous intraepithelial lesion is an indication for referral to a gynecologist for further evaluation, including appropriate biopsies.
- A smear suggestive of reactive or reparative changes or mild dysplasia can be further evaluated by the nongynecologist. If a concurrent infection is evident, the smear should be repeated after specific treatment of the infection. If no infection is present, the smear may be repeated after a 3- to 6-month interval. Women with repeatedly abnormal smears should be referred for colposcopy or biopsy.
- Screening can cease after age 65 in women with a history of regularly obtained negative smears but should be performed if not done regularly before age 65 or if smear has been abnormal.

CHAPTER 108 SCREENING FOR OVARIAN CANCER

ALBERT G. MULLEY, JR.

INTRODUCTION

Ovarian cancer is less common than breast cancer and other gynecologic malignancies; the lifetime probability is approximately 1 in 70. However, it has a high case fatality rate. Each year in the United States, more than 20,000 new cases are diagnosed and more than 12,000 women die from the disease. Ovarian cancer deaths among prominent public figures, the recent availability of new diagnostic tests, and the general trend toward increased interest in disease prevention among women has focused attention on screening for ovarian cancer. The primary care provider needs to understand the epidemiology and risk factors for this disease, as well as the value and limitations of available tests, to respond appropriately to patients' questions and, when appropriate, recommend a screening intervention.

EPIDEMIOLOGY AND RISK FACTORS

Increasing age and family history are risk factors for ovarian cancer. The annual incidence is 20 per 100,000 among women aged 30 to 50 and increases to 40 per 100,000 among women aged 50 to 75. The incidence among older women is even higher when one restricts the denominator to women who have not had their ovaries surgically removed.

A family history of ovarian cancer is present in about 10% of women with the disease. Most of these women have a family history of sporadic ovarian cancer. Some of these women are members of families with inherited predisposition to cancer, including those with *BRCA1* and *BRCA2* mutations. For some subsets of patients with inherited predisposition, cumulative lifetime risk of ovarian cancer may be as high as 85%. But for most women with *BRCA1 mutation*, the cumulative risk by age 70 years is closer to 25%. For women with *BRCA2 mutation*, the cumulative risk is lower—approximately 10% by age 70 years.

A family history of the more common sporadic ovarian cancer also confers risk. The best estimate is that ovarian cancer in one first- or second-degree relative increases risk threefold. When two relatives have had the disease, risk is increased fivefold.

Use of the oral contraceptive pill and parity are associated with reduced risk of ovarian cancer in unselected women. Any use of oral contraceptives appears to reduce risk by 35%, and use for 5 or more years by 50%. A recent case-control study indicates similar protection afforded to women with known mutations in either the *BRCA1* or *BRCA2* gene. Any pregnancy reduces risk by about 50%; increasing number of pregnancies is associated with decreasing risk. Other factors, including age at first pregnancy, infertility, menstrual history, hormone replacement therapy, and dietary factors, may modify risk of ovarian cancer, but evidence is inconclusive. Tubal ligation and possibly hysterectomy appear protective.

NATURAL HISTORY OF OVARIAN CANCER AND EFFECTIVENESS OF THERAPY

Mortality rates for ovarian cancer have changed little over the past three decades. When ovarian cancer is diagnosed after clinical presentation with signs or symptoms, three of four cases have already spread beyond the ovary. Under these circumstances, the 5-year survival rate is less than 20%. In contrast, 5-year survival rates of patients with tumor confined to the ovary has been greater than 70% in older studies and greater than 90% in recent case series. It is not surprising that there is great enthusiasm for using newer diagnostic modalities to advance the time of diagnosis and thereby reduce the burden of morbidity and mortality associated with ovarian cancer. It must be remembered, however, that we know little about the preclinical course of ovarian cancer, including variability in its biologic behavior. Any current estimates of screening benefit will be confounded by lead time and time-linked sampling biases. Until randomized trials of screening demonstrate reduction in population mortality rates, estimates of the benefits of screening will remain tentative.

DIAGNOSTIC TESTS

There has been little formal evaluation of the pelvic examination as a screening test for ovarian cancer among asymptomatic women. Evaluations that have been conducted comparing the physical examination with other diagnostic modalities have produced mixed results. In two studies, pelvic examination failed to detect three stage I tumors that were detected by transvaginal or abdominal ultrasound. However, in other studies, pelvic examination was able to detect early tumors. There is a general consensus that pelvic examination alone is insufficiently sensitive to be of value as a screening test.

Although early use of ultrasonography to diagnose ovarian cancer used the transabdominal approach, more recent work has focused on *transvaginal ultrasonography*, with the addition of color-flow Doppler techniques to improve specificity. The sensitivity of ultrasound has been estimated in studies of women with known ovarian cancer and in screening studies. In the former case, estimates of sensitivity range from 80% to 100%. Estimates are higher in the screening studies, but this may reflect failure to diagnose cancer among screened-negative study subjects. Estimates of specificity derived from screening studies range from about 75% to 97%. A recent analytic review provided summary estimates of sensitivity and specificity of 83% and 93%, respectively. Some studies have shown improvements in specificity of transvaginal ultrasound with addition of color-flow Doppler techniques, which can detect tumor neovascularization. Ultrasound is a safe diagnostic modality. Interpretations can be highly variable and depend on the skill of the operator. Timing the study to avoid ovulation may improve specificity. Cost, personnel, and patient inconvenience limit its use as a primary screening test. Furthermore, the limited specificity of the test results in low predictive values in the screening situation.

There is a great deal of interest in the use of *CA-125* to screen for ovarian cancer. CA-125 is an antigenic determinant on a glycoprotein that is present in the serum at elevated levels in 80% of women with epithelial ovarian cancers. CA-125 levels are also elevated in late-stage endometrial cancers and in about 60% of pancreatic cancers. Levels may also be elevated in patients with benign ovarian cysts, uterine leiomyoma, pregnancy, endometriosis, and pelvic inflammatory disease. Estimates of sensitivity derived from women with known ovarian cancer, using a reference level of 35 U/mL, range from 61% to 96%. In the screening situation, sensitivity has been estimated at 67% to 100%. However, reported sensitivities for stage I disease have ranged from 25% to 75%. The specificity of CA-125 in large screening studies, with the reference level of 35 U/mL, has been approximately 99%. Specificity is much lower in premenopausal women, because CA-125 levels fluctuate with the menstrual cycle and because of a higher prevalence of the benign gynecologic conditions that are associated with elevated levels.

Given the sensitivity and specificity of CA-125 and the prevalence of ovarian cancer in the population of women older than age 50, the expected positive predictive value of a CA-125 level greater than 35 U/mL in that population would be 3%. If screening were restricted to women with ovarian cancer in one first-degree relative or in two or more relatives, the positive predictive values with the same reference level would be 9% and 15%, respectively. These predictive values indicate that many screened women would have false-positive results that would require invasive diagnostic evaluation, often including laparotomy.

Evidence from a pilot randomized trial combining CA-125 and ultrasound suggests that screening may be possible with a moderate number of negative biopsies. Among nearly 11,000 women screened, 468 had levels of 30 U/mL or higher. Of these, only 29 had ovarian volume estimated 8.8 mL or greater on ultrasonography and were referred for biopsy; six had cancers.

Early work suggests that proteomic pattern recognition may play a role in improving early detection of ovarian cancer, but further evaluation is necessary to define sensitivity and specificity, as well as prediditive values in populations appropriate for screening.

Updated: 3/27/02

CONCLUSIONS AND RECOMMENDATIONS

- Women from families with genetic predisposition to ovarian cancer are at high risk and should be screened annually with CA-125 and ultrasound beginning at approximately age 35. Women known to be *BRCA1* mutation carriers are at higher risk than those with *BRCA2* mutations. Screening beginning at an earlier age

(e.g., 25 years) on a semiannual basis may be advisable.

- Women with a family history of sporadic ovarian cancer may benefit from screening with CA-125, but because of the low predictive value and the morbidity associated with further diagnostic evaluation, *routine* screening is not recommended. However, women should be advised of the potential benefits and harms of screening. Similarly, *routine* screening is not recommended for pre- and postmenopausal women without a family history of ovarian cancer.
- Women in their childbearing years should be advised of the ovarian cancer risk reduction afforded by oral contraceptive use. This may be especially important for women with a family history or with known genetic predisposition. Women should be apprised of the potential slight increase in breast cancer risk associated with current use of oral contraceptives, but it is likely that the benefit of ovarian cancer risk reduction outweighs this potential harm.

CHAPTER 109 SCREENING FOR ENDOMETRIAL CANCER

More than 95% of the cancers of the uterine corpus are adenocarcinomas arising from the endometrium. In the United States, endometrial cancer is nearly three times more common than invasive cervical cancer. There are approximately 30,000 cases and 6,000 endometrial cancer deaths among American women each year. The lifetime probability of developing endometrial carcinoma is 3%. Most cases occur in women in whom risk factors are well defined. The tumors often present symptomatically at a time when cure is still possible. Diagnostic tests suitable for indiscriminate screening are not available. It is the responsibility of the primary care provider to be aware of the risk factors and limitations of diagnostic tests, to elicit the pertinent history, and to respond to worrisome symptoms.

EPIDEMIOLOGY AND RISK FACTORS

Advancing age is an important risk factor for endometrial cancer. Most tumors occur during the sixth and seventh decades; fewer than 5% occur before age 40. The risk is increased among first-degree relatives of patients with endometrial cancer. Epidemiologic studies have also shown an association with cancer of the breast and cancer of the colon. Case-control studies have also demonstrated a surprisingly high prevalence of obesity and glucose intolerance among patients with endometrial cancer. Many studies have documented an association between obesity and endometrial cancer with relative risks ranging as high as 20 in some studies. The wide range depends in part on varying definitions of obesity, but most studies have estimated relative risks above 2.0. Up to 40% of patients with endometrial cancer in some studies have diabetes mellitus, but the strength of this association independent of obesity is unclear.

There is strong evidence that *estrogens*, either endogenous or exogenous, play a principal role in the etiology of endometrial carcinoma. The histologic precursor of endometrial cancer is atypical endometrial hyperplasia. Retrospective studies have indicated a progression from cystic hyperplasia through adenomatous hyperplasia to atypical hyperplasia, associated with unopposed estrogen effects. Prospective studies have demonstrated a cumulative incidence of carcinoma of 10% to 30% among patients with atypical endometrial hyperplasia.

A number of clinical syndromes that include ovarian estrogen excess have been associated with the increased risk of endometrial cancer. Postmenopausal women with estrogensecreting tumors have been reported to have a 10% to 24% incidence of endometrial cancer. There is also a high incidence of cancer in patients with *polycystic ovary disease*; 19% to 25% of young women with endometrial carcinoma have underlying Stein-Leventhal syndrome. It is likely that less well-defined abnormalities of estrogen control explain the association of endometrial cancer with menstrual abnormalities and infertility. Approximately half of all women with endometrial carcinoma and 20% to 30% of married women with endometrial carcinoma are nulliparous.

The principal estrogen in postmenopausal women is estrone, which is peripherally converted from androstenedione produced in the adrenal glands. Peripheral conversion of androstenedione to estrone has been shown to be increased in patients with endometrial cancer, and estrone to estradiol ratios are higher. Peripheral conversion by adipose cells may be the explanatory link between obesity and endometrial cancer.

A number of retrospective case-control studies indicate that the use of *estrogens postmenopausally* substantially increases the risk of endometrial cancer. Rates of endometrial cancer among estrogen users ranged from 4 to 14 times those among control patients. Several studies demonstrated a dose–response relationship in that use of estrogen for longer periods of time was associated with greater risk. It has been argued that the association between estrogens and endometrial cancer can be explained in part by a greater likelihood of detection of preexisting tumors in women for whom estrogens are prescribed. Implications of this link between exogenous estrogens and endometrial cancer for treatment of menopausal symptoms are discussed in Chapter 118. Case-control data suggest a 50% decrease in risk among women who have used combination birth control pills for a minimum of 12 months, with the protective effect lasting from 8 to 15 years. A program of estrogen plus progesterone for postmenopausal hormone replacement therapy is not associated with an increased risk of endometrial carcinoma.

NATURAL HISTORY OF ENDOMETRIAL CANCER AND EFFECTIVENESS OF THERAPY

Postmenopausal bleeding, by far the most common symptom associated with endometrial cancer, must always be pursued aggressively. Clinical studies have indicated that, depending on patient selection, cancer is the explanation from 10% to 70% of women who present with postmenopausal bleeding. In one review of more than 400 presentations of bleeding at least 2 years after menopause, 16% of patients had endometrial cancer. The likelihood of malignancy increased with the span of years since menopause.

In a series of more than 500 patients with endometrial cancer from the Mayo Clinic, nearly all presented with postmenopausal bleeding or similar symptoms; only 3% of the tumors were detected in asymptomatic women. In this series, there was little if any correlation between the duration of symptoms and the clinical stage of the tumor at the time of diagnosis. The prognosis for endometrial cancer is generally favorable. In the Mayo series, a 5-year survival rate of 75% was reported.

DIAGNOSTIC TESTS

Available data suggest that endometrial cancer presents with symptoms early in its natural history. There is little evidence that cytopathologic screening can appreciably advance the time of diagnosis in most patients. The diagnosis of endometrial cancer can be made on the basis of a *Papanicolaou (Pap) smear* of cells aspirated from the *vaginal pool* or scraped from the *cervical os*. However, a number of studies have indicated that the sensitivity of the Pap smear in the diagnosis of endometrial cancer is only 70% to 80%. A retrospective review of patients with endometrial cancer who had Pap smears during the year before diagnosis found that only 18% had smears that were suggestive of cancer.

Jet wash and aspiration techniques have been used for sampling cells from the uterine cavity. These techniques proved to be less painful and effective substitutes for dilation and curettage in some diagnostic situations. However, the value of using these techniques to screen asymptomatic women for premalignant and malignant lesions has not been demonstrated.

Transvaginal ultrasound has proven to be an effective means of assessing endometrial thickness related to the probability of finding significant pathology with subsequent curettage in postmenopausal women. This approach has been advocated to monitor women at high risk of endometrial cancer, including those at iatrogenic risk due to unopposed estrogen treatment for menopause (rarely advised for women with intact uteri) or tamoxifen treatment for breast cancer. Estimation of endometrial thickness has also been advocated as a means to avoid diagnostic curettage in postmenopausal women who experience abnormal bleeding. Its value in screening asymptomatic women has not been defined.

SUMMARY AND CONCLUSIONS

Endometrial carcinoma is a source of substantial morbidity and mortality and has well-defined risk factors. Evidence indicates that endogenous and exogenous estrogen stimulation play an etiologic role. Although Pap smears potentially advance the diagnosis of cervical cancer, there are no tests as suitable for endometrial cancer screening. A prompt diagnostic workup, with transvaginal ultrasound perhaps preceding endometrial biopsy, must be initiated by the primary care provider in patients presenting with postmenopausal bleeding. Ultrasound followed by endometrial sampling and other diagnostic interventions should be considered for women at risk because of hormonal therapy. Risk associated with postmenopausal estrogen therapy can be reduced by adding progesterone to the hormone replacement program (see Chapter 118).

CHAPTER 110 VAGINAL CANCER AND OTHER EFFECTS OF DIETHYLSTILBESTROL EXPOSURE

Vaginal cancer is a rare disease, accounting for approximately 1% of gynecologic malignancies. More than 90% of vaginal cancers are squamous cell tumors. Elderly women are at greatest risk, and because of the extensive lymphatic drainage of the vagina, the 5-year survival rate is only 20% to 25%.

Of greater concern to the primary care provider is adenocarcinoma, or clear cell carcinoma of the vagina, which occurs in young women who were exposed to diethylstilbestrol (DES) or other synthetic estrogens *in utero*. Although these tumors are quite rare, the population at risk is large. The anxiety among DES-exposed persons is substantial. In addition to the association with vaginal cancer, other abnormalities of the genital tract, including some that may affect reproductive function, have been reported. The primary physician should understand the risks that follow DES exposure and the natural history of the associated conditions to counsel and evaluate these patients appropriately.

DIETHYLSTILBESTROL AND ABNORMALITIES OF THE GENITAL TRACT

DES is a synthetic estrogen first produced in 1938. After early studies indicated it was helpful in preventing spontaneous abortion, it and other synthetic estrogens were used extensively from the 1940s until 1971 in pregnant women at risk for miscarriage. It has been estimated that between 100,000 and 160,000 women born between 1960 and 1970 were exposed to DES or similar drugs *in utero*. Because these agents were used more extensively in the 1940s and 1950s, well over 1 million women are estimated to have been exposed.

In 1970, a cluster of cases of the then very rare adenocarcinoma of the vagina, occurring in daughters who had been exposed to DES *in utero*, was reported from Massachusetts General Hospital. Since that time, the association has been confirmed, and several hundred cases of clear cell carcinoma have been recorded and investigated. A history of DES exposurehas been elicited in approximately two thirds of all cases of malignancy.

Subsequent prospective studies of exposed women identified the abnormalities of the cervix and vagina that can be found in women at risk, in addition to clear cell carcinoma. Vaginal adenosis, the presence of glandular epithelium in the vagina, occurred in 35% of exposed women but in only 1% of matched control subjects. Cervical erosion was present in more than 75% of exposed women and in only one third of control subjects. Gross structural abnormalities of the cervix were found in more than 20% of exposed women but were not found among control subjects. The cumulative incidence of carcinoma in exposed daughters is estimated to be 1.5 per 1,000 women. The relative risk of vaginal clear cell adenocarcinoma conferred by DES exposure has been estimated to be approximately 40. The embryonic development of the female genital tract begins as early as the 4th week of gestation and is completed by the end of the 18th week. Patients exposed early during this period (i.e., weeks 4 to 18) are most likely to have the epithelial changes and structural abnormalities.

Although tumors have been identified in pre-teenaged patients as young as age 7, more than 90% of tumors have been found in daughters age 14 or older. The peak incidence of tumors occurs between the ages of 14 and 20, suggesting that the period of greatest risk occurs when the abnormal vaginal or cervical epithelium is stimulated by ovarian hormones with the onset of puberty. Incident cases after age 29 years are rare, but incident vaginal adenocarcinoma has been reported in exposed women in their forties.

Findings from the National Collaborative Diethylstilbestrol Adenosis (DESAD) Project indicate that women exposed to the drug *in utero* have a twofold increase in risk of *cervical* intraepithelial neoplasia over nonexposed control subjects. But there is no increase in risk of invasive cervical cancer.

Questions have also been raised about the ability of DES-exposed offspring to conceive. A high prevalence of uterine and fallopian tube abnormalities has been described in case series of exposed women who have undergone hysterosalpingography. A controlled cohort study from the DESAD Project, however, found no difference in fertility between exposed and control subjects. Subsequent studies have suggested a modest increase in risk of primary *infertility* in association with the higher prevalence of abnormal hysterosalpingograms among exposed daughters. DES-exposed women who become pregnant have been shown to be more likely to have an *unfavorable outcome* of pregnancy. It has been estimated that DES-exposed women are approximately eight times more likely to have an ectopic pregnancy, twice as likely to have a miscarriage, and five times as likely to deliver prematurely. Nevertheless, more than 80% of such women had at least one full-term live birth during the course of the DESAD study.

A large cohort study with an average follow-up of 16 years found no increased risk of cancer other than clear cell adenocarcinoma of the vagina. Because of the relatively young age of the cohort, definitive conclusions await further study. Mothers exposed to DES during their pregnancy face a modest increase in breast cancer risk, with a relative risk of 1.35.

Genital abnormalities and infertility have also been described in male offspring of mothers who took DES early in pregnancy. It is likely that these findings were influenced by selection and ascertainment biases; the only controlled study addressing this question found no differences in rates of genitourinary abnormalities, infertility, or testicular cancer in exposed and nonexposed men.

SYMPTOMS AND NATURAL HISTORY OF VAGINALCANCER AND EFFECTIVENESS OF THERAPY

The natural history of clear cell carcinoma is uncertain. Cases can present with *abnormal vaginal bleeding or discharge*, but because of increasing public and professional awareness, a substantial percentage of cases are detected in the asymptomatic stage. Adenosis has been found in proximity to adenocarcinoma in more than 95% of cases, and it is therefore considered a malignant precursor by some. Transitions from adenosis to carcinoma have not, however, been clearly documented.

Limited follow-up information indicates that clear cell carcinoma is an aggressive tumor. Metastases have been found at the time of surgery in 17% of cases of stage I disease and in most cases of stage II disease. Short-term follow-up of registry cases of clear cell carcinoma has indicated that recurrence, death, or both occur in approximately 25% of patients.

It is too early to know whether cervical dysplasia and carcinoma *in situ* in DES-exposed young women have the same natural history as nonexposed women (see Chapter 107). However, it seems prudent to follow such patients with vigilance and yearly Papanicolaou (Pap) smears.

DIAGNOSTIC TESTS

Although the discovery of abnormal cytology has led to the detection of some cases of clear cell carcinoma, the *Pap smear* has been shown to have a relatively low sensitivity (80%) for detecting this lesion. This may be explained by the relatively high degree of differentiation of the neoplastic cells, which may resemble endocervical cells. The cells may also be obscured by a heavy polymorphonuclear infiltration. The initial examination of a woman exposed *in utero* to DES or similar drugs must therefore include, in addition to direct inspection of the vagina and cervix and cytologic sampling, careful *Schiller's iodine staining and biopsies* of areas that appear red or fail to stain with the iodine solution. *Colposcopy* is a complementary procedure, particularly useful in patients with abnormal iodine staining or cytology. Colposcopy should be performed by an experienced gynecologist.

Despite the poor sensitivity of the Pap smear for clear cell cancer, Pap smears should be done yearly in all women with an exposure history. This is especially important in light of the increased risk of cervical intraepithelial neoplasia, particularly among women with evidence for human papillomavirus infection or other risk factors related to sexual activity.

CONCLUSIONS AND RECOMMENDATIONS

- As many as 1 million women are at risk for abnormalities of the genital tract, including clear cell adenocarcinoma, because of *in utero* exposure to DES or other synthetic estrogens.
- Risk of malignancy among exposed women is low. Nevertheless, because of the significant morbidity and mortality associated with these tumors, careful case finding and evaluation are indicated. Because routine screening procedures such asthe Pap smear are inadequate, patients at risk must be identified by careful history taking if they are to receive proper evaluation and counseling.
- It is recommended that exposed daughters with symptoms such as vaginal discharge or bleeding are examined promptly regardless of age. Asymptomatic daughters with a history of exposure should have an initial evaluation at age 14 with subsequent yearly examinations.
- More frequent examinations are advised when extensive epithelial changes are present. When possible, such examinations should be performed by a gynecologist experienced in the use of the colposcope.

CHAPTER 111 APPROACH TO THE WOMAN WITH ABNORMAL VAGINAL BLEEDING

Abnormal vaginal bleeding is bleeding that occurs at an inappropriate time (less than 21 or more than 36 days after last period) or in an excessive amount (clots lasting more than 7 days). About one half of all women presenting with this problem are over age 40 years. In these peri- and postmenopausal patients, uterine malignancy must be ruled out. Pelvic pathology is also a possibility in younger women, but disturbances of the hypothalamic-pituitary-ovarian axis are more common precipitants of abnormal bleeding. This is especially true among adolescent and immediately postadolescent women who constitute about 20% of those presenting with abnormal bleeding. When bleeding is anovulatory and occurs in the absence of an anatomic lesion, it is sometimes referred to as "dysfunctional." The terms "anovulatory" and "dysfunctional" are used interchangeably by clinicians. The former is more explanatory and is less likely to have negative connotations for the patient.

The differentiation of anovulatory bleeding from bleeding due to anatomic pathology in the presence of normal ovulation is the goal of the primary physician's initial evaluation and an important determinant of therapy. Anovulatory bleeding is common for young women just beginning to ovulate and may last 1 to 2 years before menses become regular. It is also common as ovarian function declines in the perimenopausal woman where it presents a particular challenge, because this is also a time for increased risk of endometrial cancer.

PATHOPHYSIOLOGY AND CLINICAL PRESENTATION

Normal Menstrual Bleeding

Normally, in the absence of implantation of a fertilized ovum, the ovarian corpus luteum undergoes regression within 9 to 11 days of ovulation. Estrogen and progesterone productionfall and menstruation ensues. The normal menstrual cycle ranges from 23 to 39 days (mean, 29 days). Cycle length shortens as menopause approaches. The menstrual period usually lasts 2 to 7 days, with most blood lost during the first few days. Presence of clots or duration of bleeding in excess of 1 week indicates excessive blood loss. Abnormal bleeding may occur in the context of normal ovulation or in its absence.

Abnormal Bleeding in the Settingof Normal Ovulatory Cycles

In normally ovulating women, abnormal vaginal bleeding may present as *menorrhagia* (bleeding that is normal in timing but excessive in amount and duration) or *intermenstrual bleeding*. Most often the cause is an *endometrial or cervical lesion* (Table 111.1). However, it sometimes is the presenting symptom of a *bleeding diathesis*, most often the consequence of thrombocytopenia or a qualitative platelet disorder (see Chapter 81).

Table. 111.1. Differential Diagnosis of Abnormal Vaginal Bleeding

Normal ovulation may be accompanied by a small amount of midcycle vaginal staining and pelvic pain (especially on the right side). It is sometimes referred to as "*mittelschmerz*," which occurs in the context of ovarian follicle rupture and release.

Uterine Fibroids or leiomyomas are the most common cause and account for about one third of cases. Fibroids occur in 20% to 25% of women before age 40 and in up to half of all women overall. However, only those fibroids that are submucosal in location and involve the uterine cavity cause bleeding. Location is more important than size. Because they are so common, they may coexist with another cause of abnormal vaginal bleeding. Periods are often very heavy.

Carcinoma of the Cervix is among the more serious sources of abnormal bleeding in ovulating patients, although it accounts for only about 3% of cases. *Postcoital bleeding* and slight intermenstrual spotting are characteristic when there is surface ulceration, which may occur in early stages of the disease (see Chapter 123).

Endometrial Carcinoma is more typically a disease of abnormal vaginal bleeding in postmenopausal women (see below), but 20% have the disease while still menstruating (although almost all are over the age of 40). Heavier than normal periods are noted as well as an intermenstrual watery discharge containing small amounts of blood early on.

Polyps, Erosions, and Infection. *Cervical polyps, cervical erosions, and vaginal lesions* present similarly, with slight spotting noted intermenstrually, especially after coitus. *Pelvic inflammatory disease*, with its fever, pelvic pain, and discharge, may lead to postcoital, intermenstrual, or heavy menstrual bleeding by causing cervicitis, endometritis, or salpingitis.

Foreign Bodies. *Intrauterine devices* also alter the endometrial surface and can be similarly responsible for heavy menstrual bleeding or intermenstrual bleeding. Vaginal wall irritation from *tampon* use may lead to minor vaginal bleeding.

Anovulatory Bleeding

This type of bleeding is usually a manifestation of a disturbance within the hypothalamic-pituitary-ovarian axis. *Metrorrhagia*—prolonged bleeding occurring at irregular intervals—is characteristic.

Hypothalamic Dysfunction. The pathophysiologic common denominator is *inadequate progesterone* production, most often due to lack of a *luteinizing hormone (LH) surge* at midcycle,a consequence of an alteration in the normal pattern ofgonadotropin-releasing hormone (GnRH) release from the hypothalamus. This pattern is typical of patients with mild hypothalamic dysfunction who may experience irregular menses in the context of moderate *situational stress, weight loss, or exercise training.* However, oligomenorrhea and amenorrhea may follow if the functional disturbance is more severe, impairing follicle-stimulating hormone (FSH) secretion and estrogen production (see Chapter 112). Those who bleed have an estrogen-withdrawal type of bleeding. The severity of the bleeding is a function of the amount of estrogen produced. The bleeding that occurs from mild hypothalamic dysfunction is sometimes referred to as "dysfunctional." *Hyperprolactinemia, hypothyroidism*, and excess production of *androgen* and *cortisol* can also disturb hypothalamic rhythmicity. Even *iron deficiency anemia* has been found to inhibit ovulation.

Histoanatomically, unruptured ovarian follicles persist, and functioning corpora lutea are absent. The endometrium shows hyperplasia resulting from unopposed

estrogen effect. There is little if any secretory pattern because of the lack of progesterone.Ovulation does not occur, and anovulatory bleeding results when progesterone production returns or excessive proliferation causes sloughing of the overstimulated endometrium. There is irregularity of the menstrual interval, periods of amenorrhea, and episodes of very heavy and prolonged bleeding if there has been sufficient estrogen-induced buildup of the endometrium.

Polycystic Ovary Syndrome. This incompletely understood condition affects about 5% of reproductive-age women and represents a leading cause of chronic anovulatory bleeding. In addition to a life-long history of irregular periods, patients may report infertility, hirsutism, obesity, and amenorrhea. Disordered hypothalamic rhythmicity is believed to cause excessive LH production without a midcycle surge, leading to ovarian overproduction of *testosterone* and *androstenedione*. Some of this androgen is converted to *estrone*, which can stimulate endometrial proliferation that ends in irregular episodes of bleeding. Serum concentrations of both estrogen and testosterone rise. *Insulin resistance* with hyperinsulinism are common and believed to be linked to ovarian androgen overproduction. The consequences of androgen excess range from hirsutism to frank virilization (see Chapter 98), although the latter is uncommon. Chronic unopposed endometrial estrogen stimulation can lead to adenomatous hyperplasia, cellular atypicality, and even endometrial carcinoma. Risk of cancer is increased threefold.

Puberty. The anovulatory bleeding of puberty is a consequence of immaturity of the positive-feedback mechanism responsible for the LH surge that triggers progesterone secretion. In the absence of adequate progesterone production, estrogen-withdrawal bleeding takes place. The pattern of anovulatory bleeding is irregular and may occur anytime between 22 and 45 days.

Perimenopausal Bleeding. The irregular menstrual bleeding that characterizes the perimenopausal period is also an anovulatory estrogen-withdrawal phenomenon. As the number of functioning ovarian follicles declines, insufficient estrogen is produced to cause an LH surge and ovulation. In the absence of progesterone production, an estrogen-withdrawal type of irregular bleeding occurs. Such perimenopausal bleeding can continue for months to years, but it eventually stops when estrogen production ceases.

Postmenopausal, Pregnancy-related, and Breakthrough Types of Bleeding

Postmenopause. Here the major concern is cancer, although *uterine fibroids* still account for most cases. Women who have had chronic unopposed estrogen stimulation are at increased risk of *endometrial carcinoma*. Early on, bleeding may be subtle and little more than minor vaginal staining (see Chapter 123). Postmenopausal women with marked *atrophic vaginitis, cervical polyp, or cervicitis* from a prolapsed uterus may also experience some blood-stained vaginal discharge or minor spotting. Cervical carcinoma is uncommon after age 55 in women who have had Papanicolaou (Pap) smears regularly but may be the cause of bleeding in the early postmenopausal period.

Pregnancy. One of the most serious causes of acute abnormal vaginal bleeding in women of reproductive age is *ectopic pregnancy*, which is characterized by delay of the regular period followed by vaginal blood spotting, often in conjunction with unilateral pelvic pain. Intraperitoneal hemorrhage can ensue if tubal rupture occurs, but this happens in fewer than 5% of cases. A *failing pregnancy* may be heralded by onset of bleeding. *Retained products of gestation* represents a very common cause of abnormal uterine bleeding after abortion; blood loss is often heavy.

Oral Contraceptives. If an oral contraceptive contains insufficient estrogen or if compliance is inadequate, then abnormal vaginal bleeding may occur. The characteristic pattern is one of "*breakthrough bleeding*" or staining that occurs intermenstrually (see Chapter 119).

DIFFERENTIAL DIAGNOSIS

The differential diagnosis can be divided into ovulatory, anovulatory, postmenopausal, and pregnancy-related etiologies (Table 111.1). Among postmenopausal women, endometrial cancer accounts for up to 25% of cases of bleeding, although most are due to submucosal uterine fibroids. In women of reproductive age, the etiology is often an anovulatory disturbance, although cancer remains a concern. As noted, girls going through puberty and perimenopausal women who complain of irregular menses are most likely to have anovulatory bleeding.

WORKUP

Among women of reproductive age who complain of abnormal vaginal bleeding, the initial tasks are to rule out pregnancy and determine if the bleeding is ovulatory or anovulatory. Postmenopausal bleeding has its own workup, which focuses on identifying the anatomic site of bleeding.

History

A careful and detailed menstrual history is essential. Most important is information on the patient's normal menstrual cycle (duration, frequency, intensity) and how the current bleeding pattern compares with it. If the patient is of childbearing age, then inquiry should be made into unprotected intercourse and symptoms of pregnancy (breast engorgement, morning sickness, cessation of normal menses). If menstrual regularity persists despite an increase in intensity or duration of flow or onset of intermenstrual staining, then an ovulatory etiology is likely. This is further supported by presence of premenstrual symptoms, such as breast engorgement, pelvic cramping, fluid retention, and mood swings. Anovulatory bleeding is suggested by the absence of such symptoms plus complete irregularity of menstrual periods, especially if accompanied by months of amenorrhea. Although intensity of the bleeding (e.g., by number of pads or tampons used) is more useful for management than for diagnosis, the new onset of clots or duration of more than 7 days argues for abnormal bleeding.

Ovulatory Bleeding. History should include query into symptoms of a bleeding diathesis and medicines that inhibitnormal clotting (see Chapter 81). Equally important is checking for dyspareunia, postcoital bleeding, vaginal discharge, pelvic pain, fever, trauma, and intrauterine device use. Risk factors for endometrial carcinoma should be reviewed (see Chapter 123).

Anovulatory Bleeding. One should ask about important precipitants, such as emotional stress, weight loss, exercise, and chronic illness. If the patient is an adolescent girl, one should check for a history of irregular periods since the onset of menarche and the common precipitants just noted. Review of medications for use of oral contraceptives is essential, with attention to the estrogen dose and history of breakthrough bleeding. For the perimenopausal woman, menstrual irregularity and the skipping of periods suggest a functional etiology but do not rule out cancer. Androgen excess is suggested by symptoms of hirsutism and virilization (see Chapter 98) and a history of infertility. Rapid onset of hirsutism and virilization raises the possibility of a functioning adrenal or ovarian tumor-making androgens. A life-long history of irregular menses, hirsutism, infertility, and obesity suggests polycystic ovary syndrome. Inquiry into galactorrhea and development of cushingoid appearance check for prolactin and cortisol excess, respectively. Any symptoms of hypothyroidism (see Chapter 104) and iron deficiency (see Chapter 79) should be noted.

Postmenopausal Bleeding. Any history of bleeding, even if just minor staining, should be taken as evidence of a possible malignancy. However, inquiry into symptomatic atrophic vaginitis and uterine prolapse may provide useful clues.

Physical Examination

Regardless of presumed etiology, all patients should be checked for *postural signs* indicative of significant intravascular volume depletion. In addition, careful *speculum and bimanual pelvic examinations* are essential, with particular care taken to note any vaginal or cervical erosions, uterine or adnexal masses, focal tenderness, or purulent or bloody discharge. Signs of pregnancy (engorged breasts, pigmented areolae, bluish cervix, enlarged uterus) should be sought in women of reproductive age.

Suspected ovulatory bleeding necessitates concentrating on the pelvic examination, but one should also check for signs of a bleeding diathesis (petechiae, ecchymoses, splenic enlargement). The patient with *suspected anovulatory bleeding* should be carefully examined for hirsutism, virilization, cushingoid appearance, milky nipple discharge, goiter, dry skin, coarse hair, and "hungup" reflexes. Visual field testing is indicated if there is suspicion of a large pituitary adenoma. Presence of hirsutism or virilization necessitates thorough pelvic and abdominal examinations for an ovarian or adrenal mass.

On examination of the *postmenopausal woman*, particular note should be taken of the friability of the vaginal mucosa and cervix and the presence of any uterine or adnexal masses.

Laboratory Studies

All patients of reproductive age with abnormal vaginal bleeding should be tested for pregnancy (a *serum human chorionic gonadotropin b subunit* is the most sensitive; see Chapter 112). A *complete blood count* is always useful. The *hematocrit* will help assess the severity of chronic blood loss (although not of acute hemorrhage; see Chapter 79) and a mean *red cell volume* may reveal the microcytosis of iron deficiency.

Ovulatory Bleeding. Here the goal is identification of pelvic pathology after ruling out concurrent disease that may predispose to heavy bleeding. Determinations of *blood urea nitrogen, creatinine, and platelet count* should be obtained when there is concern about a bleeding diathesis. Otherwise, one should proceed directly to *pelvic ultrasound* examination, with transvaginal study being the most sensitive noninvasive means of searching for uterine and adnexal pathology; it is superior to the standard transabdominal approach.

A *Pap smear* is indicated if the cervix appears abnormal. In women over age 40, *vaginal cytologic sampling* from the posterior cervical fornix may detect abnormal endometrial cells shed into this accessible area. Acetic acid can be added to cytology preservative if the smear sample is bloody. A *cervical culture* for gonorrhea and for other pathogenic organisms is needed in the patient with pain on motion of the cervix and adnexal tenderness (see Chapter 117); an elevated *sedimentation rate* suggests pelvic inflammation.

Endometrial sampling is central to the evaluation of ovulatory bleeding when noninvasive evaluation is unrevealing. It is contraindicated in the presence of cervical stenosis, infection, or pregnancy. Transvaginal ultrasound or hysteroscopy should generally precede diagnostic dilation and curettage.

Anovulatory Bleeding. No additional studies are necessary when the etiology is evident (e.g., situational stress, puberty, chronic illness, marked weight loss). If perimenopausal bleeding is suspected, an *FSH* can be confirmatory; if more than 40 IU/mL, then ovarian failure is imminent. An LH-to-FSH ratio of greater than 2:1 is characteristic of polycystic ovary syndrome. When hirsutism or virilization is noted, a serum *testosterone* is the best test. If the onset of such changes is rapid or the serum testosterone is greater than 600 nmol/L (190 ng/mL), then a functioning adrenal or ovarian neoplasm may be the source and a *17-hydroxyprogesterone* can facilitate the diagnosis. A *fasting serum insulin* level is also indicated in patients with elevated testosterone (more than 350 nmol/L, 100 ng/mL). A *fasting insulin* level in excess of 180 pmol/L is suggestive of insulin resistance.

Postmenopausal Bleeding. Noninvasive study for pelvic pathology is conducted as noted above. Because concern about endometrial cancer is high in this age group, endometrial sampling or diagnostic dilation and curettage is appropriate, even when noninvasive study is unrevealing.

SYMPTOMATIC MANAGEMENTAND PATIENT EDUCATION

Acute anovulatory bleeding that is not severe can often be managed by the primary care physician in the office setting. To stop the abnormal bleeding, one can administer a course of oral *medroxyprogesterone* (Provera; 10 mg/d for 10 days) or a single intramuscular injection of *progesterone* (100 mg). These will convert a proliferative endometrium to a secretory one. Bleeding should stop within 24 to 48 hours of initiating progestin therapy, and menstrual flow should occur on its completion.If this so-called medical dilation and curettage does not stop acute bleeding, then referral for dilation and curettage and hysteroscopy is indicated.

Chronic Anovulatory Bleeding can be treated symptomatically by monthly administration of progesterone therapy. By causing regular endometrial shedding, it protects against adenomatous changes and lowers the risk of endometrial cancer associated with long-term unopposed estrogen stimulation. A course of *medroxyprogesterone* given for the last 10 to 12 days of each month will usually suffice. Cessation of further abnormal bleeding episodes argues strongly against a structural lesion, but resumption of such bleeding on progestin therapy necessitates referral for dilation and curettage.

Ovulation may resume on this program, particularly in the young person, and periodically the treatment should be halted for a month or two to observe for the return of normal cycles. If abnormal bleeding recurs despite correction of all possible precipitating factors, then maintenance hormonal therapy may be used. In patients who do not desire pregnancy, an *estrogen-progestin* oral contraceptive preparation may be used in place of the medroxyprogesterone (see Chapter 119). Oral contraceptive therapy has the advantage of improving the hyperandrogenism that accompanies some causes of chronic anovulatory bleeding. The patient with anovulatory bleeding who desires pregnancy should be referred for consideration of clomiphene therapy. Any iron deficiency (see Chapter 82) or pelvic infection should be treated (see Chapter 117).

Nonsteroidal anti-inflammatory agents may decrease bleeding by as much as 50%. They may also provide relief for any associated dysmenorrhea. They may be used along with oral contraceptives. Danazol may also be effective but has some undesirable androgenic side effects. GnRH analogues produce a menopausal state in women of reproductive age. They are used primarily for preoperative management of uterine fibroids and for endometrial preparation before ablation procedures.

When anovulatory bleeding is diagnosed, it is important for the patient to know that reproductive capacity is not lost, that some causes are self-limited, and that the possibility of malignancy is very low under age 30. Addressing any contributing factors (e.g., situational stress, dieting, excessive exercise, hypothyroidism [see Chapter 104], hyperprolactinemia [see Chapter 100], polycystic ovary syndrome [see Chapter 112]) is essential to successful therapy.

Perimenopausal Bleeding may be the result of anovulatory periods, but an irregular pattern may also represent intrauterine disease. When discussed openly, the concerns that most patients already harbor can be addressed and often lessened, because most cases are not likely to be cancerous. Once a structural lesion has been ruled out, symptomatic therapy with monthly *medroxyprogesterone* (10 mg/d for 10 to 12 days) can commence. It will correct the irregular bleeding. Therapy is continued monthly until withdrawal bleeding stops, indicating arrival of ovarian failure and menopause. Until menopause, some ovulatory periods may still take place and cause bleeding independent of progesterone therapy. In such instances, an oral contraceptive can be used as an alternative to progesterone, provided the patient is a nonsmoker, normotensive, and not hyperlipidemic.

Breakthrough Bleeding. Patients experiencing breakthrough bleeding on low-dosage estrogen oral contraceptives need to be sure they are adhering carefully to their regimen. If they are taking the medication on schedule, switching to a preparation with a higher estrogen dose is indicated.

INDICATIONS FOR ADMISSION AND REFERRAL

Immediate hospital admission is essential for any woman who is bleeding heavily and manifests signs of intravascular volume depletion. Immediate hospital admission and gynecologic consultation are particularly important if ectopic pregnancy is a possibility, because life-threatening hemorrhage is a real, albeit slight, risk. The same applies to cases of recent abortion, because placental tissue may be retained. Bleeding in pregnancy is a definite indication for an emergency obstetric consultation.

Any patient with abnormal vaginal bleeding who has a mass lesion detected on pelvic examination, an abnormal appearing cervix, an abnormal Pap test, or risk factors for carcinoma of the cervix or endometrium (see Chapter 107 and Chapter 109) should be referred to the gynecologist. The consultation is essential for any perimenopausal or postmenopausal woman who experiences the new onset of staining or abnormal bleeding, because the risk of malignancy is greatly increased. In one retrospective series, 23% of women with postmenopausal bleeding were found to have endometrial carcinoma. Dilation and curettage, generally after transvaginal ultrasound or hysteroscopy, is usually required. Patients under age 30 with an otherwise normal examination are at very low risk and need not be referred. However, risk of cancer begins to increase over age 30, necessitating consideration of referral for invasive evaluation, especially in the ovulating patient with abnormal bleeding.

When medical therapy fails to adequately control chronic bleeding, there are surgical options. By this time, most women will already have been referred to a gynecologist for invasive evaluation. They may be offered endometrial ablation or hysterectomy. The primary care provider should maintain a supportive role in the decision making, ensuring that the patient is adequately informed about the harms and benefits of surgical intervention. It is especially important that women approaching menopause appreciate that their symptoms will diminish over time with "watchful waiting" and symptomatic therapy.

CHAPTER 112 EVALUATION OF SECONDARY AMENORRHEA

Secondary amenorrhea is defined as cessation of menses for 3 or more months in a woman with previously normal cycles. The incidence of secondary amenorrhea is about 3% in unselected populations. The primary physician is frequently consulted by women who have missed one or more menstrual periods. Concerns about pregnancy and menopause are prominent. Knowing how to initiate an efficient workup for functional or structural abnormalities of the hypothalamic-pituitary-ovarian axis and knowing when to refer are important com-ponents of the primary care of women with this problem.

PATHOPHYSIOLOGY AND CLINICAL PRESENTATION

Amenorrhea reflects an interruption in the mechanisms of normal menstruation and may result from a disturbance at the level of the hypothalamus, pituitary, ovaries, or uterus.

Hypothalamic Amenorrhea most often results from a *functional disorder of gonadotropin-releasing hormone (GnRH) release* causing *loss of a luteinizing hormone (LH) surge* and failure to ovulate. The most profound disturbances of GnRH release may occur in the context of *marked weight loss* (less than 70% ideal, as in anorexia nervosa and other eating disorders; see Chapter 233), *severe emotional upset, or excessive exercise* (competitive athletes). Up to half of women who are competitive long distance runners experience secondary amenorrhea, believed linked to endorphin-mediated inhibition of normal GnRH release. Some weight-stable nonathletic women with functional hypothalamic amenorrhea exhibit evidence of subclinical eating disorders characterized by severe restriction of dietary fat. In patients with severe functional impairment of GnRH release, follicle-stimulating hormone (FSH) release and estrogen levels can fall so far below normal that the patient is at risk for osteopenia; *osteoporosis* may ensue if the condition goes untreated for a prolonged period of time. In addition, there is little or no endometrial proliferation, so that withdrawal bleeding does not occur upon uterine exposure to progesterone. Persons with severe functional hypothalamic amenorrhea can achieve a return of GnRH release and restoration of normal periods with correction of the underlying problem. However, the bone loss may be permanent.

Milder functional forms of impaired GnRH release are seen in the settings of *situational stress* and *mild weight loss*. In mild functional hypothalamic disease, FSH secretion continues at a low-normal level, allowing estrogen production that results in endometrial proliferation. Withdrawal bleeding occurs upon exposure to progesterone, be it endogenous or exogenous.

A host of endocrinopathies may cause amenorrhea by interfering with normal GnRH release. Excess production of *cortisol, androgens*, and *prolactin* have been linked to impairment of GnRH release. *Hypothyroidism* may present as amenorrhea by its ability to trigger prolactin secretion.

Drugs are sometimes responsible, including oral contraceptives and agents with dopaminergic activity (e.g., phenothi-azines). Menses usually return within 2 months of stopping oral contraceptives, although "post-pill amenorrhea" can last up to 6 months. More prolonged amenorrhea suggests underlying pathology unrelated to oral contraceptive use.

Pituitary Pathology. Most *pituitary neoplasms* are relatively infrequent causes of amenorrhea, but *prolactinomas* are responsible for up to one fourth of cases. Excess prolactin production *inhibits normal GnRH release* and impairs gonadotropin production. The characteristic clinical picture is one of *galactorrhea, infertility*, and *amenorrhea* (see Chapter 100). As prolactin levels rise, plasma concentrations of gonadotropins and estradiol begin to fall. Early on, estrogen levels may still be sufficient to produce withdrawal bleeding upon exposure to progesterone, but eventually this ceases. Most prolactinomas are small (less than 10 mm in diameter) and designated as "*microadenomas*." Patients with microadenomas usually have otherwise normal pituitary function, whereas those with "*macroadenomas*" (more than 10 mm) may experience reduced secretion of other pituitary trophic hormones. In cases where high levels of prolactin are produced that markedly impair gonadotropin secretion, *estrogen deficiency* may ensue and put the patient at risk for *osteoporosis*. If large enough, the tumor can displace pain-sensitive neurologic structures and cause headache; impinging on the optic chiasm may result in a visual field defect. Over time, most patients with microadenomas experience a decrease in prolactin production and a return of ovulation; however, among those who become pregnant, there is approximately a 10% chance of the neoplasm enlarging. Overall, only some patients with prolactinomas suffer an increase in tumor size.

Less common pituitary lesions include *sellar tumors, postpartum pituitary necrosis* (Sheehan's syndrome), *empty sella, and granulomatous disease* (e.g., sarcoidosis). These destructive lesions can impair functioning pituitary tissue. Growth hormone production is usually the first to suffer but usually without causing symptoms, followed by *reduced FSH and LH synthesis*, leading to amenorrhea, which may be the presenting complaint. Headache and visual field defects may follow later, as might manifestations of panhypopituitarism. In empty sella syndrome, there appears to be herniation of the arachnoid down into the sella, compressing its contents and producing a ballooning of the bony sella on x-ray. The typical patient is female, obese, multiparous, and complaining of headache. Mild hyperprolactinemia may result from loss of normal inhibition of prolactin secretion and may lead to amenorrhea.

The dopamine blocking effects of antipsychotics, notably risperidone, can increase prolactin to levels associated with amenorrhea.

Ovarian Dysfunction leading to amenorrhea is characterized by marked *elevations in LH and FSH* and *low levels of estrogen and progesterone*. In all types of ovarian failure, estrogen deficiency is marked and osteoporosis may ensue.

Normal Menopause results from depletion of ovarian follicles. As estrogen production declines, gonadotropins increase, reaching extreme levels as the serum estradiol concentration drops to less than 5% of normal (about 5 pg/mL). Early manifestations include hot flashes, anovulatory bleeding, and missed periods, followed by total cessation of periods (see Chapter 118). *Premature menopause* presents in a similar fashion, except that the patient is under the age of 40. There are no associated endocrinopathies or systemic illnesses in this *idiopathic* form of premature ovarian failure. There are no ovarian follicles on biopsy.

Polycystic Ovary Syndrome (formerly Stein-Leventhal syndrome) is an important ovarian cause of amenorrhea, characterized clinically by *hirsutism, anovulation, and oligomenorrhea* or *amenorrhea*. Many patients are obese and have bilaterally enlarged polycystic ovaries. Biochemical features include *elevations in free and total testosterone, reduced sex hormone-binding globulins, elevated LH levels* (without a midcycle surge), and *hyperinsulinemia*. In addition, many of these patients are *obese* and manifest *insulin resistance*, although frank diabetes mellitus is not the rule. *Infertility* occurs in about 75% of cases, hirsutism in 70%, and amenorrhea in 50%. Characteristically, both ovaries are enlarged and polycystic, although not invariably, and not all women with cystic ovaries have the hormonal syndrome. The precise pathophysiology appears to be multifactorial and remains poorly understood, but hyperinsulinemia appears to play an important role in some persons. Treatment to correct hyperinsulinemia can cause many of the biochemical features of the disease to revert toward normal and periods to resume. It is postulated that in genetically susceptible persons, hyperinsulinemia may trigger excessive ovarian production of testosterone and high levels of LH production.

Autoimmune Polyglandular Failure is associated with about one half of cases of premature ovarian failure. It may present as adrenal insufficiency and progress to ovarian, thyroid, and pancreatic endocrine dysfunction. Myasthenia gravis or pernicious anemia sometimes accompanies the condition, which is hereditary and transmitted in an autosomally recessive fashion. Cancer treatment may cause direct irreversible ovarian injury when *radiation therapy* is used (see Chapter 89) and reversible suppression in the setting of *alkylating agent chemotherapy* (see Chapter 88). Premature ovarian failure also occurs without evidence of autoimmune disease or known precipitants. Extensive *endometriosis* may compromise ovarian function, as might mumps-related *oophoritis*. *Ovarian resistance to FSH* is a rare condition, with premature ovarian follicles present on biopsy but no response to FSH. *Ovarian tumors* rarely destroy enough ovarian tissue to cause amenorrhea, but granulosa-cell tumors, which produce excess estrogen, and arrhenoblastomas, which synthesize excess androgen, may be responsible for amenorrhea.

Uterine Pathology. Endometrial scarring may occur as a consequence of radiation therapy, septic abortion, or overly vigorous curettage. Adhesions can obliterate the uterine cavity (Asherman's syndrome). Similarly, cervical trauma can result in scarring.

DIFFERENTIAL DIAGNOSIS

Table 112.1 lists the causes of secondary amenorrhea, distinguishing among hypothalamic, pituitary, ovarian, and uterine etiologies. In one representative series of patients with secondary amenorrhea, hypothalamic dysfunction accounted for 30% of cases, polycystic ovary syndrome for 30%, pituitary disease (mostly prolactinomas) for 15%, ovarian failure for 12%, and uterine problems for about 5%.

1. Hypothalamic dysfunction
   a. Mild
      1. Situational stress
      2. Dieting
      3. Concurrent illness
      4. Increased exercise
      5. Drugs (phenothiazines, oral contraceptives)
      6. Idiopathic
   b. Marked
      1. Anorexia nervosa with severe weight loss
      2. Serious emotional stress or psychopathology
      3. Serious concurrent illness
      4. Competitive long-distance running
      5. Excess androgen, prolactin, or cortisol
      6. Idiopathic
2. Pituitary disease
   a. Prolactinoma
   b. Other pituitary neoplasm
   c. Empty sella syndrome
   d. Pituitary infarction (Sheehan's syndrome)
   e. Granulomatous disease (sarcoidosis)
3. Ovarian
   a. Menopause
   b. Polycystic ovary syndrome (may have hypothalamic etiology)
   c. Premature ovarian failure (idiopathic, autoimmune disease, radiation therapy, chemotherapy, endometriosis, oophoritis)
   d. FSH resistance
4. Uterine
   a. Obliteration of uterine cavity by intrauterine scarring and synechiae formation—Asherman's syndrome (overly vigorous curettage, septic abortion, radiation)
   b. Cervical scarring with resultant os closure
5. Endocrinopathies
   a. Thyroid disease
   b. Cushing's syndrome
   c. Hyperandrogenism
6. Pregnancy

FSH, follicle-stimulating hormone.

Table 112.1. Important Causes of Amenorrhea

WORKUP

The first priority is to *rule out pregnancy*. History is reviewed for recent unprotected intercourse and symptoms of early pregnancy (e.g., morning sickness). Any possibility of pregnancy should lead directly to a *serum human chorionic gonadotropin (hCG) b subunit* determination. The test is the most sensitive and specific test for pregnancy, capable of providing a definitive answer rapidly and at a much earlier stage of pregnancy than is possible with urine testing for human chorionic gonadotropin. However, the *urine human chorionic gonadotropin-precipitation slide test* is more convenient and can be performed at home on a first-morning voided urine. It can achieve 90% sensitivity about 6 weeks after the last menstrual period under ideal conditions. But actual sensitivity when the urine testing is performed by patients is closer to 75%. A negative urine test requires retesting in a week or proceeding directly to serum testing. Once the question of pregnancy is settled, evaluationfor other etiologies can proceed in logical systematic fashion.

History and Physical Examination

History should begin with a detailed menstrual history and the circumstances of the amenorrhea. Age of menarche, character of normal cycles, timing of missed periods, and any prior pregnancies or abortions should be ascertained. A detailed psychosocial history may provide evidence for hypothalamic amenorrhea and should include inquiry into situational stresses (job, school, family, friends), emotional problems, excessive dieting, bulimia, marked weight loss, and heavy physical training. Nutritional imbalance including severe dietary fat restriction may be relevant. Oral contraceptive use and intake of other medications such as antipsychotics needs to be carefully reviewed.

Review of systems needs to include a check for hot flashes, skin changes of hypothyroidism (see Chapter 104), development of hirsutism, headache, visual disturbances, thyroid enlargement, breast changes or lactescent nipple discharge, increase or decrease in libido, and change in muscle mass or body habitus.

Several patterns are suggestive. Amenorrhea in the context of marked weight loss suggests anorexia nervosa (see Chapter 234). If periods were very irregular before onset of amenorrhea, then anovulatory bleeding was probably occurring and one of its etiologies is likely (see Chapter 111). Amenorrhea accompanied by galactorrhea is strongly suggestive of hyperprolactinemia, which may be due to a prolactinoma, a destructive lesion of the sella, or hypothyroidism (see Chapter 100). A history of irregular periods since menarche in conjunction with obesity and hirsutism raises the probability of polycystic ovary syndrome. Rapid onset of amenorrhea, hirsutism, and frank virilization suggests an androgen-producing neoplasm, usually of adrenal or ovarian origin.

Physical Examination starts by taking specific note of the patient's general appearance, especially for manifestations of low body weight, marked obesity, hirsutism, virilization (see Chapter 98), and Cushing's syndrome. The integument is examined for signs of hypothyroidism (see Chapter 104) and adrenal disease. Vision is checked for visual field defects and the breasts for a lactescent nipple discharge. On pelvic examination, note should be made of any clitoromegaly, atrophy of the vaginal mucosa, scarring of the cervical os, ovarian or adnexal masses, and uterine enlargement or masses.

Laboratory Studies

When history and physical examination are unremarkable and pregnancy has been ruled out, one needs to decide whether further evaluation is indicated. An otherwise healthy-appearing young woman undergoing situational stress can be followed expectantly if only one or two periods have been missed and pregnancy has been ruled out. In patients with more prolonged amenorrhea or clinical evidence suggestive of more serious underlying pathology, an algorithmic approach is sometimes helpful (Fig. 112.1) but is best used in the context of clinical findings rather than carried out in ritualistic fashion. For example, a woman with amenorrhea and galactorrhea should proceed directly to prolactin testing rather than be subjected first to earlier steps in the algorithm.

FIG. 112.1. Initial testing of the patient with secondary amenorrhea.

Short Course of Progesterone. Administration of either a single 100-mg dose of *progesterone* or 5 days of oral *medroxyprogesterone* (10 mg/d), is typically the first test performed after pregnancy has been ruled out. Onset of *withdrawal bleeding* after progestin administration indicates adequacy of FSH secretion, estrogen synthesis, and uterine responsiveness but inadequate progesterone synthesis. Another way to make the same assessment is to note the pattern made by cervical mucus on a glass slide: the mucus from a patient with adequate estrogen secretion forms a fernlike pattern.

Patients with Withdrawal Bleeding in response to a progestin trial have a problem with proper LH release from the pituitary. It may be due to *mild hypothalamic dysfunction* disrupting normal GnRH release, which impairs the LH secretion necessary to trigger ovulation and ensure a functioning corpus luteum. Alternatively, the patient who exhibits withdrawal bleeding may be suffering from too much LH secretion, as seen in *polycystic ovary syndrome*. In both, there is no LH surge, but the former is characterized by too little circulating LH and the latter by too much. Serial serum *LH determinations* can help differentiate. Persistently high or high-normal levels without a midcycle surge are characteristic of polycystic disease. Low or low-normal levels that lack a midcycle surge are consistent with mild hypothalamic

dysfunction.

The patient with withdrawal bleeding, a life-long history of menstrual irregularities, infertility, hirsutism, and an elevated LH has a high probability of polycystic ovary syndrome and is a candidate for further testing. Serum levels of *estrone, androstenedione*, and *total testosterone* may be elevated and support the diagnosis, but sometimes only the *free testosterone* level is abnormally high. The latter is a rather expensive test but may provide the only biochemical evidence of androgen excess. *Ultrasonography* for detection of enlarged polycystic ovaries can be performed for anatomic evidence of the condition, although the finding is nonspecific and its absence does not rule out the diagnosis. *Laparoscopy* and biopsy are reserved for difficult cases.

Patients Without Withdrawal Bleeding are likely to have more serious hypothalamic dysfunction, pituitary disease, or ovarian failure. In rare instances, the cause is uterine. If uterine disease is not a serious consideration, then one can proceed directly to an *FSH determination* to differentiate ovarian from pituitary and hypothalamic etiologies. The FSH is more sensitive than the LH for this purpose.

Low or Low-Normal FSH is consistent with both severe hypothalamic dysfunction and pituitary disease. Most hypothalamic etiologies are functional and suggested by the history (e.g., competitive athletics, marked weight loss, psychiatric disturbance, anorexia nervosa). Those due to excessive production of androgen, prolactin, or cortisol are usually shown by the clinical presentation (e.g., hirsutism/virilization, galactorrhea, cushingoid appearance, respectively) and can be confirmed by serum determination of the suspected hormone (*testosterone,prolactin, or cortisol*). Rapid onset of hirsutism suggests a functioning ovarian or adrenal tumor, especially if accompanied by virilization and a serum testosterone in excess of 2.0 ng/mL. An overnight 1-mg dexamethasone suppression test with 8 a.m. serum cortisol remains the best screening test for Cushing's syndrome. A markedly elevated prolactin level suggests a pituitary prolactinoma.

Some authorities recommend that all amenorrheic patients should have a prolactin level obtained because of the frequency with which hyperprolactinemia is responsible for amenorrhea, even in the absence of galactorrhea. To avoid making a false-positive diagnosis of a hyperprolactinemic condition, the prolactin determination should be done with the patient off all medications known to stimulate prolactin secretion, including estrogens, phenothiazines, and reserpine. L-Dopa, nicotine, and ergotamine reduce prolactin output and may mask or blunt an elevation.

If prolactin is found elevated, then a search for pituitary and suprasellar pathology is indicated. *Computed tomography of the sella* is the most sensitive test for detection of small pituitary tumors (resolution is measured in a few millimeters). *Magnetic resonance imaging* is best for imaging larger pituitary tumors and suprasellar pathology (see Chapter 100). If an adenoma is found, it should be monitored closely if the patient becomes pregnant, because a small percentage of prolactinomas will grow.

A check for primary hypothyroidism by thyroid-stimulating hormone (TSH) determination is also indicated, because the thyrotropin-releasing hormone elevation that develops in this condition can stimulate prolactin secretion (see Chapter 100 and Chapter 104).

Elevated FSH is a strong indicator of ovarian failure, especially in the context of a four- to fivefold increase. Confirmation can be obtained by a serum *estradiol* determination. In the absence of a readily evident cause for ovarian failure (e.g., radiation therapy, chemotherapy), one should consider autoimmune disease, which is likely to involve the adrenals, thyroid, and the ovaries. Appropriate testing of these glands (*Cortrosyn stimulation* testing [see Chapter 104] and *TSH* determination in conjunction with serum *free thyroxine* [see Chapter 104]) is indicated.

Patients with No Withdrawal Bleeding but Normal FSH and Normal Estradiol . are likely to have uterine pathology. History should be very suggestive (e.g., previous endometritis from abortion or delivery, vigorous curettage). Failure of a course of conjugated estrogens (1.25 mg/d for 21 days) followed by pro-gestin (medroxyprogesterone 10 mg/d for 5 days) to induce withdrawal bleeding is strongly supportive of the diagnosis of uterine disease and necessitates gynecologic referral for further evaluation.

SYMPTOMATIC THERAPY

Mild Hypothalamic Dysfunction: Patients with Withdrawal Bleeding. Usually, patients with *mild hypothalamic amenorrhea* need only advice and reassurance (see below). Their periods are likely to return quickly once the precipitant is withdrawn (be it situational stress, dieting, or exercise). There is no immediate medical need to reestablish menstrual cycles unless the patient is uncomfortable living with the uncertainty of waiting for menstrual flow to resume or the condition is chronic and associated with prolonged unopposed estrogen stimulation of the endometrium (a possible risk factor for endometrial cancer). In such instances, a periodic 5-day course of *medroxyprogesterone* (10 mg/d) will usually cause shedding of the proliferative endometrium and bring on withdrawal bleeding; the process can be repeated as needed on a monthly or bimonthly basis. The bimonthly program allows for detection of spontaneous remission.

Severe Hypothalamic Dysfunction. When the cause is anorexia nervosa, menses will not resume until *weight* is *restored* to 90% or more of normal. Treatment can be difficult (see Chapter 234). However, if weight begins to return to normal, GnRH secretion will revert from a prepubertal pattern to a pubertal one. Competitive athletes may have to cut down on their training program to achieve restoration of menses. They sometimes exhibit excessive weight loss and eating disorders, which may also contribute to the problem and deserve attention. Those with marked hypothalamic dysfunction due to chronic illness will have to await the resolution of their underlying illness before normal menses will resume.

When severe hypothalamic amenorrhea results in inadequate secretion of both estrogen and progesterone (as seen by absence of withdrawal bleeding after progestin administration), then *hormonal replacement therapy* should be considered to prevent osteoporosis. A typical replacement program includes *conjugated estrogens* (0.625 to 1.25 mg/d) on days 1 to 25 plus *medroxyprogesterone* (10 mg/d) starting on day 15 and continuing for 12 days. The progesterone is added to induce adequate shedding of endometrial tissue. Some authorities recommend withholding such therapy periodically (e.g., every 6 months) to see if menses have returned.

Pituitary Disease. Patients with *hyperprolactinemia* can often achieve restoration of normal GnRH release, ovulation, and menstruation with use of the dopamine agonist *bromocriptine*, which blocks excessive prolactin secretion in up to 95% of cases (see Chapter 100). More invasive treatment is reserved for patients with a pituitary tumor that threatens adjacent structures (e.g., other areas of the pituitary or the optic chiasm).

Patients with destructive pituitary lesions (Sheehan's syndrome, tumor, granulomatous disease) may require *replacement therapy*. The program should be tailored to the deficiencies detected. Estrogen and progesterone are usually necessary; thyroid hormone and adrenal steroids are less commonly required.

Ovarian Etiologies. Patients with ovarian failure should receive *estrogen/progesterone* replacement therapy. Because some forms may be reversible, a 1- to 2-month pause every year is recommended to see if there is a return of ovarian function. Premature ovarian failure and drug-induced disease are among the reversible forms.

Polycystic Ovary Syndrome. Not all women who suffer from infertility, hirsutism, or glucose intolerance require treatment. To restore ovulation and fertility, bilateral *wedge resection* of the ovaries remains a traditional approach, although benefit is usually short term only. *Clomiphene* administration and preparations of *GnRH*, *GnRH analogues*, and *gonadotropins* are used by fertility specialists to achieve ovulation. *Oral contraceptives* will inhibit gonadotropin release and ovarianandrogen overproduction. Alternatively, *spironolactone* (50 to 150 mg/d for days 1 to 25) can be used for its ability to antagonize androgen effect without causing glandular suppression. Both finasteride and flutamide have also been used, most often to reduce hirsutism. Flutamide is more effective in this regard. Glucose intolerance and hyperinsulinism are best treated by a program of weight loss and exercise, supplemented, if necessary, by oral hypoglycemics (see Chapter 102). *Metformin*, effective for treatment of insulin resistance and hyperinsulinemia in obese diabetics, is being studied as a possible therapy for polycystic ovary syndrome. Initial studies show ability to normalize the hyperinsulinemia and most other biochemical abnormalities associated with the condition.

Uterine Disease. When the cause is granulomatous disease, treatment of the underlying disease offers the best hope for restoration of menses (see Chapter 49 and Chapter 51). Asherman's syndrome may respond to a combination of *recurettage* that severs bridging synechiae, which obliterate the uterine cavity, and *glucocorticosteroids*, which inhibit formation of new scar tissue.

PATIENT EDUCATION

Patient education occupies a central role in the management of amenorrhea. Little could be of more concern to a woman than her reproductive capacity and endocrinologic health. For the person with mild hypothalamic dysfunction, addressing fears such as pregnancy, infertility, and premature menopause and reviewing

how situational stresses can lead to the amenorrhea comprise the principal means of treatment. Simple advice regarding proper degrees of exercise and dieting and how to cope with situational stresses ensure a good outcome. The competitive marathon runner with more severe hypothalamic dysfunction may care little about menses and fertility at this stage of her life, but she needs to be informed about the risk of osteoporosis and the need for hormonal replacement therapy.

Patients whose amenorrhea followed use of oral contraceptives can be reassured that they have not been rendered infertile and that normal ovulatory periods resume in more than 99% of patients by 6 months. If conception is not desired, the need for mechanical contraception should be stressed, because the incidence of spontaneous ovulation is high in functional amenorrhea.

Women in their late 30s and early 40s who become amenorrheic fear premature menopause and its consequences. Usually, such concerns are best met by prompt assessment for ovarian failure (see above) and communication of results rather than by adopting a wait-and-see approach.

Patient education is no less important when the suspected etiology is more serious (e.g., pituitary tumor, polycystic ovary syndrome, anorexia nervosa). Sometimes, such patients may rationalize their amenorrhea, ascribing it to a benign etiology, and delay proper evaluation and treatment.

INDICATIONS FOR REFERRAL

A very significant proportion of the initial amenorrhea evaluation can be effectively carried out by the primary physician. However, referral for more intensive study and treatment is indicated when there is evidence of serious anatomic disruption (e.g., uterine synechiae), neoplasm (e.g., pituitary tumor), premature ovarian failure, or marked hypothalamic dysfunction. A gynecologic endocrine consultation can be very helpful, especially in the setting of severe functional disease, hyperprolactinemia, or premature ovarian failure. Such referral is of particular importance to the woman who desires to become pregnant, because a number of therapeutic options are available. Rapid onset of hirsutism, especially if accompanied by virilization and elevations in serum androgens, suggests a functioning ovarian or adrenal tumor and necessitates prompt endocrinologic consultation. Management of a large pituitary neoplasm that threatens adjacent structures requires the advice of the endocrinologist and neurosurgeon. Patients with idiopathic hyperprolactinemia or a microadenoma (especially those desiring to become pregnant) will appreciate a gynecologic endocrine consultation for confirmation of the diagnosis, counseling, and consideration of bromocriptine therapy.

CHAPTER 113 EVALUATION OF BREAST MASSES AND NIPPLE DISCHARGES

A solitary or dominant breast mass or an abnormal nipple discharge may be a harbinger of breast cancer, the most common malignancy among women. Because such a finding, whether discovered by the patient or by her physician, will raise legitimate fears, the primary physician must be able to proceed with deliberate speed in reaching a diagnosis that excludes carcinoma.

PATHOPHYSIOLOGY AND CLINICAL PRESENTATION

Breast Mass

Pathophysiology. A breast mass may represent proliferative changes in epithelial or mesenchymal tissue or fluid-filled cysts. The breast is a complex organ composed of epithelium that forms acini and ducts, fibrous tissue that provides support, and fat. It is exquisitely sensitive to its hormonal milieu. Estradiol stimulates proliferation of epithelial cells and accompanying increases in periductal vascularity. Progesterone induces the development of acini and opposes the mesenchymal actions of estrogens.

With each menstrual cycle, the breast exhibits its own cycle of proliferation and desquamation of duct lining. But the response of epithelium, fibrous tissue, and fat to the same hormonal stimulation is variable. Certain areas of the breast may overshoot in the monthly preparation for pregnancy, causing thickening of the breasts and lumpiness. The overgrowth may involve proliferation of fibrous tissue alone or also involve epithelial cells of the ducts and glands, leading to *fibroadenomas* or *ductal dysplasia*. Lumps can also be caused by the collection of fluids, essentially colostrum or dissolved cellular debris, which form microcysts or macrocysts.

These physiologic events may combine to produce a breast that is *fibrocystic* in quality (hence the advice by experts to drop the term *fibrocystic disease*). Fibrocystic changes can be found clinically in approximately 50% of women during their reproductive years and histologically in 90%. Most investigators believe that benign breast disease, including neoplasms such as fibroadenomas and intraductal papillomas and fibrocystic change, represents a spectrum of responses to normal hormonal stimulation rather than distinct diseases.

Although the variable response of breast tissue to physiologic proliferative and involutional hormonal stimuli is responsible for most benign masses, there are other causes. *Infection*, usually associated with duct obstruction, can result in an inflammatory mass. Redness, warmth, and tenderness are prominent features. *Mammary duct ectasia* can result in infection and yet may simulate cancer, because it can produce nipple discharge, nipple inversion, and a mass. Periareolar infection may ensue. Blunt trauma can lead to hematoma formation.

The proportion of solitary or dominant breast masses that prove to be cancers varies from 5% to 20%. It depends on the age of patients and on where in the clinical process the case series is assembled. Masses noted by either patients or primary care clinicians are often not confirmed on surgical examination. The proportion of confirmed masses that prove to be cancer is higher than the proportion of all masses brought to their attention.

Breast cancers derive from ductal or epithelium cells. They may invade immediately or grow *in situ*. Breast cancer in younger women tends to be *lobular* in pathologic appearance and multicentric but not calcifying or rapidly invading. *Ductal* carcinomas are prominent in older women. They are typically unicentric, readily calcified (producing the characteristic microcalcifications helpful in radiologic detection), and much more rapidly invasive than lobular lesions.

Growth is often associated with increasingly malignant behavior, characterized by loss of estrogen and progesterone receptors, metastasis, and more aggressive local invasion. Although metastasis can occur early, it is not an invariably early event and usually does not occur in lesions less than 1 cm in diameter (unless lymphatics have been invaded). Local growth may extend to the skin or chest wall. Axillary nodes are typically the first clinical site of spread beyond the breast.

Clinical Presentation. Cancer in the breast typically presents as a painless discrete mass. Pain is a presenting symptom in fewer than 7% of cases and is almost always accompanied by a mass. Early on, the mass may be movable; later, it can become fixed. Nipple retraction or inversion of new onset may also herald an underlying cancer. Signs of more advanced disease include skin retraction, change in breast contour, thickening or dimpling of the skin, and fixation of the mass to the chest wall. A ductal carcinoma may present as an isolated serosanguinous nipple discharge (see below).

Benign lesions may be present in a manner clinically indistinguishable from that of cancers, but a few patterns are characteristic. In *fibrocystic change*, the breasts are diffusely lumpy and fibrous in quality. One breast may be more involved than the other. An isolated cyst may also be a presentation of benign disease, but those that yield blood on aspiration or recur after aspiration may be related to a malignant process.

Nipple Discharge

A nipple discharge that is unilateral, spontaneous, and localized to one duct should be considered pathologic. Nonlactescent unilateral breast discharges may reflect local inflammatory or neoplastic lesions, most of which are benign. Benign etiologies include chronic cystic mastopathy and intraductal pap-illoma. Many papillomas are not palpable. Approximately 5% of women with a breast discharge have cancer. The most worrisome nipple discharge is a bloody one, which occurs in 70% to 85% of cancers that present with a nipple discharge. However, only 25% of bloody discharges prove to be due to cancer. The discharge may predate onset of a clinically detectable mass. The chance of a nipple discharge being associated with cancer increases with age. Onset of a lactescent nipple discharge (galactorrhea) in a woman who is not nursing may be a sign of a prolactinoma (see Chapter 100).

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of a breast mass is confusing because of lack of agreement or standardization in clinical and pathologic terminology. The category of "fibrocystic disease" has been dropped because it does not represent a pathologic state. Among lesions that come to biopsy, the most common discretely palpable solid mass is the fibroadenoma. As many as 20% of solitary or dominant breast masses are cancers.

A serous or bloody discharge may occur with intraductal papillomas, ductal ectasia, and ductal carcinoma. In one reported series, 44% had papilloma or papillomatosis, 23% had ductal ectasia, 16% had fibrocystic changes, and only 11% had cancer.

WORKUP

Breast Mass

Physical Examination. The key finding is a *dominant nodule*. Most glandular tissue is found in the upper outer quadrant of the breast and changes with the menstrual cycle. Dominant masses are characterized by their unchanging and persistent nature throughout the cycle. Breast tenderness to examination in the absence of a dominant mass is of no pathologic significance.

Much is made of the clinical characteristics of breast masses in estimating the probability of malignant disease. Easy mobility within the breast, regular borders, and a soft or cystic feel on palpation all suggest a benign process. However, these signs are not reliable; 60% of cancers are freely movable, 40% have regular borders, and 40% feel soft or cystic. A "benign" physical finding reduces the probability of cancer no further than to approximately 10%.

The young woman with multiple nodules and diffuse thickening consistent with fibrocystic change has difficult breasts to evaluate. Reexamination at different times in

the menstrual cycle is often informative and reassuring when no dominant nodule emerges. A persistent solitary or dominant nodule requires biopsy.

Examination of the lymph nodes is required in all patients with a breast lump, because it may provide important supporting evidence for a malignancy, especially if otherwise unexplained adenopathy is found in the ipsilateral axilla.

Breast Imaging. *Mammography* can be a valuable diagnostic test, especially in the woman over 30 with breast symptoms, but it must be emphasized that a negative mammogram does not obviate the need for biopsy of a clinically suspicious breast mass. Studies in which the most advanced techniques were used by the most experienced clinicians have repeatedly indicated that mammography has a false-negative rate of 8% to 10%. A mammogram should be obtained before biopsy and preoperatively for any woman undergoing breast surgery. The preoperative study can also help to delineate the mass and identify any occult lesions in the ipsilateral or contralateral breast. Mammography is used to guide needle biopsy of small lesions.

Ultrasonography can be used to differentiate a cystic from a solid palpable mass, especially in women under 30, and help guide needle aspiration. A host of improved imaging techniques are under development.

Biopsy. *Needle aspiration biopsy* of solid and cystic lesions, with cytologic examination of the material obtained, is sometimes a means to avoid open biopsy. It can be performed in the office or in the radiologic suite under the guidance of imaging techniques. Adequate specimens are obtained in about 60% to 85% of instances. Among adequate samples, sensitivity is in excess of 80% and specificity is over 99%. Negative cytology from a solid lesion does not rule out cancer. However, a cystic lesion that is successfully aspirated, cytologically negative, and nonrecurring requires only follow-up breast examination and mammography. Solid lesions that have negative or suspicious cytology and cystic lesions containing serosanguineous fluid require *excisional* biopsy. The procedure is usually done as an outpatient procedure.

Nipple Discharge

The patient should undergo a careful *breast examination* that includes careful palpation and noting if the discharge is unilateral or bilateral, spontaneous or expressible, and localized to one or many ducts. If unilateral and expressed only from a single duct, one should note the quadrant of the breast from which it seems to be coming. Guaiac testing helps to detect occult blood, and cytologic examination may sometimes reveal abnormal cells, although sensitivity is low. These measures are followed by *mammography*, looking for dilated ducts or occult masses. Patients with nipple discharge that remains unexplained (especially if bloody) requires referral to a surgeon experienced in evaluating breast disease. The risk of cancer in such patients remains real, and *ductal exploration* may be the only means of detecting an early ductal malignancy.

Symptomatic Management and Patient Education

The woman with painful breasts associated with fibrocystic change can be reassured that the discomfort is not a sign of cancer and that symptoms usually improve with the cyclical decrease in hormonal stimulation. Moreover, it is important to emphasize that the finding is not a risk factor for breast cancer. The physiologic nature of fibrocystic changes, their extremely high prevalence, and their favorable natural history can be reviewed. Oral contraceptives provide no benefit in treatment or prevention of the condition. Commonly recommended measures include use of a support bra, Vitamin E supplements plus avoidance of chocolate and caffeinated beverages. Efficacy is variable.

The woman with a dominant breast mass or bloody discharge is more concerned with the possibility of breast cancer than with symptoms. Explaining that the likelihood of a benign etiology is still greater than that of cancer can provide a modicum of reassurance and perspective while more definitive diagnostic measures are undertaken. A prompt efficient diagnostic evaluation is the best medicine. Reassurance can be given to the patient who fears spread of cancer from breast compression (as occurs with mammography) or needle biopsy.

CHAPTER 114 EVALUATION OF VULVAR PRURITUS

Vulvar itching can be a very annoying symptom for the patient. In the genital area, only the vulvar and perineal skin have sensory receptors that trigger the sensation of itching. However, vulvar pruritus may be secondary to a vaginal infection and a vulvar dermatitis or primary skin disease. In older women, it is likely to be related to declining estrogen levels and, in rare cases, may be a manifestation of a malignancy. The primary care physician should be familiar with the appearance of inflammatory, infectious, and malignant conditions of the vulva to tailor appropriate therapy and avoid delays in the detection of carcinoma.

PATHOPHYSIOLOGY AND CLINICAL PRESENTATIONS

The most common causes of vulvar pruritus are listed in Table 114.1. Patients with vaginitis often complain of itching. In *candidal vulvovaginitis*, the vulva is erythematous, often with a sharp scalloped border demarcating the area of involvement. "Satellite" lesions are characteristic, as is the cheesy discharge of the associated vaginitis (see Chapter 117). Primary cutaneous candidiasis of the vulva can also occur without evidence of vaginitis or discharge. It is more commonly seen in women with diabetes or those who are pregnant or obese. Intensevulvar inflammation also occurs with *trichomonal infection*, and, rarely, bacterial vaginosis may present with itching. *Hidradenitis suppurativa*, which is caused by inflammation or infection of the apocrine sweat glands in the vulva, can cause itching or burning and progress to fistula formation.

Infections
  Candida
  Trichomonas
  Bacterial vaginosis
  Hidradenitis suppurativa
  Herpes simplex
  Human papillomavirus
  Dermatophytes
  Scabies
Dermatoses
  Lichen sclerosis
  Lichen simplex chronicus
  Lichen planus (erosive vaginitis)
  Psoriasis
  Seborrheic dermatitis
Low Estrogen States: Atrophic Vaginitis
  Postpartum
  Postmenopausal
Premalignant/Malignant Conditions
  Vulvar intraepithelial neoplasia
  Squamous cell carcinoma
  Adenocarcinoma
Irritants
  Contact dermatitis

Table 114.1. Causes of Vulvar Pruritus

Lesions of *herpes genitalis* are caused in most cases by herpes simplex virus type 2. The lesions, which begin as vesicles and progress to ulcers, cause burning, itching, and often pain and tenderness of the vulva. Vulvar lesions caused by *human papillomavirus* (HPV), also called condyloma acuminata, are generally multifocal and appear on the labia or fourchette, causing itching and often vaginal discharge. The umbilicated lesions of *molluscum contagiosum* may also be pruritic. This infection, which is generally self-limited, is also sexually transmitted. Dermatophyte lesions (tinea cruris) are a rare cause of itching in women.

Infestation with mites or lice can cause intense pruritis. Scabies produces papular lesions and itching, which may occur in several areas on the body, including wrists, finger webs, elbows, axillae, genitals, and buttocks. *Pediculosis* is confined to areas covered by hair, because eggs are deposited on the hair shafts (see Chapter 195).

The term vulvar dystrophy has been replaced by the term *vulvar dermatoses* to describe the large group of nonneoplastic papulosquamous lesions that occur on the vulva. All of these may cause pruritus in addition to other symptoms. Any of the lesions may appear white, because they are hyperkeratotic, but less than 5% are premalignant. *Lichen sclerosis* presents as a symmetric "keyhole" pattern of pale atrophic epidermis with fine wrinkling or scaling on a whitened dermis. Chronic contact or *irritant reactions* can cause persistent scratching and lichenification (lichen simplex chronicus), which leaves the vulva thickened and furrowed. *Lichen planus*, a chronic erosive vaginitis, occurs with pruritic purple polygonal papules and plaques ("the five Ps"). *Psoriasis* may appear as moist red plaques with a silvery scale on the labia majora. *Seborrheic dermatitis* of the vulva presents with scaling erythematous lesions of the vulva.

Atrophic vaginitis occurs in low estrogen states, including postmenopause (natural and surgical) and postpartum (see Chapter 117). The mucosa is red and thin; sometimes a mild discharge is present.

Malignancy may develop in association with dermatoses such as lichen sclerosis or with infections; vulvar intraepithelial neoplasia in association with HPV is an example. Paget's disease of the vulva, which appears as a diffuse scaling process often involving the anal region as well, is associated in 5% of cases with an underlying adenocarcinoma.

Squamous carcinoma of the vulva is the most ominous cause of vulvar pruritus, occurring primarily in older women: 70% of cases appear in women older than age 60. Delay in presentation is common; often the patient gives a history of unsuccessful trials of topical agents for symptomatic relief from itching. Squamous cell carcinoma of the vulva may present with single or multiple papules or macules, which can be confluent or discrete, usually on the labia majora or minora. The lesions can be red, white, or pigmented and may be in multiple locations on the labia. They typically arise on the vulvar skin in areas already long involved with premalignant change. Spread is to inguinal and deep pelvic nodes. Occasionally, a patient with carcinoma complains of a lump or an ulcerated lesion. Itching may be intense, sometimes in conjunction with a slightly bloody discharge.

Vulvar intraepithelial neoplasia, which occurs in younger women (mean age, 39), is akin to cervical intraepithelial neoplasia in its relationship to previous HPV infection. A certain percentage of women who have one will have the other, necessitating a full evaluation with colposcopy. However, vulvar intraepithelial neoplasia progresses to malignancy at a much slower rate than cervical intraepithelial neoplasia.

Vulvar irritation caused by scratching, maceration, and chemical agents is common. Deodorants, soaps, douching agents, bubble baths, and contraceptive foams may incite allergic reactions or chemical irritations, leading to itching. The vulva may appear erythematous, and edema or secondary excoriations may be present. The precipitant may be inadequate or overly aggressive genital hygiene. A warm moist environment, which promotes infection, can occur in patients who are obese or who wear tight-fitting pants or nylon underwear. Chafing fosters maceration of the mucosa in conjunction with the itching and scratching. Elderly women, who experience urinary incontinence, may be forced to wear pads, which can cause irritation. Younger women who shave their pubic hair are often bothered by pruritus from a secondary folliculitis.

DIFFERENTIAL DIAGNOSIS

In young women, vaginitis, pediculosis, scabies, chemical irritants, and allergic reactions are the major causes of vaginal itching. The same etiologies apply to older women, but atrophic vaginitis, dermatoses, and vulvar carcinoma also become major considerations. In any woman with a persistently pruritic vulva, the possibility of a primary dermatosis should be considered.

WORKUP

It is important to inquire about vaginal discharge, any skin rashes, urinary incontinence, vulvar lesions, and other sites of itching. Possible irritants and allergies need to be identified, such as creams, soaps, bubble baths, vaginal deodorants, douches, and contraceptive foams. The sexual history or presence of genital itching in partners or roommates may suggest infection or infestation. Information related to the duration of the problem and responses to prior treatments can be useful. Presence of an ulceration or nodule that has persisted or grown should be ascertained. Any history of HPV or herpes simplex virus–associated lesions or abnormal Papanicolaou smears should be obtained.

The vulva and perineal skin is inspected for macules, papules, scaling, erythema, ulcerations, pigmented lesions, hypopigmentation, excoriation, rash, lice, and mites. A close look at the hair shaft may reveal lice eggs (nits), which are pathognomonic of the infestation (see Chapter 195). A speculum examination helps to identify any vaginitis or discharge (see Chapter 117). Inguinal nodes should be palpated. A smear of the discharge for identification of an organism and a urinalysis for glycosuria are the major laboratory studies needed. Any suspicious lesions should be referred for biopsy.

SYMPTOMATIC MANAGEMENT, PATIENT EDUCATION, AND INDICATIONS FOR REFERRAL

The management of vulvar pruritus is most likely to be successful when a specific etiology can be identified. Self-treatments and use of potentially irritating soaps or creams should be stopped. Atrophic vaginitis responds well to a topical estrogen cream (see Chapter 118). Occasionally, an antihistamine may be used at night to relieve itching and break the itch/scratch cycle. In some cases, where the etiology is known, the short-term use of steroid creams may be beneficial to reduce inflammation. Any persistent suspicious vulvar lesions should be referred to the dermatologist or gynecologist for biopsy.

Patients should be educated about factors that contribute to persistent vulvar irritation, including excessive hygiene or moisture (secondary to tight-fitting jeans, panty hose, nylon underwear, or exercise clothes). Women should be encouraged to perform regular vulvar self-examination. They should be taught to use a hand mirror to inspect the vulva, looking for moles, changes in pigmentation, warts, ulcers, and sores.

CHAPTER 115 MEDICAL EVALUATION OF FEMALE SEXUAL DYSFUNCTION

Sexual dysfunction is highly prevalent. Community-based surveys conducted in the United States and the United Kingdom indicate that the prevalence among women is greater than 40%. The problem focus may be one of the sexual pain disorders, including dyspareunia and vaginismus. Alternatively, problems may relate to the woman's level of interest in and desire for sexual activity, her physiologic and subjective level of arousal in response to sexual stimuli, or the frequency with which she achieves orgasm. These disorders of desire, arousal, and orgasm may either cause or result from difficulties in the relationship with a spouse or partner. Most women do not discuss sexual problems with their physicians. The primary care physician is often in the best position to open the dialogue, begin the evaluation, and facilitate definitive treatment of these conditions that can have a significant negative impact on quality of life when left unaddressed.

PATHOPHYSIOLOGY AND CLINICAL PRESENTATION

Dyspareunia may be the form of female sexual dysfunction most likely to be brought to the attention of the primary care clinician. Several mechanisms may be responsible for painful intercourse (Table 115.1), depending on whether the symptoms occur with initial insertion of the penis or deep penetration. Pain is experienced in the former case because of failure of lubrication or inadequate stimulation, vaginal or vulvar irritation, and structural impediments secondary to surgery, inflammation, or anatomic variants. Deep pain can arise from friction against inflamed tissue or by jarring of inflamed parametrial structures. The psychological mechanisms of dyspareunia reflect a variety of issues.

Pain greatest on insertion	Pain greatest on deep penetration
Inadequate lubrication	Pelvic inflammatory disease
Vaginitis	Ovarian cyst
Incompletely ruptured hymen	Endometriosis
Bartholin's gland cyst	Pelvic adhesions
Stricture	Relaxation of pelvic support
Inadequate episiotomy	Uterine fibroids
Vulvovaginal atrophy	
Vulvar vestibulitis	
Pudendal neuralgia	
Vaginismus	

Table 115.1. Important Causes of Dyspareunia

Pain on Insertion can also be caused by irritation of the vulva, which in turn is caused by multiple factors, including vulvovaginal infections (see Chapter 114 and Chapter 117). A *cyst* of the *Bartholin's gland duct* occurs when mechanical irritation and the attendant inflammatory reaction obstruct the ductal lumen. Thin vulvar surface and vaginal mucosa are less resilient and more susceptible to *trauma*. These vaginal changes take place in women who are anorexic, breastfeeding, or menopausal or who have had pelvic irradiation.

In premenopausal women, *inadequate lubrication*, because of insufficient foreplay, is among the most frequent causes of dyspareunia. Women who are postpartum may also experience short-term vaginal dryness and resultant dyspareunia, which can continue while they are breastfeeding. In postmenopausal patients, vaginal atrophy is the most important cause of inadequate lubrication. Finally, scant production of vaginal secretions may reflect fears about sexual intercourse or risk of infection, misunderstandings, or conflicts with a sexual partner.

Chronic vulvar vestibulitis, an uncommon cause of introital dyspareunia, is defined as pain of the vestibule on vaginal entry, associated with erythema of the vulva. The syndrome may be associated with subclinical human papillomavirus infection, recurrent candidiasis, or bacterial vaginosis and an elevated vaginal pH. A biopsy shows only chronic inflammatory changes.

Pudendal neuralgia is another cause of vulvar burning; patients with this symptom may complain of superficial burning or deep aching pain, but few have physical findings. *Vaginismus* is defined as involuntary spasm of the perineal muscles induced by an attempt at physical penetration. It is an important and treatable, though uncommon, cause of dyspareunia usually with a large psychogenic component.

Deep Dyspareunia may occur with endometriosis, ovarian cysts, adhesions, and pelvic inflammatory disease. Penile thrusting moves the entire uterus, with resultant pulling on the peritoneum. Acute or defervescing *pelvic inflammatory disease or endometritis* will produce pain even on gentle motion.

Inhibited or *hypoactive sexual desire* and *difficulty achieving orgasm* are more common than the various forms of painful intercourse. In each case, it is important to determine whether the dysfunction is primary or secondary. The physician is most likely to encounter patients with secondary dysfunction from a variety of causes. Psychological etiologies, including relationship difficulties, predominate. Systemic illnesses when present is often a major contributor.

Drug-induced decrease in sexual desire may be caused by many medications, especially antihypertensive agents and antidepressants. Selective serotonin reuptake inhibitors are associated with sexual dysfunction in 40% to 80% of men and women taking them. Problems with desire and arousal and/or orgasmic dysfunction predominate among women. Libido is a very sensitive indicator of general physical health, and any intercurrent illness (acute or chronic) will blunt it. There is no evidence that estrogen deficiency alone has an impact on libido, but androgen deficiency does; several studies suggest that small doses of testosterone may be helpful for postmenopausal women who experience loss of libido (see Chapter 118).

Secondary orgasmic dysfunction from medical causes is seen in patients who previously functioned normally. As with desire and excitement phase problems, any illness can interfere with this part of sexual activity. For example, in one study, loss of orgasmic capacity occurred in 35% of diabetic women and severity correlated with duration of the diabetes.

DIFFERENTIAL DIAGNOSIS

All the causes of dyspareunia, listed in Table 115.1, should be considered according to the age of the patient and whether there is pain on insertion or on deep penetration. Causes of problems with desire, excitement phase, and orgasm are listed in Table 115.2.

Medical	Psychiatric
Cushing's disease	Bipolar disorder
Addison's disease	Anxiety disorder
Diabetes mellitus	Major depression
Hypopituitarism	Panic disorder
Hyperprolactinemia	Somatization disorder
Degenerative joint disease	Somatiform pain disorder
Hypothyroidism	
Multiple sclerosis	
Temporal lobe lesions	
Coronary heart disease	

Table 115.2. Secondary Causes of Sexual Dysfunction

WORKUP

In the history, one needs to determine whether dyspareunia was noticed with the first experience of sexual intercourse or has developed recently, secondary to organic change or a situational problem. The patient should be asked whether pain occurs before penetration, on penetration, or only after deep penetration. It is important to establish whether the patient can insert a tampon without pain; if she can, mechanical obstruction is unlikely. A history of recent infection, previous surgery, or pelvic pathology may suggest the etiology. The clinician should take a complete history, including current and previous sexual experiences. Recent studies underscore a new awareness of the prevalence of sexual abuse, including incest, rape (including date rape), and domestic violence. It is not surprising that the patient may not be forthcoming with these experiences. Any history of sexual fears should be explored. An understanding of the patient's current sexual experience (circumstances, time spent on foreplay, etc.) and feelings toward the partner should be sensitively obtained (see Chapter 229). Sexual problemscluster with self-reported psychological and social problems among women. Interviewing the husband or sexual partner is part of a complete evaluation and is appropriate in many cases.

The most important part of the workup is the pelvic examination. The physician inspects for signs of vulvovaginitis, atrophic vaginitis, narrowed introitus, cervicitis, and congenital abnormalities. Palpation may identify a uterine mass, a retroverted uterus, or tenderness. The cervix should be manipulated to see if pain is produced. Examination for loss of pelvic support, rectocele, or cystocele is needed. A smear should be obtained for cervical cytology to detect underlying malignancy.

A complete blood count, sedimentation rate, and cervical culture are indicated if there is evidence on physical examination suggesting pelvic inflammatory disease (see Chapter 116). Pelvic ultrasonography may be indicated to help define a suspected pelvic mass. Referral to a gynecologist for laparoscopy is indicated if endometriosis, adhesions, or an adnexal mass is under consideration.

Vaginal anatomy, measured by introital caliber, length, and vulvovaginal atrophy, does not correlate well with sexual function, including symptoms of dyspareunia and vaginal dryness. Studies of the biopsychosocial profiles of women with dyspareunia indicate that pain with intercourse is greatest among those with evident pathology on examination, including for instance vulvar vestibulitis. Psychological symptoms are no more prominent among these women than among women without dyspareunia. Women with dyspareunia who do not have evident pathologic findings are more likely to have psychological symptoms and/or relationship maladjustment.

SYMPTOMATIC MANAGEMENT, PATIENT EDUCATION, AND INDICATIONS FOR REFERRAL

The patient without organic pathology who is troubled by inadequate lubrication should be reassured and offered advice about the benefits of more prolonged foreplay or the use of a water-soluble lubricant jelly. Contraceptive creams should not be used for lubrication, because they often cause dehydration and may worsen soreness. A variety of lubricant products are available over the counter. Oral-genital foreplay, trying different positions for coitus, and guiding the man's penis for insertion are other suggestions that can be made. The postmenopausal woman with an atrophic vaginal mucosa can be given estrogen cream to use topically on an intermittent basis (see Chapter 118).

If there is an underlying vaginal or pelvic infection, it should be treated and the patient advised to refrain temporarily from intercourse (see Chapter 116 and Chapter 117). A cyst of the Bartholin's gland duct may spontaneously drain after frequent warm soaks in the bathtub, which sometimes relieves the obstruction; marsupialization by a gynecologist may be required to provide adequate drainage if the cyst is badly inflamed and infected. Patients troubled by pain from herpes simplex infection can obtain relief with use of acyclovir (see Chapter 193). Retained suture material in episiotomy scars, vulvar islands of adenosis (ectopic columnar epithelium), or nerve endings previously damaged by herpetic infection may require local excision for relief of pain.

As noted, there is little correlation between vaginal introitus caliber or other measures of vaginal anatomy and dyspareunia. Nonetheless, the patient with an unusually narrow introitus might be referred to a gynecologist for consideration of a trial of vaginal dilators. Vaginismus may be managed by education, relaxation, and Kegel exercises, all of which are usually best accomplished by an experienced therapist or sex therapy clinic. Patients bothered by pain on deep penetration may be more comfortable lying on one side during coitus so that deep penetration is limited.

Initial failure to identify or relieve dyspareunia should prompt referral. This should be done only after a thorough evaluation has been performed, the sexual history has been elicited, any infection has been treated, advice on sexual technique has been provided, and lubricants have been tried. If there is still uncertainty about an anatomic etiology, referral to a gynecologist would be appropriate. Otherwise, referral to a psychologist or sex therapist, involving both the patient and her sexual partner, might be considered (see Chapter 229).

In a few cases where the problem focus is related primarily to desire, excitement, or orgasm, the cause may be easily identified in the primary care setting. Changes in antihypertensive or antidepressant regimens may be enough to solve the problem. When selective serotonin-reuptake inhibitors are implicated but clearly indicated, the addition of buspirone has been shown to be effective in alleviating symptoms. But for many cases, referral to a sex therapist for the patient and her partner will be indicated when medical causes have been ruled out. Small doses of testosterone has been used to increase desire in postmenopausal women. Sildenafil is being studied to assess its effects on vaginal lubrication, clitoral sensation, and orgasm. Ephedrine and oral phentolamine have also been used to treat female sexual arousal disorder. Because of the preliminary nature of this evidence and the strong interplay with psychological and relationship issues, referral is the prudent course for the primary care clinician who has not developed special expertise in this area. It is important to be aware of well-trained resources in the community. Recognition of underlying psychopathology and psychosocial distress is also essential (see Chapter 229).

CHAPTER 116 APPROACH TO THE PATIENT WITH MENSTRUAL OR PELVIC PAIN

ALBERT G. MULLEY, JR.

INTRODUCTION

Pelvic pain is a major source of concern and morbidity for many women. Dysmenorrhea, or painful periods, affects approximately half of menstruating women at some time, and an estimated 10% of women are significantly impaired by the problem. Acute episodes of pelvic pain are also common and may represent potentially serious pathology. The primary care physician should be able to distinguish pain of a functional nature from that due to infection or an anatomic lesion and know when referral to a gynecologist or urgent hospital admission is indicated. The generalist should also be able to initiate treatment and educate patients about the most common causes of pelvic pain.

PATHOPHYSIOLOGY AND CLINICAL PRESENTATION

The causes of pelvic pain can be organized into acute, chronic, and recurrent categories, with the latter group subdivided based on the relationship of the pain to the menstrual period (Table 116-1).

Acute Pain
  Pelvic inflammatory disease
  Ectopic pregnancy with rupture
  Torsion of the fallopian tube, ovary, or ovarian cyst
  Ruptured ovarian cyst
  Extrapelvic disease (e.g., appendicitis)
Recurrent Pain with Menstruation
  Primary dysmenorrhea
  Secondary dysmenorrhea
    Endometriosis
    Adenomyosis
    Chronic pelvic inflammatory disease
    Intrauterine devices
Recurrent Pain Unrelated to Menstruation
  Mittelschmerz (midcycle pain)
  Leaking ovarian cysts
  Nongynecologic pathology: adhesions, IBD, functional bowel
Chronic Pain
  Benign neoplasms
  Malignancy
  Enigmatic or psychogenic pain

IBD: inflammatory bowel disease.

Table 116-1. Important Causes of Pelvic Pain

Acute Pain

Pelvic pain of acute onset may result from pelvic inflammatory disease, ectopic pregnancy, torsion of the fallopian tube or ovary, rupture of an ovarian cyst, or extrapelvic pathology such as acute appendicitis or ureteral stones.

Pelvic Inflammatory Disease (PID). Pelvic inflammatory disease (PID) usually causes little pain until the infection has spread from the cervix through the lymphatics into the parametria and fallopian tubes. This process may not occur until weeks or even months after initial exposure to an infected partner. The consequent acute salpingitis is characteristically bilateral, although one side may be more involved than the other. Peritoneal signs may occur if infected discharge escapes from the fallopian tube and soils the overlying peritoneum. Mixed microbial infection is common. Organisms commonly implicated include a streptococci, *Chlamydia trachomatis, Escherichia coli, Neisseria gonorrhea, Mycoplasma*, and anaerobic organisms such as *Bacteroides.*

Although epidemiologic reports of sexually transmitted diseases suggest that *N. gonorrhea* infections are decreasing in incidence, antibiotic resistance appears to be increasing. All cases of PID should be treated presumptively for penicillin-resistant *N. gonorrhea*, pending cultures. The PID associated with chlamydia appears to be less acute in onset (higher likelihood of asymptomatic cases) than that due to gonorrhea, but it is more likely to result in tubal damage and subsequent ectopic pregnancy and infertility. Because of the high prevalence of mixed infections, treatment regimens should always include coverage for *C. trachomatis* and *N. gonorrhea* (see Chapter 117).

Sequelae of PID include recurrent PID, ectopic pregnancy, infertility, and chronic pelvic or back pain. Twenty-five percent of patients with PID will have a subsequent pelvic infection. A prior episode of PID increases the risk of ectopic pregnancies 7- to 10-fold. Recurrent pelvic infections also increase the risk of infertility: one episode is associated with a 12% risk of infertility, two episodes with 35% risk, and three episodes with a risk of 75%. Pelvic infection may also result in chronic pelvic pain.

Physical examination in patients with PID is notable for purulent cervical discharge, friability of the cervix, cervical motion tenderness, or adnexal tenderness. Occasionally, there may be peritoneal signs.

Ectopic Pregnancy. Ectopic pregnancy is a much-feared cause of acute pelvic pain because catastrophic hemorrhage can result from tubal rupture. The incidence of ectopic pregnancies in the United States from 1970 to 1987 increased from 4.5 to 16.8 per 1,000 pregnancies. The case-fatality rate, however, decreased dramatically, from 35.5 per 10,000 to 3.4 per 10,000 ectopic pregnancies. The drop in fatality rates was probably caused by improved diagnosis resulting from the sensitive radioimmunoassay for human chorionic gonadotropin (hCG), high-resolution ultrasonography, and the frequent use of laparoscopy. In most cases of ectopic pregnancy, the menses is delayed by 1 to 2 weeks, followed by recurrent spotting. Pain is generally unilateral. Severe hemorrhage occurs in fewer than 5% of cases, causing sudden extreme pain and hypotension.

Patients with a prior history of PID, prior ectopic pregnancies, tubal surgery to enhance fertility, use of intrauterine devices, or ovulation-inducing drugs (which alter steroid hormone levels and affect tubal motility) may be predisposed to subsequent ectopic pregnancies.

Torsion. Torsion of the fallopian tube with or without ovarian involvement is seen most commonly in women of reproductive age. The adnexae may be normal except for the resulting ischemia, although most cases have cysts of the ovaries. Severe, acute, unilateral pain and distension are found without an elevation of white blood cell count, fever, or increased sedimentation rate, unless complicated by ischemic necrosis. Most patients will have an adnexal mass on ultrasound.

Ovarian Cysts. Ovarian cysts may spontaneously rupture or twist on their pedicles. Rupture can be associated with rapid blood loss, similar to a ruptured ectopic pregnancy. More commonly, only small amounts of fluid or blood are released, resulting in unilateral and often recurrent discomfort. Torsion of the pedicle of the cyst can cause ischemia and lead to extreme pain with acute peritoneal signs, fever, and leukocytosis.

Extrapelvic Pathology. Extrapelvic pathology that can cause acute pelvic pain includes appendicitis, kidney stones, urinary tract infections, bleeding from a Meckel's diverticulum, intestinal obstructions, and intestinal abscesses.

Chronic or Recurrent Pain

Conditions that result in recurrent or chronic pelvic pain are generally less urgent than those responsible for acute pain. Common etiologies include primary dysmenorrhea; secondary dysmenorrhea caused by endometriosis, adenomyosis, chronic PID, and intrauterine devices (IUDs); uterine fibroids; ovarian cysts; nongynecologic pathology such as adhesions, inflammatory bowel disease, or irritable bowel syndrome; and psychogenic pain.

Primary Dysmenorrhea. *Dysmenorrhea* represents the major source of recurrent pelvic pain. It is classified as "primary" when there is no pelvic pathology and "secondary" when it occurs in the setting of an underlying gynecologic problem, such as endometriosis, PID, or IUD use. Primary dysmenorrhea affects as many as 50% of postpubertal women. It occurs in ovulatory cycles, therefore beginning at the time of menarche or soon after when the cycles become regular. The pain occurs at the onset menstrual blood flow and generally lasts for 48 to 72 hours. It is generally cramping in nature and can be located in the suprapubic region, the low back, or the inner aspect of the thighs. Dysmenorrhea, which begins several years after menarche, is usually secondary to gynecologic pathology.

Menstrual pain occurs because of increased prostaglandin production and release by the endometrium, which leads to abnormal uterine muscle activity. Several studies have showed increased menstrual fluid prostaglandin levels (primarily PGF$_{2a}$) and increased circulating leukotriene and vasopressin levels in women with primary dysmenorrhea. High levels of these hormones lead to increased uterine tone and dysrhythmic contractions followed by reduction in uterine blood flow and ischemia. The pain may be either from the abnormal contractions, uterine ischemia, or stimulation of sensory pain fibers by the prostaglandins and bradykinin. NSAIDs, which reduce prostaglandin synthesis, are extremely effective at reducing menstrual pain.

Premenstrual Syndrome. Many physiologic changes occur during the menstrual cycle. Women who suffer from premenstrual syndrome (PMS) appear to have an *abnormal response* to the *normal hormonal changes* associated with the menstrual cycle, particularly those changes that precede the midluteal phase. The precise mechanisms by which normal hormonal changes result in symptoms are poorly understood, but their effects on *serotonergic* and g-*aminobutyric acid receptors* appear to be important. For example, serotonergic activity decreases in some women with PMS during the luteal phase. Personality testing done during symptomatic periods does reveal abnormalities, but retesting at other stages of the menstrual cycle shows resolution of the changes, suggesting that psychologic factors may be a manifestation rather than a cause of the problem. PMS is thought to be pathophysiologically distinct from dysmenorrhea, unrelated to prostaglandins, and unresponsive to nonsteroidals.

Symptoms, which may seriously disrupt daily activities and impair life-style, include pelvic pain, irritability, fatigue, bloating, food cravings, headache, inability to concentrate, breast tenderness, anxiety, and depression. Onset is typically 7 to 10 days before menses commence, continues through 4 days of blood flow, and is recurrent with each cycle. The diagnosis of PMS is based on the history of symptoms and their correlation with the menstrual cycle. It is helpful to have patients keep a daily chart of their symptoms and their menses for 2 or more months to assess the pattern.

Endometriosis. Endometriosis is presumed to be a common cause of secondary dysmenorrhea. Endometriosis is caused by the presence of functioning ectopic endometrial tissue, located in such places as the ovaries, uterosacral ligaments, cul de sac, and peritoneum. It occurs in 1% to 5% of reproductive women and approximately 30% of infertile women between ages 30 and 40. Pain from this condition can begin days or even a week before menstruation. It tends to subside with the onset of bleeding. It is usually bilateral and may radiate to the rectum or perineal region. There is frequently a history of infertility, dyspareunia, or menorrhagia. Symptoms of endometriosis depend on actively functioning endometrial tissue, with resolution at menopause. The frequency of dysmenorrhea has been found to be no different in patients with endometriosis compared with normal control subjects; however, patients with extensive endometriosis (stage III or IV by laparoscopy) were more likely to have acyclic pain. Diagnosis of endometriosis can only be made by laparoscopy or laparotomy.

Adenomyosis. Adenomyosis is caused by the presence of functioning ectopic endometrial tissue in the myometrium. It appears to be most common in women aged 41 to 50. The condition can cause menorrhagia, dysmenorrhea, and an enlarged sometimes tender uterus. Pain may be referred to the back and rectum. There is a slightly increased rate of endometrial carcinoma in patients with adenomyosis.

Chronic PID. Chronic PID is another source of secondary dysmenorrhea. A history of previous sexually transmitted disease, dyspareunia, menstrual irregularity, backache, rectal pressure, or pelvic pain with fever is often obtained. The physical exam-ination typically reveals tender thickened adnexae. Bilateral involvement is characteristic, although one side may predominate.

IUD. IUD are an important source of secondary dysmenorrhea. The rate of removal because of pain and bleeding ranges from 4% to 15%. Crampy menstrual pain may occur in a woman with a newly placed IUD who has never experienced dysmenorrhea. It is important to rule out concomitant PID in women with abdominal pain and an IUD.

Ovarian Cysts. Ovarian cysts are usually painless unless complicated by torsion or rupture, which produces severe abdominal pain. Chronic intermittent discomfort that is worse at the time of ovulation or in the latter half of the cycle may be seen secondary to leakage of irritant contents.

Uterine Fibroids (Leiomyomas). Uterine fibroids (leiomyomas) may produce a constant chronic ache in the pelvis or back. They may also cause urinary symptoms (increased frequency and incontinence) and bleeding, particularly when they are submucosal. Significant pain and/or obstruction of the ureters is noted usually when the uterus is larger than 12 weeks gestation. Severe pelvic pain and fever, in a woman with a history of fibroids, can suggest necrosis of the tumor.

Nongynecologic Pathology. Nongynecologic pathology may also cause chronic pelvic pain; this would include adhesions, inflammatory bowel disease, and irritable bowel syndrome. Of note, symptoms from irritable bowel syndrome such as pain, cramping, and change in bowel habits may also worsen in the second half of the menstrual cycle secondary to the effect of progestins on gastrointestinal motility.

Mittelschmerz. Mittelschmerz or intermenstrual pain is not a form of dysmenorrhea, because it occurs in midcycle at the time of ovulation. It is more common on the right side than the left and may be accompanied by bleeding. There is some evidence that the ovary is the source of the blood loss. The pain, believed due to distention of the ovarian capsule, is harmless but annoying and a source of concern.

Enigmatic or Psychogenic Pain. The terms *enigmatic pain* and *psychogenic pain* are applied to chronic pelvic pain lasting more than 6 months without clear organic pathology. Approximately one third of laparoscopies performed for long-standing symptoms fail to reveal any pathology. Even when pathology is found, it is unclear whether or not it is the cause of the pain. Studies have found, for instance, that endometriosis and adhesions are as common in women without pain as in those with pain.

Numerous theories for the pain have been proposed, including pelvic vascular congestion, retrodisplacement of the uterus, and rotation of the fundus on the cervix as a universal joint (this was believed to be secondary to lacerations of the broad and cardinal ligaments from prior obstetric procedures and to cause pain because of the hypermobility of the cervix with relation to the fundus in all directions). Surgical treatments have included antefixation of a retroverted uterus, hysterectomy with or without salpingo-oophorectomy, and presacral neurectomy. Although initial reports demonstrated some success with each of these techniques, most patients continued to have pain. Studies have also reported continued symptoms in patients even with total exenteration of pelvic organs.

Because of lack of improvement with current surgical and medical regimens and the low incidence of demonstrable pathology, attention has turned to psychogenic etiologies and treatments for patients with chronic pelvic pain. Recent reports have demonstrated a significant association between a childhood history of sexual abuse and chronic pelvic pain. Women with chronic pelvic pain have also been found to have higher rates of alcohol and drug dependency, although it is unclear whether this is in response to their chronic pain.

WORKUP

In the patient with acute pain, it is important to determine the need for immediate hospitalization. Vital signs, including a rectal temperature, and postural changes in blood pressure and pulse are essential. Physical examination should determine whether there are signs of peritoneal irritation (rigidity, percussion tenderness, rebound), presence of bowel sounds, cervical motion tenderness, or abnormal masses. Laboratory evaluation should include a complete blood count, differential, sedimentation rate, urinalysis, and serum b-hCG subunit pregnancy test. Urine hCG testing is less sensitive; a negative urine hCG test within the first 6 weeks after the last menstrual period does not rule out an ectopic pregnancy. The serum hCG radioimmunoassay, on the other hand, can be positive as soon as 1 week postovulation.

Any patient with a high fever, orthostatic hypotension or tachycardia, or an acute abdomen should be sent immediately to the hospital, even before laboratory studies are available. However, even if the situation is urgent, a few historical facts can help establish the diagnosis. Important questions would include any delay in the menstrual period, dyspareunia, IUD use, shaking chills, abnormal vaginal discharge or bleeding, recent abortion, and the location and radiation of the pain. Development of generalized severe pain is a worrisome symptom, indicating possible peritoneal involvement, especially in conjunction with a rigid abdomen and absent bowel sounds. Unilateral pain suggests a local tubal or ovarian problem, whereas bilateral involvement is more indicative of PID or diffuse pelvic irritation. Symptoms of constipation, nausea, vomiting, diarrhea, flank pain, and dysuria need to be elicited to rule out nongynecologic etiologies such as appendicitis, acute pyelonephritis, or urethral stone.

If the pain is chronic or recurrent, a more detailed history should be obtained during the office visit, including the relationship of the pain to the menstrual cycle and a complete menstrual and obstetric history. Onset of pain, quality and radiation of pain, and any exacerbating or ameliorating factors should be noted. Pain due to cervical, uterine, or vaginal pathology is often referred to the low back or buttock, whereas that due to tubal or ovarian problems is generally localized to one side and referred to the medial aspect of the thigh. A detailed pelvic and rectal examination should be done to look for adnexal thickening, cervical discharge, uterine masses, fixation of any structures, ovarian masses, and focal tenderness.

Laboratory testing should include a serum hCG, complete blood count, sedimentation rate, urinalysis, and culture of the cervix and rectum for gonorrhea and chlamydia. If a mass is felt, ultrasonography (possibly with transvaginal probe) is indicated to confirm the finding, better localize the mass, and distinguish a solid from a cystic lesion. Laparoscopy or dilation and curettage may be necessary to establish the diagnosis.

TREATMENT

Acute Pelvic Pain. PID may be treated on an outpatient basis if the patient is nontoxic and reliable. Antimicrobial regimens should include coverage for *N. gonorrhea* and *C. trachomatis* (see Chapter 117). Patients and their partners should be educated about safe sexual practices and the sequelae of PID to prevent subsequent infections.

Other etiologies of severe acute pelvic pain, such as ectopic pregnancy, torsion of the fallopian tube or ovary, and ruptured ovarian cysts, are best managed by a specialist and should be referred immediately to a gynecologist.

Recurrent Pelvic Pain. *Primary dysmenorrhea* can be managed symptomatically with *NSAIDs*. Lower dose over-the-counter formulations are frequently effective. Treatment is started up to a week before expected onset of menses and continued several days into it. Oral contraceptive pills are also helpful in decreasing dysmenorrhea because they suppress ovulation. Progestins also inhibit ovulation but do not appear to be as effective at reducing pain. This may be related to their effects on prostaglandin synthesis. Patient education about the mechanism of pain during menstruation may be helpful in alleviating symptoms.

PMS is related to normal hormonal events during the menstrual cycle; therefore, there is no benefit to hormonal manipulations such as estrogen and/or progesterone supplementation. In controlled study, such supplements have not proven useful and might even worsen symptoms. However, complete ovarian hormonal suppression by use of a *gonadotropin releasing-hormone agonist* (GnRH) such as *leuprolide* will terminate symptoms in many PMS sufferers. Alternatives proven effective in randomized controlled trials and shown to dramatically reduce both the physical and psychological symptoms of PMS include the *semiselective serotonin reuptake inhibitors (SSRIs) and alprazolam (Xanax)*, which act on GABA receptors. SSRIs have a more rapid onset of action than when used for depression; therapy can be limited to the luteal phase. In fact, some studies suggest that such intermittent therapy is more effective than therapy that continues through the follicular phase. There appears to be more benefit for behavioral symptoms (75% reduction) than for the physical symptoms (40% reduction). Vitamin B6 in doses up to 100 mg/d may well reduce symptoms. Though conclusions are limited by poor quality of most studies, a systematic review of randomized trials of vitamin B6 suggests an odds ratio relative to placebo of overall symptom improvement of 2.32. A randomized trial of calcium supplementation at 1,200 mg/d showed a smaller but significant effect. Symptoms were reduced by 48% compared with 30% with placebo. *Life-style changes* such as participating in regular aerobic exercise and eliminating xanthines, alcohol, and salt from the diet offer only limited improvement. PMS, unlike primary dysmenorrhea, is unresponsive to NSAID therapy.

Endometriosis will most likely be managed by specialists, because the diagnosis is made only by laparoscopy or laparotomy. However, it is important to be aware of the medications used to treat endometriosis because they can have some significant side effects. Oral contraceptive pills may be used continuously to achieve a "pseudo-pregnancy" effect on the endometrial tissue. Cessation of menstrual periods may decrease the painful symptoms. Danazol and GnRH agonists both inhibit gonadal function, leading to a pharmacologic menopause. Danazol is associated with androgenic side effects such as hirsutism, acne, and weight gain, whereas GnRH agonists typically have more hypoestrogenic side effects, such as hot flashes, osteoporosis, and vaginal dryness.

Other causes of recurrent pelvic pain, such as IUDs, uterine fibroids, and ovarian cysts, are best managed by a gynecologist. Indications for hysterectomy for uterine fibroids are substantial bleeding, significant pelvic pain or obstruction, or anemia refractory to iron replacement.

Chronic Pelvic Pain. This is best managed by a combination of psychological, behavioral, and medical treatments. Primary care physicians are in a unique position to coordinate this type of therapy. Patients with chronic pain need reassurance that further diagnostic testing is unnecessary, that the physician is not abandoning them, and that there is treatment for their suffering. Psychological therapy can help pinpoint triggers for their pain and address previous sexual trauma (if any). Behavioral therapy can help decrease pain through relaxation techniques. Self-hypnosis may also be beneficial. Because of the frequency of concomitant depression and the known beneficial effects of the tricylic antidepressant amitriptyline in patients with chronic pain, it may be useful to consider an antidepressant medication in some cases.

INDICATIONS FOR REFERRAL

Patients with pelvic pain and an acute abdomen should be sent immediately to the hospital with referral to a gynecologic surgeon. Women with a pelvic mass detected by physical examination should be referred, although it may be helpful to obtain an ultrasound before the patient's initial visit with the gynecologist. Suspicion of chronic PID, endometriosis, adenomyosis, ovarian cyst, or other condition best assessed by laparoscopy should prompt consultation with a gynecologist.

CHAPTER 117 APPROACH TO THE PATIENT WITH A VAGINAL DISCHARGE

Vaginal discharge is one of the most common reasons that women consult physicians in office practice in the United States. Vaginal infections not only are extremely prevalent but also result in considerable discomfort for symptomatic patients. Some vaginal infections put women at risk for upper genital tract disease and complications of a concurrent pregnancy. A history; a systematic examination of the vulva, vagina, and cervix; and a microscopic examination of the discharge will enable one to identify the cause in most cases and choose the appropriate therapy. Patient education can help to allay fears, encourage compliance, and reduce recurrences.

PATHOPHYSIOLOGY AND CLINICAL PRESENTATION

Normal vaginal discharge contains desquamated vaginal epithelial cells, secretions from cervical glands and from the uterus, and bacteria and bacterial products, including lactic acid. Under the microscope, the vaginal microflora of healthy asymptomatic women appear as moderate numbers of unclumped rodlike organisms. These consist of a wide variety of anaerobic and aerobic bacterial genera and species dominated by *Lactobacillus*. The pH of a normal vagina is between 3.5 and 4.1. The vaginal environment, which is in a delicate balance, is easily altered by numerous internal and external influences. The amount or quality of vaginal discharge can be affected by normal changes in the body's hormonal milieu, such as midcycle mucus production with ovulation, menstruation, or the atrophic mucosal changes that occur after menopause.

The most common cause of an abnormal discharge is infection with bacteria, yeast, or parasites (Table 117.1). Infections with organisms such as *Trichomonas vaginalis* and *Candida albicans* generally induce an inflammatory response in the vaginal wall, which is accompanied by an increased number of leukocytes in the vaginal fluid, so-called "vaginitis." The most common infection causing vaginal discharge is *bacterial vaginosis*, a condition of bacterial overgrowth in which inflammation is not a feature. Bacterial vaginosis is responsible for 40% to 50% of vaginal infection, followed closely by vulvovaginal candidiasis (20% to 25%) and finally trichomoniasis, which occurs less frequently (15% to 20%). The clinical presentation, including type, amount, and odor of discharge, depends in part on the underlying etiologic agent.

Infectious
    Bacterial vaginosis
    Vulvovaginal candidiasis
    Trichomonas vaginitis
    Mucopurulent cervicitis (C. trachomatis)
    Gonorrhea
    Condyloma acuminata
    Herpes virus type 2
    Cytolytic vaginosis
Normal Discharge Secondary to Hormonal Changes
    Physiologic leukorrhea (midcycle cervical mucus/postintercourse)
    Atrophic vaginitis
Other
    Chemical/allergic vaginitis, foreign body
    Desquamative inflammatory vaginitis (erosive lichen planus)
    Chronic cervicitis
    Cervical ectropion
    Cervical polyps
    Cervical and endometrial cancer
    Collagen vascular diseases

Table 117.1. Common Causes of Vaginal Discharge

Trichomoniasis occurs in approximately 3 million women annually. Contrary to previous belief, *Trichomonas vaginalis*, a small mobile protozoan, is not part of normal vaginal flora. It is sexually transmitted and frequently occurs in the presence of other infections. It occurs in 13% to 25% of women attending gynecologic clinics and 7% to 35% of women attending clinics for sexually transmitted diseases. Sexual contact may not be the only mode of transmission. *T. vaginalis* can survive in hot tubs, tap water, and chlorinated swimming pools. The belief that *T. vaginalis* is sexually transmitted is also supported by the high prevalence (30% to 70%) in male partners of infected women and the improved cure rates of infected women whose partners are also treated. Fewer than 20% of men with *T. vaginalis* in their urine are symptomatic. A substantial percentage of women with trichomoniasis (10% to 50%) are also asymptomatic, but one third of asymptomatic infected women become symptomatic within 6 months.

Symptoms include vaginal discharge, pruritus, dyspareunia (caused by vulvar edema), dysuria, increased frequency of micturition, and abdominal pain. Physical examination generally reveals vulvar erythema and edema and, occasionally, characteristic petechial hemorrhages of the external genitalia and cervix (strawberry cervix is seen by the naked eye in only 1% to 2% of patients). Vaginal discharge may be minimal or abundant, frothy, and foul smelling. Signs and symptoms alone are not sufficiently helpful to make the definitive diagnosis.

Candidiasis is very common in the vagina. Yeast is often recovered as a commensal organism in the vagina. In one private practice study, the incidence of candidiasis was 8.5%, and of these individuals, 25% were asymptomatic. In women with symptoms, complaints include vulvar pruritus and burning associated with a discharge. Symptoms are usually rather rapid in onset, occurring shortly before menstruation when the pH of the vagina falls. On physical examination, erythema, edema, and excoriation of the vulva are often prominent; sometimes there are pustules apparent on the skin. The discharge is typically thick, white, and adherent, often described as resembling cottage cheese.

Bacterial Vaginosis, previously referred to as gardnerella vaginitis or "nonspecific vaginitis," can be asymptomatic in up to 50% of women. The clinical picture tends to be one of mild discomfort, although in 10% to 20% of cases the vaginal burning and itching are more pronounced. Sometimes patients note a disagreeable odor. The discharge ranges from grayish to occasionally a yellow-green color. Wet mount of the discharge shows short motile rods and characteristic "*clue cells*" (vaginal epithelial cells with a stippled appearance due to the adherence of bacilli on their surfaces). The diagnosis of bacterial vaginosis is made by the presence of three of the four following criteria: vaginal pH greater than 4.5; thin, white, homogenous discharge; positive amine test; and clue cells on saline wet prep.

Several other infectious etiologies need to be considered in the differential diagnosis of a vaginal discharge. *Gonorrhea* (also covered in Chapter 137) can produce a thick, purulent, irritating discharge involving the cervix, vagina, and urethra. In *type 2 herpes virus* (discussed in Chapter 192), the infection can extend to the cervix in 75% of cases, producing ulceration, friability, and a grayish exudate in conjunction with a profuse watery discharge. *Condyloma acuminata*, genital warts caused by papillomavirus, can cause in severe cases a profuse irritating vaginal discharge (see Chapter 141). *Mucopurulent cervicitis* caused by *Chlamydia trachomatis* is characterized by a thick yellow-white discharge coming from the cervical os in conjunction with 10 or more leukocytes per microscopic field (high-power oil immersion) on Gram's stain examination. Erythema, friability, and ectocervical ulceration may occur.

Cytolytic Vaginosis is a condition thought to be caused by an overgrowth of lactobacilli and possibly other bacteria, which causes cytolysis of vaginal epithelium and a frothy white discharge. Symptoms, which usually increase during the second half of the menstrual cycle, include dyspareunia, vulvar pruritus, and dysuria. Physical examination is remarkable for the presence of white frothy discharge and a pH level between 3.5 and 4.5. The four diagnostic criteria observed on wet mount are absence of *Trichomonas*, bacterial vaginosis, and *Candida*; few leukocytes; increased lactobacilli; and cytolysis of vaginal epithelial cell. Patients with cytolytic vaginosis are frequently misdiagnosed as having chronic yeast infections and treated unsuccessfully with various antifungal medications, especially when the health care provider relies on the patient's symptoms and not on a thorough examination of the wet mount.

Atrophic Vaginitis is the most common cause of vaginal discharge in older postmenopausal women. Among postmenopausal women attending a vaginitis clinic in one study, a defined diagnosis of *T. vaginalis*, *C. albicans*, or bacterial vaginosis could be made in only one third. Estrogen deficiency leads to thinning of the vaginal epithelium with a decrease in the superficial layer. The vaginal pH increases to 7.0, and the potential pathogens change from those listed above to streptococci,

coliform bacteria, and gut anaerobes. Symptoms include vaginal and vulvar burning and soreness, occasional bleeding or itching, and dyspareunia. External burning on urination is sometimes noted, resulting from localized irritation of raw and inflamed mucosa rather than from infection of the urinary tract. Examination of the vaginal mucosa reveals a thin erythematous surface and scant watery discharge.

Other Causes. A variety of other processes cause vaginal discharge less frequently. *Lichen planus* is an idiopathic inflammatory mucocutaneous disease that causes a desquamative vaginitis. Certain *collagen vascular diseases* can also produce a type of vaginal inflammation and discharge. *Chronic cervicitis* can result from extensive chronic cervical inflammation and has been implicated in the pathogenesis of cervical eversion, squamous metaplasia, basal cell hyperplasia, leukoplakia, polyps, and carcinoma. The discharge is thick, tenacious, and yellowish white and may be streaked with blood. Cervical inspection reveals edematous, grossly inflamed, and friable tissue. *Cervical ectropion* is found in 15% to 20% of healthy young women. It represents columnar epithelium that is found farther out on the exocervix, causing the cervix to appear granular and red. An increase in a nonirritating vaginal discharge consisting of mucus can be seen with a large ectropion.

DIFFERENTIAL DIAGNOSIS

The most common cause of an abnormal vaginal discharge in women of childbearing age is infection. If an infectious etiology is not identified, other causes must be considered, including hormonal changes, allergens, and foreign bodies. The most common irritants are intrauterine devices; condoms; spermicidal foams, jellies, and creams; deodorants; sprays; soaps; and any chemical douches. Foreign bodies include forgotten tampons, condoms, diaphragms, and intrauterine devices. Some vaginal discharge is expected after conization or cauterization. Cervical polyps and uterine fibroids and neoplasms of the vulva, vagina, uterus, ovaries, or fallopian tubes may produce abnormal discharge (Table 117.1).

WORKUP

History should include the onset of the discharge, its appearance, amount, odor (if any), and any associated symptoms. The relation of the discharge to phase of menstrual cycle, coitus, and use of medication (especially antibiotics) should be noted. Details about associated symptoms such as dysuria, pruritus, pain, dyspareunia, and skin rash provide additional information. Use of a pad or tampon can be a precipitating factor or a sign of excessive discharge. Asking the patient for a detailed sexual history will aid in understanding whether she is at particular risk for any infections. Questions should be asked about possible exposure to sexually transmitted diseases and whether the patient's partner has a complaint of penile discharge or lesion. Known allergies need to be reviewed in conjunction with use of spermicidal preparations and douches. Patients should be asked about use of foreign bodies and bubble baths, soaps, or genital deodorants. A history of a previous vaginal infection, diabetes, or the recent use of antibiotics or corticosteroids needs to be considered in a search for alterations in vaginal flora or host defenses. Any self-treatment should be carefully inquired about, because antifungal medication is now readily available over the counter. Women with chronic or recurrent discharge also turn to a wide range of alternative treatments, including oral and vaginal acidophilus pills, oral and vaginal yogurt, and douches with vinegar and boric acid. These self-remedies may complicate diagnosis and management.

Physical Examination begins with careful inspection of the vulva and vaginal canal for evidence of lesions, discharge, erythema, atrophy, or prolapse. During the speculum examination, the surface of the cervix should be examined carefully, looking for any lesions, erosion, erythema, or friability. The color, consistency, pH, and odor of the discharge can provide useful clues to the etiology. On bimanual examination, the provider should check for tenderness on cervical motion and for adnexal and uterine masses.

Laboratory Studies. A wet-mount examination of the discharge is simple and potentially diagnostic. A fresh sample is placed on a microscopic slide to which a drop or two of normal saline is added, and a cover slip is placed over the suspension. The pH should be tested and the slide examined before the sample dries. Although the sensitivity of the wet mount for the detection of the motile, ovoid, trichomonads is low (25%), the finding is very specific and permits immediate diagnosis. The sample pH for *Trichomonas* is usually greater than 5.0. Although Gram's and Giemsa stains show no advantage to wet mount, cultures (which have been anaerobically incubated) have a sensitivity of up to 95% for the presence of trichomonads.

Saline wet mount of patients with bacterial vaginosis characteristically show few polymorphonuclear neutrophils and many (more than 20%) clue cells. Two additional diagnostic criteria for bacterial vaginosis are a sample pH higher than 4.5 and a positive amine test (the presence of a "fishy odor" after adding potassium hydroxide [KOH] to a sample).

Adding a drop of 10% KOH to a sample of the discharge also aids in the recognition of *Candida*. The KOH dissolves most cellular material except for the filamentous hyphae and budding forms of *Candida*; the sensitivity of the test ranges from 40% to 80%. Gram's stain has an even higher sensitivity for detection of *Candida*. The vaginal pH with a Candidal infection is closer to normal. Vaginal cultures for *Candida* are not routinely used but can be done on Nickerson's medium if microscopy is negative and presentation is highly suggestive of *Candida*. A wet smear of a patient's discharge that is suspected to have cytolytic vaginosis should show few leukocytes; no *Trichomonas*, clue cells, or filamentous hyphae; and an increased number of lactobacilli with evidence of epithelial cytolysis and a pH close to normal.

When other causes of vaginal discharge, such as gonorrhea and chlamydia, are being considered, a Gram's stain of the discharge can yield additional information (see Chapter 125 and Chapter 137). A Gram's stain is useful in identifying mucopurulent cervicitis due to chlamydial infection, because the presence of more than 10 leukocytes per oil-immersion field distinguishes it from other types of cervicitis. Further suspicion of *chlamydia* infection can be followed up with direct immunofluorescent staining or culture.

A few other laboratory studies may be helpful. A complete blood count is indicated if pelvic pain or dysuria is present. Urinalysis should be obtained to check for pyuria and bacteriuria, especially if there is concurrent dysuria or flank pain. Women with poorly controlled and, occasionally, new-onset diabetes mellitus can present with persistent or recurrent yeast infections, and a fasting blood sugar may be useful. A Papanicolaou (Pap) smear should be done, recognizing that it may be abnormal in the presence of inflammation (see Chapter 107). In some patients with obvious infection, it may be reasonable to defer the Pap test until the vaginitis or cervicitis has been treated. However, with chronic inflammation of the cervix, Pap testing and probably colposcopy are indicated.

MANAGEMENT

Trichomonal Vaginitis. *Metronidazole* is the treatment of choice for trichomoniasis (Table 117.2). This drug is probably most effective if administered orally in a dosage of 500 mg twice daily for 7 days, with cure rates up to 95%. A one-time oral dose of 2.0 g is less effective (80% to 88%) but has better compliance rates. Efficacy for single-dose therapy is increased if the male partner is also treated. Some authorities advocate simultaneous treatment of male sexual partners in all cases; others treat the male only if the female relapses. Recommended therapy for recurrent *T. vaginalis* infections is an additional 1-week treatment with metronidazole (500 mg twice a day) and, if symptoms persist, 2 g every day for 3 to 5 days. Patients should be instructed to avoid alcohol intake while taking the drug because of its disulfiram-like effects. Other side effects include nausea and transient neutropenia. Meta-analyses have not found an association between metronidazole exposure during pregnancy and birth defects. The one-time oral dose of 2.0 g is generally recommended. For patients allergic to metronidazole, alternative but less-effective therapies include topical clotrimazole or Betadine jelly. Vinegar douches may be palliative.

Table 117.2. Treatment for Common Vaginal Infections[a]

Candidal Vaginitis. In considering treatment for Candidal vaginitis, precipitants such as the use of broad-spectrum antibiotics, oral contraceptives, or corticosteroids or the presence of diabetes need to be addressed. First-line treatment for candidiasis for women with infrequent episodes is the use of over-the-counter preparations of topical miconazole and clotrimazole, generally for 7 days. Miconazole is also available in a more concentrated form for 3-day regimens. These agents often provide symptomatic relief within 2 days, although patients should be encouraged to complete their treatment course (3 to 7 days). The lower dose miconazole in the form of 100-mg suppositories for 7 days is usually recommended during pregnancy. Symptomatic relief of vulvar irritation can be obtained by using witch hazel compresses or cool water and recovery hastened by application of nystatin or a synthetic imidazole cream directly to the vulva.

Prescription regimens can generally be reserved for women who do not improve with the over-the-counter regimens. Terconazole (as a 0.4% cream for 7 days, a 0.8% for 3 days, or an 80-mg suppository for 3 days) may be more effective against *Candida glabrata*. One-day oral regimens include fluconazole 150 mg or itraconazole 200 mg. They are as effective as longer topical regimens, but as many as 15% of women suffer gastrointestinal side effects.

For recurrent vulvovaginal candidiasis, prophylactic treatment has been achieved with 100 mg ketoconazole each day for 6 months, but the drug is very expensive, and hepatotoxicity is a concern with such prolonged use. Fluconazole, 150 mg weekly or monthly, is an alternative with less hepatotoxicity. When infection is related to menstruation, 100-mg clotrimazole vaginal suppositories nightly for several days preceding menstruation may be effective. An alternative is 200 mg ketoconazole orally twice a day for 5 to 7 days beginning before menstruation. Because *Candida* is normally found in the gastrointestinal tract, perianal contamination is thought to be a possible cause of recurrent infections. Therefore, educating the patient about proper hygiene is important (see patient information section). Treatment of male partners is not usually recommended.

Bacterial Vaginosis. The best results for treatment of bacterial vaginosis have occurred with *metronidazole* therapy with a usual oral dose of 500 mg twice daily for 7 days. A single dose of 2 g metronidazole is also effective and is generally recommended for treatment during pregnancy. Single-dose therapy is less likely to lead to secondary yeast infections and is just as effective with initial cure rates of 80% to 90% but may be associated with higher recurrence rates than 7-day regimens. Metronidazole intravaginal *gel* 0.75% for a 5-day twice-daily treatment is equally effective with fewer systemic side effects but is more expensive than oral metronidazole regimens. This disadvantage may be mitigated by recent evidence that once-daily dosing with the gel for 5 days is as effective as twice-daily dosing. If there are contraindications or side effects to metro-nidazole use, oral (300 mg twice daily for 7 days) or topical (2% cream vaginally for 7 nights) *clindamycin* is an alternate. Only limited success in treatment has occurred with use of ampicillin or amoxicillin, because of b-lactamase produced by vaginal flora. Treatment of the sexual partner is not indicated.

Mucopurulent Cervicitis. This condition results from *chlamydia* and responds to *doxycycline* (100 mg twice a day for 7 days) or *erythromycin* (500 mg four times a day for 7 days), with treatment of the partner and follow-up culture 1 week after completed treatment. Ofloxacin and azithromycin are also effective but more expensive.

Cytolytic Vaginosis. This is treated with *sodium bicarbonate douches* two to three times a week and then once or twice a week as needed to increase the pH of the vagina and decrease the amount of lactobacilli. The recommended douching solution should include 30 to 60 g of sodium bicarbonate to 1 L of warm water. Commercially prepared sodium bicarbonate douches are also available.

Atrophic Vaginitis. *Estrogen cream* applied vaginally works to restore mucosal layers of squamous epithelium. Treatment is best achieved by topical use of estrogen cream for 1 to 2 weeks, followed with treatment for 1 to 2 days for occasional symptom control. Although they are less effective, oral conjugated estrogens can be prescribed (see Chapter 118).

PATIENT EDUCATION AND INDICATIONS FOR REFERRAL

Patient education is important whether the vaginal discharge is caused by normal physiologic changes, an infection, or a noninfectious process. All women should be educated about hormonal changes and their effect on the presence and appearance of normal physiologic vaginal discharge. Most infectious causes of vaginal discharge, except for bacterial vaginosis, candidiasis, and cytolytic vaginosis, are known to be sexually transmitted. Patients with discharge caused by *Trichomonas* or *Chlamydia* should be given information about the need for examination and concurrent treatment of partners and the role of barrier methods of contraception. In the prevention of these infections, women with recurrent yeast infections should be advised to avoid nylon underwear, panty hose, wet bathing suits, and tight jeans.

All patients with vaginitis, especially allergic vaginitis, should be advised to avoid douches, irritant soaps, bubble baths, and genital deodorants. Patient education about personal hygiene, including wiping from front to back after urination, is important. Often the patient's vulvar and vaginal discomfort is relieved after a few days of treatment, yet the patient should be encouraged to complete the treatment course and to abstain from intercourse during treatment to prevent recurrence or further irritation.

Referral is needed for any patient with suspicious cervical or vaginal lesions, especially if there are erosions and ulcerations that fail to clear with treatment of a known pathogen. Colposcopy and biopsy are indicated.

CHAPTER 118 APPROACH TO THE MENOPAUSAL WOMAN

ALBERT G. MULLEY, JR., ALLAN H. GOROLL

INTRODUCTION

Using the generally accepted definition of menopause as a full year without menstrual flow in a previously menstruating woman, the incidence of menopause is 10% by age 38, 20% by age 43, 50% by age 48, 90% by age 54, and 100% by age 58. In addition, the prevalence of surgically induced menopause is estimated to be 25% to 30% of women in their mid-fifties. Despite its inevitability for the woman who lives through her sixth decade, menopause can be difficult in a society that ostensibly celebrates youthfulness. Although many of the emotional and physical changes blamed on menopause are not related to decreased estrogen levels, the cessation of menstruation has major symbolic significance, and, as a result, many symptoms and complaints are attributed to it. Hormone replacement therapy (HRT) is very effective in dealing with the specific symptoms of estrogen deficiency. During recent decades HRT was also believed to confer significant disease-prevention benefits, particularly for prophylaxis of osteoporosis and cardiovascular disease. But recent large-scale randomized trials indicate that reduction of cardiovascular risk is not an indication for HRT and that potential harms, including *increased* risk of cardiovascular disease as well as increased risk of breast cancer, may outweigh benefits for many women. This new evidence has left many women uncertain about HRT decisions. The primary care physician can do a great deal to help women cope with menopause and make informed choices regarding options for symptom relief and disease prevention.

Updated: 04/16/03

PHYSIOLOGY AND CLINICAL PRESENTATION

The essential cause of menopause is decreased estrogen due to decreased responsiveness to follicle-stimulating hormone in aging ovaries. This results in cessation of menses and increase in gonadotropins. Some estrogen production continues, but its source is primarily peripheral conversion of androstenedione. The diagnosis of menopause is confirmed by a marked increase in the gonadotropins; maximum levels of follicle-stimulating hormone and luteinizing hormone occur within 1 to 2 years of onset and remain high for 10 to 15 years. The physiologic events are similar in surgically induced menopause, but the time course is shorter, with follicle-stimulating hormone and luteinizing hormone rising to high levels within 20 to 30 days. Approximately 25% of women do not experience any symptoms, perhaps because of nonovarian sources of estrogen production.

Hot Flashes. *Hot flashes*, associated with the rate of estrogen withdrawal and resultant vasomotor instability, are among the most specific of menopausal symptoms. An uncomfortably warm sensation radiates upward from the chest to neck and face and lasts seconds to a few minutes before subsiding. Skin temperature generally increases by about 2.5°C. The response is thought to be triggered by a hypothalamic mechanism related to catcholamine metabolism. Eating, exertion, emotional upset, and alcohol are known precipitants. As many as 20 episodes per day may occur; in most patients, the condition lasts for 2 to 3 years, but it may continue for 6 years or more. Prevalence of severe disabling hot flashes ranges from 10% to 35% of menopausal women. No link between emotional makeup and symptoms has been shown, though it is clear that the flashes can be the cause of considerable morbidity.

Atrophy of the Vaginal and Vulvar Epithelium with Associated Sexual Dysfunction. *Atrophy of the vaginal and vulvar epithelium with associated sexual dysfunction* is another important manifestation of estrogen decline. The vagina becomes smaller and less compliant; lubrication decreases. Women may present with complaints of itching, discharge, bleeding, or painful intercourse. The uterus becomes smaller, but this causes no symptoms. Of interest is the finding that sexually active women show less vaginal atrophy. Whether this is a cause or effect is unclear.

Sleep Disturbances. *Sleep disturbances* occur in many menopausal women. Some are associated with nocturnal hot flashes. In addition, abnormalities in the sleep pattern, with decrease in rapid-eye-movement sleep, have been documented independent of hot flashes.

Cardiovascular Disease. *Cardiovascular disease* is the leading cause of mortality among postmenopausal women. Loss of estrogen is associated with an unfavorable change in lipoprotein profile. Estrogens increase high-density-lipoprotein cholesterol and decrease low-density-lipoprotein cholesterol. Observational studies involving tens of thousands of women had suggested that as much as a 50% decrease in cardiovascular disease risk could be achieved with estrogen replacement. As a result, estrogen replacement has been prescribed for tens of millions of women with the intention of lowering cardiovascular risk. Large scale randomized controlled trials, first among women with known heart disease (the Heart and Estrogen/progestin Replacement Study), and subsequently among women without heart disease (the Women's Health Initiative trial), failed to confirm that estrogen plus progestin was effective for secondary or primary prevention of cardiovascular disease.

Updated: 08/19/03

Osteoporosis. *Osteoporosis* represents an important consequence of estrogen decline; decreased activity, inadequate nutrition, and the aging process also contribute, to varying degrees. Although irreversible by HRT, osteoporosis can be prevented by prophylactic administration of estrogen at the onset of menopause (see below and Chapter 164). Risk factors for postmenopausal osteoporotic fractures include thin body build, premature surgical menopause, cigarette smoking, and heavy alcohol use. Prolonged bedrest is a potent stimulus of osteoporosis. Long-acting benzodiazepines, anticonvulsants, caffeine, and impaired visual function are other risk factors for hip fracture.

Other Symptoms. *Other symptoms*, such as *headache, nervousness, and depression,* which frequently occur during the climacteric, are more a reflection of the emotional stress that may be associated with this stage of life rather than a result of a change in hormonal milieu. Some women report feeling better emotionally on estrogen therapy, but this may represent a placebo effect. No specific psychiatric problems have been linked specifically to menopause. Women who experience a prolonged symptomatic perimenopausal phase may exhibit some depressive symptoms, but depression is not a consequence of the menopause itself.

Cosmetic Changes. *Cosmetic changes* associated with aging have been attributed by some to a decrease in estrogens, but clinical evidence is to the contrary. Breast atrophy, loss of skin turgor, and redistribution of fat to the abdomen and thighs have not been shown to be influenced by estrogen therapy and most likely are part of the more general process of aging.

PRINCIPLES OF MANAGEMENT

Short-term objectives are to alleviate any bothersome symptoms that result from estrogen deficiency and to provide support for any emotional and functional problems that may accompany this phase of life. Relatively short-term therapy suffices for symptom relief. Benefit and potential for harm will vary for different women and must be assessed with attention to the individual's response to symptoms and her risk factors for events that may be made more likely by HRT including heart disease and breast cancer. Nonhormonal approaches also exist and provide women with a choice of options for dealing with menopausal changes.

Updated: 04/16/03

Hormone Replacement Therapy

Because much of the medical morbidity of menopause, including symptoms such as hot flashes and vaginal dryness, relate to estrogen deficiency, the clinician and patient are faced with the difficult decision of when to use HRT. This necessitates careful consideration of benefits and risks.

Benefits of Hormone Replacement Therapy. The benefits include symptom relief, reduced risk of osteoporosis and related fractures, and reduced risk of colorectal cancer.

Updated: 04/28/03

Resolution of Hot Flashes. Hot flashes severe enough to be a serious bother to the patient are an important indication for estrogen replacement. In most instances, the symptoms are self-limited, but relief during the year or two that symptoms are most severe can mean a great deal. HRT is effective in the vast majority of cases; both severity and frequency of hot flashes were reduced by 80% in one randomized trial. Women should be advised that it may take several weeks to achieve relief.

Reversal of Atrophic Vaginitis. Atrophic vaginitis responds well to both topical and oral administration of estrogen. Even when vaginal creams are used, systemic estrogen absorption does take place and risks of adverse estrogen effects must still be considered a possibility, though probably to a lesser degree than with the use of systemic therapy. Milder symptoms (e.g., mild dryness with intercourse) may respond well to use of a water-soluble vaginal lubricant and obviate the need for estrogen in the woman who wants to avoid its use.

Improvement of Sleep Disorders. Sleep disorders do improve with estrogen replacement. Increases in the rate of rapid-eye-movement sleep have been documented, regardless of whether or not hot flashes have been experienced. Randomized trial results indicate that improvement in sleep disturbance may be too small to be clinically meaningful.

Prevention of Postmenopausal Osteoporosis. Osteoporosis can be prevented by long-term prophylactic estrogen therapy. Controlled studies have shown that rates of vertebral, wrist, and hip fractures can be reduced very significantly by estrogen replacement and that this protective effect is not impaired by addition of progestin. The risk of hip fracture is reduced by 25% in women who have used estrogen in the past and to an even greater extent among current and recent users.

For women willing to accept the increased risk of breast cancer and other possible risks associated with very prolonged HRT use (see below), the combination of estrogen therapy in conjunction with exercise and dietary calcium supplementation offers one of the best options for prevention of postmenopausal osteoporosis (see Chapter 164). But in the light of recent trial evidence, many women and their clinicians consider the risks of long-term HRT too great. They should be strongly encouraged to engage in regular weight-bearing exercise and maintain adequate calcium intake (see below). These measures can slow osteoporotic changes. Women who are reluctant to take HRT and who are at particular risk for osteoporosis should be encouraged to consider additional approaches to prevention of osteoporosis such as alendronate or raloxifene (see Chapter 164).

Reduction in Risk of Colorectal Cancer. HRT reduces risk of colorectal cancer. In the Nurses' Health Study, the relative risk of colorectal cancer among current hormone users was 0.65 (95% confidence interval, 0.50 to 0.83). This risk reduction was confirmed in the Women's Health Initiative trial in which the colorectal cancer relative risk was 0.63.(confidence interval 0.43 to 0.92).

Other Benefits of Hormone Replacement Therapy. There is also suggestive evidence that women who use estrogens are at lower risk of Alzheimer's disease, with a risk reduction of as much as 50% in some groups. Longer followup of women who participated in randomized trials will be necessary to confirm this benefit. The Heart and Estrogen/progestin Replacement Study has showed no benefit with 4 years of followup. Finally, hormone replacement may prevent the decrease in wound healing that occurs in postmenopausal women. The Women's Health Initiative trial found no clinically significant improvement in measures of quality of life with estrogen and progestin replacement.

Risks of Hormone Replacement Therapy. Although relief of symptoms and disease prevention benefits have been clearly documented, so have risks of HRT.

Endometrial Cancer. This is a major risk associated with use of unopposed systemic estrogen. More than 35 epidemiologic studies have evaluated the association between estrogen replacement therapy and endometrial cancer, and the vast majority have found a significant and substantial increase in risk. Relative risk of endometrial cancer among estrogen users has been estimated to be as low as 2 and as high as 15. Risk increases with dosage and duration of estrogen use. Pooled relative risk estimates range from 2.31 for women who have ever used exogenous estrogens to 8.22 for those taking them for 8 or more years, including some who were using doses higher than those used today. For women taking 0.625 mg for at least 5 years, risk is increased fourfold.

Estrogens cause cystic hyperplasia of the endometrium, a premalignant condition. Prolonged continuous use causes excessive stimulation, leading to malignant change. Fortunately, the tumors induced by estrogen therapy in postmenopausal women tend to be of low grade and in early stages when detected. Progestins prevent the development of endometrial hyperplasia that is otherwise associated with unopposed estrogen use. The incidence of atypical or adenomatous endometrial hyperplasia decreases from 35% to 1% with progestin use. At least five studies have examined the effect of estrogen plus progestin therapy on endometrial cancer risk, and none found a significant increase.

Breast Cancer. After considerable uncertainty, it now seems that risk of developing breast cancer increases significantly with duration of exposure to estrogen replacement therapy. The addition of progestin confers no protective effect. Previous analytic studies found a history of any estrogen use produced little increase in relative risk (estimate, 1.01). However, as confirmed in the Nurses' Health Study, the relative risk of developing breast cancer is a function of duration of treatment and ranged from 1.09 to 1.46. There was a 43% increase in deaths from breast cancer in patients who took HRT for more than 10 years. Pooled estimates of relative risk for women who have used estrogen for 8 to 15 years have been in the 1.25 to 1.30 range. Duration of therapy less than 5 years does not appear to cause a significant increase in breast cancer risk. The relative risk in the Women's Health Initiative trial was 1.26 (confidence interval 1.00 to -1.59), with excess risk becoming evident after 3 years of HRT.

Risk of Cardiovascular Disease. Observational studies among tens of thousands of women indicated that coronary heart disease morbidity and mortality were markedly reduced by HRT. Relative risk of cardiovascular mortality among women who are current users of HRT compared to those who have never used HRT ranged from 0.50 to 0.89. Benefit was greatest for women with multiple cardiovascular risk factors. However, the Heart and Estrogen/progestin Replacement Study, a randomized trial among women with established cardiovascular disease, showed that HRT increased coronary events during the first year after which there appeared to be a reduction in the rate of new events. It was hypothesized that the early increased risk could be explained by the thrombogenic effect of estrogen (see below) in women with established coronary disease and that the later reduction in risk was a result of reduced progression of atherosclerosis.

The Women's Health Initiative trial of estrogen plus progestin included more than 16,000 women without heart disease and demonstrated the same early increase in coronary heart disease risk among women without prior disease. The trial was stopped early because of excess harms relative to benefits. With an average follow-up of 5.2 years, women randomized to HRT were 24% more likely to have an acute coronary event with risk most apparent at 1 year of followup (hazard ratio 1.81, confidence interval 1.09 to 3.01). A smaller and nonsignificant excess risk occurred in years 2 through 5.

There appears to be a three-fold increased risk of *thromboembolism* among menopausal women on estrogen replacement, but the absolute risk remains very low for women who are otherwise healthy and active. A history of thromboembolism is a relative contraindication to estrogen use. The relative risk of pulmonary embolus in the Women's Health Initiative Trial was 2.13 (confidence interval 1.39 to 3.25).

The Women's Health Initiative trial also documented an increased risk of stroke in previously healthy women. The excess risk of stroke became apparent after 1 year and continued for the remainder of the study's mean followup of 5.2 years. The relative risk was 1.41 (confidence interval 1.07 to 1.85).

Other Adverse Effects. Other effects of exogenous estrogen include *fluid retention, blood pressure elevation, gallstones* (due to a change in bile cholesterol content), *glucose intolerance,* and *headaches*. Often there is *recurrent uterine bleeding*, especially with cyclic progesterone use (see below). This bleeding can complicate clinical recognition of endometrial cancer and cause inconvenience and concern.. In the Nurses' Health Study, estrogen replacement has been associated with a twofold increase in risk of *systemic lupus erythematosus*, but the absolute risk is very low.

Specific Treatment Regimens. HRT regimens have evolved over the years to reduce risks, side effects, and inconvenience without compromising efficacy. Progestin use has nullified the endometrial cancer risk and can eliminate cyclic bleeding without any apparent loss in benefit from estrogen replacement or increase in other risks. Because clinical benefits and adverse effects of HRT are a function of dose and duration of therapy, it is important to pay considerable attention to design of the treatment regimen.

Dosing. The established dose of conjugated estrogens (Premarin) necessary to prevent osteoporosis and capable of reducing cardiovascular risk is 0.625 mg daily. Lower doses (e.g., 0.3 mg or the equivalent) often suffice to control hot flashes, but as much as 2.5 mg/d may be necessary. Symptomatic atrophic vaginitis may be

treated with vaginal estrogen cream, 1 g every 2 to 3 days, but this is not effective for osteoporosis prophylaxis. Progestin doses of 2.5 to 10.0 mg/d of medroxyprogesterone (Provera) are required to induce either endometrial atrophy when used continuously or endometrial shedding when used cyclically.

Oral Regimens. Three approaches to oral hormone replacement are commonly used.

1. *Continuous estrogen with cyclic progesterone* was the first estrogen/progesterone replacement program designed for postmenopausal women with an intact uterus. The rationale for cyclic progesterone is to produce endometrial shedding so as to avoid continuous endometrial proliferative stimulation. A typical program is 0.625 mg conjugated estrogens (Premarin) daily with 10 mg of medroxyprogesterone acetate (Provera) for 10 to 14 consecutive days each month. Lower doses of Provera (5 mg) may be substituted. In the PEPI trial, cyclic micronized progesterone (200 mg daily for 12 days each month) had a more favorable impact on high-density-lipoprotein cholesterol than cyclic Provera. Disadvantages of this regimen include periodic bleeding and the difficulty in telling if the bleeding is a sign of underlying endometrial pathology.
2. *Continuous estrogen with continuous progesterone* has surpassed the cyclic progesterone program in popularity among women with an intact uterus because it does not result in cyclic bleeding. The advantage of this regimen is induction of endometrial atrophy and eventual cessation of uterine bleeding. Long-term safety is yet to be established but appears similar to the cyclic progesterone regimen. A standard daily regimen consists of 0.625 mg of conjugated estrogen daily plus 2.5 to 5.0 mg of medroxyprogesterone. The proper progesterone dose is that which results in full cessation of vaginal bleeding. This is program is taken continuously.
3. *Continuous unopposed estrogen* is best reserved for postmenopausal women without a uterus. Unopposed estrogen (i.e., 0.625 mg of conjugated estrogens) is taken daily. The practice of interrupting estrogen dosing for 5 to 7 days confers no additional advantages. Moreover, cyclic estrogen therapy does not reduce rates of endometrial hyperplasia or endometrial cancer in women with an intact uterus. Consequently, unopposed estrogen is not recommended for women with a uterus. Moreover, its use in such women necessitates special monitoring for development of endometrial cancer (see below).

Transdermal Estrogen. *Transdermal estrogen* is also an option. A 50-mg patch applied twice each week produces estradiol levels similar to those resulting from oral doses of 0.625 mg of Premarin daily. This approach might make most sense for the woman without a uterus who has no need for progestins. Cost is increased and beneficial effect on lipoproteins may be less than with oral therapy.

Topical Estrogen. *Topical estrogen* is effective for atrophic vaginitis causing dysuria or dyspareunia. Symptoms will respond to topically applied estrogen cream used as seldom as once or twice a week. Systemic absorption occurs, and there is concern about localized endometrial stimulation with prolonged daily use, but limited use on a short-term basis is probably safe. Some women find estrogen-eluting vaginal rings, active for 3 months after initial insertion, more convenient. **Updated: 04/28/03**

Duration of Therapy. Programs for symptomatic relief are usually short term (1 to 2 years) and self-limited. This duration of therapy does not appear to increase risk of breast cancer. It does, however, increase risk for cardiovascular disease. Periodic attempts to withdraw therapy should be advised every 6 months. Tapering estrogen, lowering either the daily dose or the number of days per week that it is administered, may make symptom recurrence less likely. **Updated: 04/28/03**

Patient Selection. In regards to HRT for prevention of osteoporotic fractures, patient selection requires assessment of osteoporotic risk (see Chapter 164). Women with increased risk of osteoporosis and hip fracture are likely to benefit most from hormone replacement. A single measurement of bone mineral density may be useful if the decision to treat would be influenced by the threefold increase in risk associated with low bone density. Because of the increased risk of breast cancer with prolonged estrogen exposure, women concerned about breast cancer risk might best be offered alternative treatment for osteoporosis (e.g., exercise, calcium supplementation, vitamin D, bisphosphonates; see Chapter 164).

Given the serious adverse effects of HRT and the fact that some are still poorly defined, the primary physician must exert care and judgment in selecting patients for HRT. The decision to use such therapy needs to be made with full consideration of the patient's willingness to undertake the risks in exchange for specified benefits. One woman may be willing to accept the risk of breast cancer and cardiovascular disease in return for prevention of disabling osteoporosis and colorectal cancer; another might not. Women should be advised of alternative prevention strategies, including exercise, calcium supplementation, vitamin D, bisphosphonates for osteoporosis (see Chapter 164), and periodic colonoscopy for detection and removal of polyps to prevent colorectal cancer. **Updated: 04/28/03**

Monitoring. Current evidence does not support definitive recommendations for monitoring women taking HRT. However, because of the increased risk of breast cancer with increasing duration of HRT, it is recommended that clinical breast examination and mammography should be performed yearly in women taking HRT. Women taking progestins, as well as estrogens, do not need either baseline or subsequent routine endometrial evaluations.

For the occasional case of a women with an intact uterus who desires to take unopposed estrogens, a baseline pelvic examination with endometrial sampling and a baseline mammogram may be well advised. An alternative to endometrial sampling is screening with transvaginal ultrasound, with sampling reserved for women with a thickened endometrium. Any vaginal bleeding should be reported by the woman taking unopposed estrogens, and the report should prompt endometrial evaluation. In the absence of bleeding, screening with transvaginal ultrasound and/or endometrial sampling should be performed yearly.

Other Treatment Modalities

There are alternative treatments for hot flashes. None are nearly as effective as estrogen replacement. Selective serotonin reuptake inhibitors have been effective in randomized trials. Clonidine is an alternative that is helpful for some women. Soy protein from dietary sources has been promoted to help relieve hot flashes, but women must eat fairly large amounts (at least 40 grams daily of products that contain about 75 mg of phytoestrogens). Pills or supplements containing isoflavones are not equivalent to dietary sources of soy. Herbs or plant-based therapies such as black cohosh or wild yam have also been promoted, but there is little or no good evidence that most alternative therapies are effective. **Updated: 04/28/03**

Advances in the prevention and treatment of osteoporosis (see Chapter 164) and cardiovascular disease provide menopausal women a host of preventive and therapeutic options for conditions related to menopause. For example, a *diet* low in fat, high in calcium, combined with regular weight-bearing aerobic *exercise* can do much to reduce cardiovascular and osteoporotic risks. Even patients at high risk for osteoporotic disease have highly effective nonhormonal options, such as *bisphosphonates* (see Chapter 164).

Diet and exercise can slow osteoporotic changes but not as effectively as estrogen. Nevertheless, the addition of 1.0 to 1.5 g of dietary calcium carbonate per day will compensate for the intestinal malabsorption of calcium that results from estrogen deficiency and will retard bone loss, especially when combined with regular exercise. *Vitamin D* treatment is not beneficial unless serum levels of 25-OH vitamin D_3 are low. Small doses (400 U/d) are helpful in preventing vitamin D deficiency in elderly women; large doses are unnecessary. Bisphosphonate therapy (e.g., alendronate) can reduce vertebral compression fractures by close to 50%.

Patients with worrisome lipid profiles have multiple lipid-lowering options (see Chapter 27) to supplement dietary measures. Vaginal dryness that interferes with intercourse can be treated nonhormonally with a *water-soluble lubricant*, if there is a reason to avoid any estrogen exposure. Decrease in libido and/or orgasmic dysfunction that was clearly associated with the onset of menopause but persists with estrogen replacement might justify consideration of androgen therapy (see Chapter 115).

Overly medicalizing menopause by emphasizing HRT runs the risk of turning a normal phase of life into a disease state and unintentionally triggering depression. A more constructive approach is to advise the menopausal women about her options, emphasizing the range of possibilities and providing a sense of empowerment rather than one of hopelessness.

PATIENT EDUCATION

Because the emphasis in our society is on youth and vitality, the physician has an important supportive role to play in helping the menopausal woman adjust psychologically and maintain her sense of self-worth and well-being. Discussion of the physiologic consequences of menopause and their clinical manifestations can give the patient a rational basis for understanding her own symptoms and properly attributing them. This might save many anxious phone calls and office visits. One can take advantage of this milestone to interest the patient in a program of regular exercise, attainment of ideal weight, and cessation of self-destructive habits, such

as smoking. The patient needs to know that any incapacitating symptoms caused by lack of estrogen can be controlled and that many are self-limited. During the perimenopausal period, women should be reminded to use contraception because ovulation and unwanted pregnancy may occur. Reassurance that capacity for normal sexual activity will continue after menopause is often tremendously comforting. Lack of need for special vitamin supplements should be pointed out because the lay press heavily encourages their use, and this unnecessary expense can be considerable.

If estrogen therapy is being considered, the patient must share in the decision with full awareness of the potential risks and benefits. Patients with intact uteri on unopposed estrogen therapy must be reminded about the need for regular endometrial evaluation. The need for regular follow-up and prompt reporting of any abnormal vaginal bleeding, breast masses, leg swelling, and so forth must be emphasized.

INDICATIONS FOR REFERRAL

Women with an intact uterus who are taking HRT and who experience irregular vaginal bleeding that does not clear with adjustment of progesterone dose require gynecologic evaluation to rule out important endometrial pathology. The postmenopausal patient who develops major depression and does not respond to first-line antidepressant therapy and counseling should be considered for psychiatric consultation.

THERAPEUTIC RECOMMENDATIONS

- **Review Risks and Benefits.** Decisions about treatment of postmenopausal changes require careful weighing and thorough discussion of risks and benefits. The postmenopausal woman's preferences and concerns should be elicited and addressed in the design of any program.
- **For Hot Flashes.** For symptomatic relief of incapacitating hot flashes, consider *oral estrogen* at the lowest dose necessary (often as little as 0.3 mg/day of conjugated estrogens). The need for continued treatment should be reevaluated regularly. Withdrawal attempts every 6 months should use a tapering schedule. If the patient has an intact uterus and requires treatment indefinitely, then consider adding a *progestin* to the program (see below). A trial of SSRI antidepressant therapy or clonidine provides an alternative course. **Updated: 04/28/03**
- **For Atrophic Vaginitis.** For atrophic vaginitis with severe dysuria or unacceptable dyspareunia, prescribe a *topical estrogen preparation* (e.g., conjugated estrogen cream) applied as seldom as once or twice a week. An estrogen-eluting vaginal ring may be preferred as more convenient. Systemic absorption occurs, but its effect is uncertain. However, avoid prolonged daily use because of the risk of endometrial stimulation. In instances of painful coitus only, advise trying a *water-soluble lubricant*, especially if there is a desire to avoid estrogen exposure. **Updated: 04/28/03**
- **For Depression.** Treat specifically for depression with supportive psychotherapy and/or a standard antidepressant drug regimen (see Chapter 227); HRT is not a substitute.
- **For Prophylaxis of Osteoporosis.** Explain the need for long-term therapy and its attendant risks. Consider bisphosphonate therapy as an alternative to indefinite hormone supplementation, particularly in a patient with a prior vertebral compression fracture (see Chapter 164). HRT cannot replace lost bone; it is *not* a therapy for reversing established osteoporosis. However, for women without increased risk of osteoporosis, HRT may reasonably be delayed until age 60.
- **Oral Hormone Replacement Regimens.** For women with an intact uterus, treat with either continuous daily estrogen combined with daily low-dose progestin (e.g., 0.625 mg conjugated estrogens plus 2.5 to 5.0 mg/d of medroxyprogesterone acetate or equivalent) or continuous daily estrogen plus cyclic progestin (e.g., 0.625 mg conjugated estrogens plus 5 to 10 mg of medroxyprogesterone acetate added on 10 to 14 consecutive days of the month). Choice should be based on desirability and acceptability of periodic vaginal bleeding.
- **For women who have had a hysterectomy**, treat with continuous daily estrogen therapy (e.g., 0.625 mg/d of conjugated estrogens). There is no benefit to adding a progestin.

CHAPTER 119 APPROACH TO FERTILITY CONTROL

NANCY J. GAGLIANO, SUSAN OLIVERIO

INTRODUCTION

The ideal contraceptive is perfectly safe, effective, inexpensive, acceptable, and available. None exists. The efficacy of individual contraceptive agents is expressed in several ways. *Theoretic effectiveness* refers to the ability of the medication, device, or procedure to prevent pregnancy if applied under ideal conditions. *Use effectiveness* combines theoretic effectiveness with inherent patient-related lapses in application. *Extended use effectiveness* adds the dimension of time. All are important aspects of evaluation of approaches to fertility control.

The primary physician should be knowledgeable about the effectiveness, difficulties, and adverse effects of available contraceptive methods to help the patient or couple intelligently select the one that suits them best.

NATURAL METHODS

Natural methods of birth control do not meet the demands of most sexually active individuals in industrialized societies. Faithfully practiced *rhythm*, with daily basal body temperature recording, usually results in one pregnancy every 2 years or at least one more child than planned by the couple by their late thirties. Rhythm practiced by abstinence according to menstrual dates is less effective. Rhythm controlled by following the cervical mucus cycle is confounded by infections, dietary changes, douching habits, oral medications, patient understanding of her anatomy, and availability of testing materials. One needs to understand reproductive anatomy and physiology and to have privacy to conduct such tests. These ingredients are unavailable to many Americans. The *amenorrhea of lactation* is useful, but the duration of ovarian inactivity in an individual is hard to predict or follow. *Withdrawal* is probably the most commonly used natural contraceptive technique. Unfortunately, sperm migration from the female perineum can occur, due to discharge of semen before ejaculation.

BARRIER CONTRACEPTIVES

Condoms. Condoms have moderate extended use effectiveness. Pregnancies may occur in up to 15 per 100 couples per year using condoms. When properly used, this method is 85% to 95% effective. For a few cents more than the cheapest devices, high-quality thin condoms are available, use of which is accompanied by very little loss of sensation. When used in conjunction with a spermicidal foam or jelly, its effectiveness may rise to 96%. The condom is inexpensive and widely available. It requires no medical intervention or prescription. Failure by means of rupture is rare but easily recognized. The condom has received more attention recently due to its protective effects against infectious agents such as the HIV, *Chlamydia*, gonococci, herpes simplex virus, and possibly the human papillomavirus. This effect appears to be dependent on the use of nonoxynol-9, a spermicide found in most condoms.

Diaphragms. Diaphragms are synthetic latex barriers mounted on covered rims that deny access of sperm and penis to the anterior vaginal wall and cervical os. The largest diaphragm that will cover the cervix and anterior vagina from the pubis symphysis to the posterior fornix should be selected. The diaphragm should be comfortable so that the woman barely notices its presence. It should not stretch the rest of the vagina or put undue pressure on the urethra. Only significant weight changes of 25% or more of body weight require diaphragm refitting. Refitting should be performed 6 weeks or more postpartum as well. When used properly, diaphragms with a small amount of spermicidal cream or jelly are up to 96% effective. Four pregnancies per 100 fertile women per year would be expected. The cream facilitates insertion but need not be used in the large amounts recommended by the manufacturers, as it is unpleasantly messy. Additional spermicidal cream needs to be applied intravaginally for repeated intercourse. The diaphragm is worn for 6 hours after the last coital event, because this is the length of time during which sperm motility persists. It may be worn for longer periods of time, but like all vaginal contraceptives, it will then become associated with an unpleasant odor. It may also be worn while the patient is swimming or during menstruation.

The two most frequent complaints regarding the diaphragm are latex allergy and increased frequency of urinary tract infections. The Wide Seal diaphragm may be prescribed to women with urinary tract infections. The wider band around the rim puts less direct pressure on the urethra and may reduce the frequency of urinary tract infections. The woman should also be advised to void after intercourse and use adequate lubrication. The Wide Seal diaphragm is often not stocked by pharmacies, and the practitioner who frequently prescribes diaphragms may wish to stock this item.

A physician, nurse, or trained technician must fit the diaphragm to the individual woman. The cost of the diaphragm is reasonable, but manufacturers advocate massive use of creams, which adds to the expense. The patient must have some understanding of her anatomy and not be concerned about exploring her reproductive organs. Some adolescents reject the diaphragm because they are uncomfortable with touching themselves. Its use represents premeditated sexual intercourse, which they find less acceptable than spontaneous events. Women in their twenties seldom voice such a complaint. Some women cannot be fitted adequately with a diaphragm for anatomic reasons. The cervix may not protrude into the vagina adequately (absent pars vaginalis). The cervix may be displaced posteriorly by retroversion or extreme anteversion.

Cervical Caps. Cervical caps fit snugly over the cervix and are slightly more difficult to insert and remove. Their use requires significant physician or nurse teaching, and they are more costly than diaphragms. Currently, four sizes are manufactured, and some women cannot be fit. For these reasons, they are less popular than the diaphragm. For women who have recurrent urinary tract infections, however, they are particularly useful because they do not press on the urethra. Additionally, they can be worn for 48 hours, during which time intercourse may be repeated without the addition of spermicidal cream. There is evidence of a 4% increased incidence of abnormal Papanicolaou (Pap) tests; therefore, it is recommended that a Pap test is performed 3 months after initiating use of the cap. If the Pap smear is normal, then the woman can proceed with yearly Pap tests.

Female Condoms. Female condoms are approved by the U.S. Food and Drug Administration (FDA). The condom is a lubricated polyurethane pouch that lines the vagina. One outer ring lies outside the body and a smaller inner ring is pushed up toward the cervix to hold the condom in place. It gives a woman an additional choice and freedom to protect herself from sexually transmitted diseases and pregnancy. Because it is made from polyurethane, the female condom can be used by latex allergic individuals. Female condoms appear to have failure rates similar to those of the male condom. Unfortunately, they currently cost about twice as much as the male condom.

Spermicidal Creams and Jellies. Spermicidal creams and jellies may have a high theoretic effectiveness, but they have lesser use effectiveness. Most contain nonoxynol-9 as the spermicidal agent. The physical nature of the creams and jellies and difficulty in their application often result in inadequately smearing the cervical os, so that sperm invasion is not prevented. Both men and women complain of the dehydrating effect of spermicidal agents and may report burning sensations. Nonoxynol-9 has the added advantage of being toxic in vitro to HIV, gonococci, *Chlamydia*, and other genital pathogens; some clinical evidence suggests an in vivo effect as well. *Foams* have better physical properties, allowing more adequate smearing of the cervical os; however, foams are effective for short periods of time only, and reapplications are necessary. This increases their cost. They also contain nonoxynol-9 and may cause irritation. Failure rates up to 25% are reported. When used in conjunction with the condom, excellent pregnancy protection has been demonstrated, reaching 96% effectiveness. Foams have the advantage of being readily accessible in both supermarkets and drugstores, and they do not require medical instruction or prescription.

INTRAUTERINE DEVICES

The idea of inserting materials into the uterine cavity to prevent nidation is ancient. Nevertheless, the precise mechanism of intrauterine device (IUD) action remains unknown. What appears to be important is the area of surface contact. Copper enhances effectiveness. The 1% to 5% first-year pregnancy rates with IUD use are among the lowest attainable form of birth control method and are comparable with those of oral contraceptives. The lack of constant compliance greatly enhances efficacy. Another advantage is the lack of systemic effects, a major problem with oral contraceptives (see below). A major limitation to efficacy is expulsion, which is particularly frequent in nulliparous women. The overall expulsion rate is 19 per 100 women per year, lower with copper devices. Occasionally, it is necessary to remove an IUD because of bleeding or pain, which occurs at a rate of about 11% per year. Copper devices are better tolerated by nulliparous women.

The confirmation of a markedly increased risk of tubal infertility associated with IUD use has greatly discouraged IUD placement as a means of safe birth control, especially among nulliparous women. In 1986, sale of all IUDs, except Progestasert, was discontinued. In 1988, Paragard, a new copper IUD, was approved by the FDA. Clinical or subclinical pelvic inflammatory disease is believed to account for the tubal infertility. Risk of pelvic inflammatory disease in nulliparous sexually active women with an IUD has been found to be seven times that for similar women not using an IUD; for parous women, the risk is three times greater. In view of the infertility risk, IUD use is best confined to multiparous women and nulliparous women with a single sexual partner. The nulliparous woman considering an IUD as a means of birth control should be fully informed of the risk of tubal infertility before any decision is made regarding its use.

ORAL CONTRACEPTIVES

Combinations of synthetic estrogen and progesterone have been found to have use effectiveness rates that exceed most estimates of effectiveness of barrier methods, spermicides, and IUDs. Although some report failure rates as high as 5% to 10%, most report only one failure per 100 users per year. The combination pill appears to prevent cyclic release of follicle-stimulating hormone (FSH) and luteinizing hormone, which are required for ovulation; alter the cervical mucus, thereby decreasing sperm motility; and alter the endometrial lining to inhibit implantation. At the present time, combination pills consist of an estrogen (ethinyl estradiol or mestranol) and a progestin (norethindrone, norethynodrel, norgestrel, levo-norgestrel, ethynodiol diacetate, desogestrel, gestodene, and norgestimate). Pill cycles are 28 days long. Pill packets contain 21 or 28 pills depending on the brand. Twenty-eight–day packets contain placebo pills for part or all of the last week of the pill pack. Patients are instructed to start on the first Sunday of the menstrual cycle or the first day of bleeding.

Preparations. More than two dozen combination preparations are available in the United States. In general, it is most useful to renew any prescription with which a patient is satisfied, as long as the patient has no new symptoms or habits that warrant discontinuation of any oral contraceptive.

Cardiovascular risks have been a significant concern when prescribing the pill. Because of the concern that these risks might increase with estrogen dosage and progestin potency, emphasis in recent years has been on use of preparations that have the lowest effective estrogen dose (20 to 35 µg ethinyl estradiol) and the least progestin potency. Fortunately, efficacy of 30 to 35 µg of estrogen for prevention of pregnancy is about the same as that of the older 50-µg estrogen pill.

It is best to begin with a pill containing 30 to 35 µg of ethinyl estradiol. The lowest possible progestin dosage helps minimize bothersome side effects such as increased appetite, steady weight gain, acne, and depression. Many newer and more expensive oral contraceptives are heavily marketed. They may offer some theoretic benefits and perhaps fewer actual ones. Currently, a line of generic birth control pills offer a range of options at a much lower cost to the patient or insurer. It is prudent to reserve the high-cost oral contraceptive pills for patients who have a medical need for a specialized contraceptive pill. A good basic pill to start with contains 1 mg norethindrone and 35 µg ethinyl estradiol (generic Necon 1/35Ortho Novum 1/35).

Patients who have a history of symptoms suggesting hyperresponsiveness to endogenous estrogens (premenstrual breast engorgement and soreness, cyclic weight gain, heavy periods) may benefit from a preparation containing a low estrogen and a progestin with minimal estrogenic effect (e.g., Necon 0.5/35, a generic preparation; norethindrone 0.5 mg/ethinyl estradiol 35 µg; or Ovcon with ethinyl estradiol 35 µg and norethindrone 0.4 mg). Similarly, a patient bothered by acne or hirsutism should be given a preparation with low androgenic progestin such as desogestrel or norgestimate (Table 119-1). Other side effects such as nausea seem related to estrogen content.

ESTROGENIC	ANDROGENIC
Norethynodrel	Norgestrel
Ethynodiol	Norethindrone
All others have none	Norethindrone acetate
	Ethynodiol
	Norethynodrel (has none)

*In order of decreasing potency.

Table 119-1. Effects of Synthetic Progestins*a*

The disadvantages of using lower dose agents are higher rates of spotting, breakthrough bleeding, and amenorrhea. Moreover, women who use oral contraceptives containing less than 30 µg of estrogen may experience a greater chance of pregnancy. To counteract this reduced efficacy, newer pills with 20 µg of ethinyl estradiol have lengthened the hormone cycle with as few as 2 days of hormone-free placebo in the 28-day cycle. In an attempt to improve rates of breakthrough bleeding and pregnancy associated with low-estrogen/weak- progestin formulations, manufacturers have developed *biphasic* (e.g., Ortho-Novum 10/11) and *triphasic* (e.g., Ortho-Novum 7/7/7, Tri-Norinyl, Triphasil) formulations. The rationale is to more closely mimic normal ovarian patterns. Efficacy is similar to that obtained with other low-estrogen/weak-progestin preparations; no controlled evidence to date suggests that they are superior in terms of breakthrough bleeding. There is evidence that the monophasics are superior to triphasic pills in suppressing ovarian function and should be the pill of choice in women with a history of large ovarian cysts. All low-dose preparations need to be taken religiously to be maximally effective and to minimize the chances of breakthrough bleeding.

Progesterone -only pills—"the minipill"—are available and prescribed for women who should not take estrogens. Lactating women, women with complex migraine headaches, women over age 35 who smoke, and women with thromboembolic disease may be given this preparation.

It is helpful to become familiar with four or five pills and their minor differences rather than using the most recently marketed combinations. Providing the patient with full understandable information at the initiation of therapy will ward off many anxious phone calls. In particular, if one pill is missed, it can be made up by doubling the next dose. If two pills are missed, the patient should double the dose for the next 2 days, but barrier contraception is recommended for the remainder of the cycle. If three or more consecutive pills are missed, the pills should be stopped altogether, allowing withdrawal bleeding to occur. A new pill pack should be started 1 week after the last pill was taken. Recurrent failure to take oral contraceptives regularly is an indication for trying another form of birth control.

Because contraceptive pills are often prescribed until menopause, knowing just when to stop or switch to postmenopausal estrogen replacement can give the patient and physician pause. One approach is to check an FSH near the age of 50. The FSH should be checked on day 7 of the placebo or pill-free week. If the FSH is significantly elevated (close to 100), then it would be appropriate to stop or switch to estrogen replacement therapy. If the FSH is normal or midrange, then continuing the pill and rechecking the FSH in another year would be prudent.

Breakthrough bleeding is a common side effect of the pill. If it occurs late in the cycle or in the first few months of initiation of the pill, it is usually caused by too little progesterone. If it occurs early in the cycle or after years of use, it may be caused by inadequate estrogen. This problem may be temporarily resolved by having the patient take two pills a day for 3 days. The additional pills should be obtained from a separate package of pills.

If the problem recurs repeatedly after the first 3 months, then changing the pill to a stronger estrogenic or progestinal pill would be appropriate. The physician should

always rule out other causes of irregular bleeding, such as infection and pregnancy.

Another common complaint is that of *morning nausea*. It may be improved by having the patient take the pill with her evening meal and then consume a light breakfast daily. If the symptoms persist, switching to a lower estrogen pill or a progesterone-only pill (e.g., Micronor) may be indicated.

Patients require follow-up care 6 to 12 weeks after initiation of the birth control pill to check for hypertension, review proper use, and discuss side effects. The patients should then be seen yearly, checking for headaches, hypertension, breast masses, cervical abnormalities, phlebitis, and signs of cardiovascular or cerebrovascular disease.

Physicians are generally unaware of the high discontinuation rate among oral contraceptive users. Factors involved include the patient's perceptions of need and attitudes about taking medications that affect the sex organs. Oral contraceptives are expensive and require a medical prescription, important barriers for adolescents. Despite these factors and known side effects, birth control pills continue to be the most used safest birth control method for most nonsmokers. The pill's relative safety is most apparent in countries where the risk of dying in childbirth is high.

Adverse Effects. The major hazards of oral contraceptives are cardiovascular. The relative risks of cardiovascular events in users compared with nonusers had been reported to be 4 to 11 times greater for *thromboembolism*, 4 to 9.5 times greater for *thrombotic stroke*, 2 times greater for *hemorrhagic stroke*, and 2 to 12 times greater for *myocardial infarction*. These earlier studies, which demonstrated a slight increase in risk, were done on women taking 50-µg doses of estrogen. Currently, it is thought that any increased risk is due to embolic events. The Nurses' Health Study demonstrated no significant differences in the rates of various cardiovascular diseases between never-users and past users of oral contraceptives. The studies consistently showed increased risks *in smokers*. Mortality from myocardial infarction rises sixfold in women older than age 40 who are smokers. The overall excess death rate annually has been estimated to be 20 per 100,000, with risk concentrated in women older than 35, especially if they smoke cigarettes and have used oral contraceptives for 5 years or longer. Division of data at age 35 is arbitrary, and it would be prudent to assume that risk gradually increases with age. Cardiovascular risk is much lower with 35-µg estrogen pills.

Progestin potency may also be associated with increased cardiovascular risk, probably because of its ability to raise low-density-lipoprotein (LDL) cholesterol and lower high-density-lipoprotein (HDL) cholesterol (see Chapter 15). Initial concern that the newer progestins such as desogestrel may be related to an increase in thromboembolic disease and deep vein thrombosis (DVT) has not been borne out in further studies.

Any population of women provided with oral contraception will show a rise in mean blood pressure in about 3 months. Prospective studies have found that the incidence of *hypertension* increases two- to sixfold in users compared with nonusers. It is wise to check blood pressure before renewing a patient's prescription. The progesterone in the birth control pill, like the progesterone in the secretory phase of the menstrual cycle, increases aldosterone secretion, and estrogen increases renin substrate.

There is a twofold increase in the risk of *gallbladder disease* in users compared with nonusers, because of increased cholesterol saturation of bile. The frequency of gallstones appears to rise after 2 years' usage and to reach a plateau after 4 to 5 years' usage. This risk must be balanced against the increased risk of gallbladder disease associated with multiparity. Another hepatobiliary problem is the rare development of highly vascular *hepatic adenomas*, which can rupture spontaneously, resulting in serious hemorrhage. Isolated cases have appeared in the literature; in most cases, patients had been using the pill longer than 5 years. The actual risk is unknown. Finally, estrogen use has been associated with *cholestatic jaundice*, but oral contraceptive use does not worsen cases of mild viral hepatitis and need not be discontinued unless cholestasis or hepatocellular injury is severe.

Studies concerning risk of breast cancer associated with the use of oral contraceptives have produced conflicting results and much controversy. Although pooled analysis of such studies suggested there may be a small but statistically significant increase in risk of breast cancer, many of the studies examined had methodologic flaws and included use of high-dose preparations, which are no longer used. A more recent large-scale observational study involving women who used low-dose preparations reveals no increase in risk, even among those with a family history of breast cancer. If there is an increased risk, it appears, at most, to be very small in most populations of women and probably only important to consider in women at high genetic risk (e.g., BRCA positive). The literature should be followed for additional data on this important issue.

Updated: 7/22/02

It is important to remember that estrogens may stimulate the growth of certain cancers; these include carcinoma of the breast (see Chapter 122), cervix, and endometrium (see Chapter 123). Most studies have shown diminished incidences of fibroadenomas, ovarian and endometrial cancers, and benign fibrocystic disease of the breast in pill users.

Metabolic and endocrinologic effects are numerous. Thyroid-binding globin levels increase, which in turn raises the serum thyroxine level. Glucose tolerance falls as circulating growth hormone rises and peripheral resistance to insulin occurs. Triglyceride levels increase, sometimes dramatically, with the concurrent boost in lipoprotein production. The estrogen component tends to result in a rise in HDL cholesterol, whereas the progestin may result in a rise in LDL cholesterol. There is no evidence to suggest that the oral contraceptive pill should not be prescribed in women with hypercholesterolemia. However, it may be prudent to use a pill shown to have minimal lipid-worsening effect. Such pills are those with low doses of norethindrone (e.g., Necon 0.5/35 or Ovcon) or those with newer progestins (e.g., Desogen).

A few miscellaneous effects are noteworthy. Birth control pills may increase the frequency of *migraine headache* in patients with prior migraine attacks. However, they are only contraindicated in the woman with neurologic symptoms associated with her migraine headache. Anecdotal reports of *exacerbation of lupus erythematosus* appear in the obstetric literature. Sensitivity to sunlight and chloasma (mask of pregnancy) are seen in some users and fade with discontinuation.

Certain medications such as antibiotics and seizure medications have been found to affect the efficacy of the oral contraceptive pill. Anticonvulsants such as Dilantin induce hepatic metabolism and therefore effect the circulating level of hormone. Gabapentin is not metabolized and therefore unlikely to effect contraceptive hormone levels. It is prudent to advise women who are prescribed oral antibiotics to use back-up contraception for that month. However, the data to support this practice are limited.

A number of gynecologic conditions are affected by use of these agents; effects may be beneficial or detrimental. Patients with menstrual irregularities before oral contraceptive use will have regular pill-induced periods while taking the medication. Patients should have a full evaluation of the etiology of their irregular menses before initiation of the oral contraceptive pill. On discontinuation of the pills, some will revert to their previous irregularity. Rarely, *amenorrhea* due to ovarian suppression will persist for several months, even a year after pill cessation (see Chapter 112). Usually, menses return promptly, and fertility rates in the first 3 months of discontinuation are increased. Occasionally, a patient will notice nipple discharge (nonpuerperal lactation) with use of oral contraceptives. The mechanism is not clear. No increased incidence of pituitary prolactinomas has been observed.

Many patients with *dysmenorrhea* find marked relief with oral contraceptives (see Chapter 116). If the dysmenorrhea is associated with endometriosis, the response is variable, with many patients complaining of exacerbation of symptoms rather than relief.

With these side effects in mind, absolute and relative contraindications can be listed (Table 119-2). Patients exposed to diethylstilbestrol have used birth control pills with no evidence to date of either beneficial or deleterious effects.

Absolute Contraindications
 Thromboembolic disorders, cardiovascular disease, throm-
   bophlebitis, or a past history of these conditions or other con-
   ditions that predispose to them
 Markedly impaired liver function from severe hepatitis, alco-
   holism, etc.
 Known or suspected estrogen-dependent neoplasm (cancers of
   the breast, endometrium, etc.)
 Undiagnosed genital bleeding
 Known or suspected pregnancy
Relative Contraindications
 Migraine headache
 Hypertension
 Familial hyperlipidemia
 Epilepsy
 Uterine leiomyoma
 History of idiopathic obstructive jaundice of pregnancy
 Smoking one-half pack or more per day
 Diabetes mellitus
 Severe heart disease
 Patient unreliability
 Age >35 yr

Table 119-2. Contraindications of Oral Contraceptives

Postcoital (Emergency) Contraception. Several regimens provide 97% to 99% effective emergency contraception if started within 12 to 24 hours of unprotected intercourse: 1) *estrogen/progestin* (ethinyl estradiol 100 mg plus levonorgestrel 1.0 mg – eg, 2 Ovral tablets) repeated in 12 hours; 2) *high-dose estrogen* (ethinyl estradiol 0.5 mg) bid for 5 days; 3) *progestin* only (levonorgestrel 0.75 mg) repeated in 12 hours; or 4) *mifespristone* (600 mg, single dose; FDA approval pending). Nausea and vomiting occur with estrogen-based programs The only contraindication is pregnancy. If emesis occurs within one hour of taking an estrogen containing pill then the dose can be repeated.

SUBDERMAL AND INTRAMUSCULAR PROGESTINS

Norplant is a method of contraception using six slender Silastic tubes surgically implanted subdermally. Levo-norgestrel, a progestin, is released continuously at a very low level for 5 years and appears to suppress ovulation. Cumulative pregnancy rates over the 5 years are 0.6% to 4% and are highest among women who have regular menstrual cycles while using Norplant. The advantages are 5 years of continuous contraception and very low hormone levels, resulting in no clinically significant metabolic effects. The disadvantages are irregular bleeding (in 66%) lasting many months and a cost of hundreds of dollars.

Depo-Provera has also been FDA-approved for use as a contraceptive. Medroxyprogesterone acetate 150 mg is administered intramuscularly every 3 months. Care should be taken to ensure that the woman is not pregnant initially, and it is recommended that the drug be administered during the first 5 days of the cycle. If a patient waits longer than 14 weeks between injections, a pregnancy test should be performed before her next injection. The pregnancy rate is 1% if used correctly. Disadvantages include irregular bleeding and the displeasure of patients receiving injections.

ABORTION

See Chapter 121. Studies by Planned Parenthood have not found that a substantial number of American women rely on abortion as the sole method of birth control or has any trend to such a reliance been noted. Rather, abortion is used as a backup when other methods fail. Frequently, the necessity for an abortion initiates effective contraceptive use, particularly in those younger than age 20. No adverse affect of first-trimester induced abortion on future childbearing has been demonstrated. The effect of second-trimester abortions in rupturing cervical tissue is controversial. Rarely, an anomalous cervix may become incompetent, requiring cerclage if the patient wishes to carry future pregnancies to term. Morbidity and mortality in teenagers from induced abortion is lower than in older women.

Since 1988, mifepristone (RU-486), an antiprogesterone, has been successfully used in Europe for medical termination of early pregnancy. It is given as an oral dose in combination with a self-administered vaginal prostaglandin analogue. It has been found to be safe, highly effective, and acceptable to women. In addition, it is being studied for other clinical uses, including the treatment of leiomyomata, endometriosis, breast cancer, and potential estrogen-free contraceptive. To date, it has yet to gain FDA approval for use in the United States, likely due to social issues surrounding the abortion debate.

OVERALL RISKS

Used alone by women younger than 30, condoms, diaphragms, IUDs, birth control pills, and first-trimester abortion have a mortality risk of 1 to 2 per 100,000, significantly lower than the 12 per 100,000 delivery-related risk rate. After age 30, the risk of birth control pills rises, especially in smokers, but it is still less than the morbidity and complications of childbearing without fertility control. The birth control pill may be prescribed to women until menopause, but it is contraindicated in a smoker past the age of 35. The lowest level of mortality is achieved by a combination of contraception with access to early abortion.

STERILIZATION

In 1965, one third of the married couples in the United States used oral contraception, sterilization, or IUDs. By 1975, almost three fourths used one of these methods. Sterilization is now the most frequently used method of contraception among couples married for a decade or longer and among couples who have had all the children they want.

Vasectomy. Vasectomy is the simplest and safest means of sterilization. Only a few surgical instruments and local anesthesia are required. The procedure may be done in a clinic, doctor's office, ambulatory surgical day care unit, or hospital. The procedure does not lead to impotence; rather, men with problems associated with impotence may blame vasectomy. It takes about 90 days of average ejaculatory activity to completely empty the spermatic cord and accessory glands of residual sperm. Thus, the vasectomy subject should have a postoperative semen analysis before he is considered sterile. Alternative methods of birth control should be used in the interim. Circulating antibodies to sperm may be induced by foreign proteins and by sperm. The effect of elevated sperm antibodies on a man's health is not clear but has been the subject of much concern. Retrospective cohort study of more than 10,000 vasectomized men fails to support such concerns; no serious immunopathologic consequences of vasectomy were noted. Further evidence of safety emerges from use-control and cohort studies showing no relation between vasectomy and cardiovascular disease. The only adverse effects are an increased risk of epididimitis, orchitis, and testicular changes leading to infertility (see below). Some epidemiologic studies suggested an increased risk of late onset prostate cancer, but subsequent well-designed, larger-scale case control studies failed to confirm the concern. Vasectomy still appears safe and effective, and it is the least expensive form of permanent sterilization. Recanalization when ends of the vas are tied too closely together may account for failures. Reanastomosis may be carried out with microsurgical techniques; however, only about one third of patients undergoing reanastomosis father live-born children. The causes of diminished fertility are multifactorial and include damage to nerves adjacent to the vas, the development of interstitial fibrosis within the testicle, and age.

Procedures on the Fallopian Tubes (Tubal Sterilization). Tubal sterilization is currently the leading form of contraception in the United States, with over 10 million women having undergone the procedure and 1 million being performed annually. The procedure is not foolproof; the pregnancy rate is 1% to 2%, depending on the type of tubal procedure performed. Of the pregnancies that do occur after tubal sterilization, a substantial proportion (0.15 to 0.65) are ectopic.

Postpartum Surgical Division of the Fallopian Tubes. Postpartum surgical division of the fallopian tubes shortly after delivery is easily accomplished, either with normal vaginal delivery or with cesarean section. The procedure adds 1 to 2 days to the patient's hospitalization. Procedures that leave the two ends of the fallopian tubes in close proximity (Pomeroy technique, in which a suture ties a knuckle of tube and the apex of the knuckle is excised) may have a failure rate of 2%. Other methods that leave the two severed ends well separated have failure rates of less than 1%. When there is concern for the survival of the newborn, postpartum sterilization is contraindicated.

Vaginal Tubal Ligation. Vaginal tubal ligation is usually not done postpartum through the vagina because of the increased vascularity and the risk of sepsis. A skilled obstetrician-gynecologist can do interval sterilizations under local anesthesia, usually in a day care or hospital facility. However, leiomyoma, endometriosis, or previous infection may obstruct the approach to the tube.

The *minilaparotomy* involves a small abdominal incision of 1 to 2 inches done under local anesthesia through the peritoneum. Each fallopian tube is identified, ligated, and divided. The incision is closed with resorbable sutures, and a bandage is applied. The patient is able to go home within a few hours.

These methods have the advantage of simplicity and require commonly used instruments. They have been taught to surgical technicians in Third World countries. Such procedures may be unsuitable in an obese or anxious patient. In fact, other methods are more commonly used in the United States.

Laparoscopy. Laparoscopy requires expensive special instrumentation and an experienced gynecologist or surgeon. Although it can be done under local anesthesia, general endotracheal anesthesia is more commonly used. A fiberoptic endoscope is inserted through a subumbilical incision, and a second instrument accompanies the endoscope or is inserted through the pelvic incision. The tubes are cauterized or both cauterized and divided. Alternatively, plastic rings or clips are used to occlude them. Cauterization has the lowest failure rate; however, clips are advocated as being less likely to cause damage to bowel. In fact, complications and failures with clips are often remedied by cauterization. Furthermore, the half-life of the plastic materials used for occlusion has not been clearly defined, and very little

5-year data are available.

In experienced hands, laparoscopy is highly effective with minimal risk in a healthy woman. Laparoscopy may be accomplished on a 1-day basis or in day care facilities. The patient may be expected to continue her normal menstrual life and menopause. Anastomosis of severed fallopian tubes can be accomplished by careful surgical procedures with or without optical magnification. However, as with vasectomy, the rate of achieving patency is higher than that of live births. Motivating factors, patient age, concurrent disease, or attitudes of the partner and surgical technical details account for the low fertility rate.

In general, tubal sterilization should be considered irreversible. The procedure is indicated when the patient requests it. Many requests for anastomosis of divided tubes come when the procedure is initially advocated by a physician or partner. A woman of 23 with three children may be firm in her desire for sterilization, whereas a woman of 34 with five children may be unwilling to consider it. On the average, women are aged 28 to 30 at the time of tubal sterilization; 88% are married, 6% have never been married. Of note, risk of ovarian cancer appears to be reduced by tubal sterilization procedures; the mechanism is unknown.

The federal government will not reimburse for sterilization done at the time of abortion, because the combined procedure has been found to be more hazardous than either done separately. The rare instance in which this does not hold true is the patient in whom the risk of anesthesia is unduly high, such as a woman with myasthenia gravis. There is no federal reimbursement for sterilization of minors or mentally incompetent patients. Though awkward in individual cases, on the whole such regulations have been necessary to prevent widespread abuse of easily accomplished low-risk surgical procedures done without due respect for the patient's understanding or desires. In addition, the government will not pay for hysterectomies done solely for the purpose of sterilization.

CHOICE OF METHOD

The choice of birth control is best viewed in terms of the patient's age and family expectations. *Unmarried adolescents and women in their early twenties* may use oral contraceptives with a high degree of safety and acceptability. Contraindications are infrequent in this age group, and the cost, in general, is not beyond their reach. Diaphragms may be as effective but often are less acceptable. Condoms and foam are an excellent choice given their effectiveness and protection from sexually transmitted diseases. Their use depends on motivation, which can be lacking at times. Though less effective and not usually recommended by physicians as a sole means of contraception, the sponge is convenient and, as such, more likely to be used by young women. IUDs are effective, but the risk of pelvic sepsis that may affect future childbearing is a concern.

For sexually active *26 to 35 year olds*, birth control pills, diaphragms, and condoms may be equally effective, and choice is simply a matter of preference. IUDs may be a reasonable choice for parous women aware of the small risk of pelvic inflammatory disease and willing to seek help promptly at the first sign of infection. The smoker should be asked to stop tobacco use if she wants to use oral contraceptives. Many patients in this age group have completed their families and request sterilization. Nulliparous women in this age group who desire sterilization present a problem to many health care providers. If the patient is not well known to the clinic or physician, one can suggest she practice contraception for a year, then undergo sterilization if she still wants to. When such advice is given, perhaps half the patients return for the procedure. The others go elsewhere or change their minds.

For *women older than age 35*, the birth control pill may be prescribed as long as she is a nonsmoker. Diaphragms, condoms, sterilization, and more recently the pill are commonly chosen by *women older than age 40*.

PATIENT EDUCATION

There are few areas in primary care in which patient education is so important to decision making. Diagrammatic and written materials are available from most commercial distributors of contraceptive products, Planned Parenthood, many women's advocacy organizations, the American College of Obstetrics and Gynecology, and the American Medical Association. It is most important that information is clearly written in the patient's native language and that the patient is given an opportunity to ask questions and demonstrates her understanding.

The need to offer sympathetic and nonjudgmental counseling cannot be overemphasized. Regardless of the physician's personal views on abortion and birth control, the patient should be able to obtain factual information from her primary care physician or should be referred to someone who is willing to provide the information and care desired.

INDICATIONS FOR REFERRAL

Patients may need or request referral for counseling on emotional responses to sexual activity and contraceptive techniques. Referral to a social worker, sex therapist, or psychiatrist with an interest in the area may be useful, but thorough discussion between the primary physician and patient usually suffices.

When a surgical procedure is being considered, the patient should meet with the gynecologist to discuss the issue in more detail. Referrals of medically uncomplicated patients may be made by phone. For patients with known medical problems, a careful history and physical examination and written referral to the specialist are helpful, so that the risks of the various procedures may be carefully discussed and therapy individualized. Patients who seem unable to use any form of birth control offered may also be referred to any of the above-named specialists, in the hope that an alternative approach will enhance motivation.

CHAPTER 120 APPROACH TO THE INFERTILE COUPLE

A couple that has been engaging in regular sexual intercourse without contraception for at least a year without conceiving is considered infertile. Ten percent to 20% of American couples in their childbearing years are infertile. New technologies and rising expectations have produced significant increases in the numbers of couples seeking help, more than doubling in the past decade and now exceeding three million. The primary physician is often the first to be consulted and is responsible for initiating a medical evaluation of the couple. Although the usual request is to find or rule out a medical cause for the problem, there is also a need to identify any psychological or socioeconomic barriers to conception. Treatment is frequently carried out by individuals specializing in infertility, but the primary care physician should become proficient in performing the initial assessment and knowing when referral is indicated. Principal tasks include providing accurate advice and uncovering treatable etiologies.

PATHOPHYSIOLOGY AND CLINICAL PRESENTATION

Any disorder involving the male or female reproductive system may interfere with function to a degree sufficient to cause infertility.

Men

Infertility in the male can be classified in terms of gonadal, gonadotropic, obstructive, and functional etiologies and considered according to whether they present with azoospermia, oligospermia, or normal sperm counts.

Azoospermic Etiologies. Patients with primary hypogonadism affecting both spermatogenesis and testosterone synthesis have azoospermia, a low testosterone, and elevations of luteinizing hormone (LH) and follicle-stimulating hormone (FSH). *Klinefelter's syndrome* is the archetype example, characterized by two X chromosomes and one Y chromosome. The extra chromatin is visible as the Barr body seen on examination of buccal mucosa cells.

Men with predominantly germinal compartment failure are also azoospermic but manifest relatively normal testosterone and normal LH and elevated FSH. *Sertoli cell–only syndrome*, adult *mumps* orchitis, and *cancer therapy* are among the more common congenital and acquired varieties, respectively. In a study comparing childhood and adolescent cancer survivors to sibling control subjects, overall relative fertility was 85%, with radiation therapy below the diaphragm reducing it by 25% and alkylating therapy alone causing a 40% reduction.

Hypogonadotropic hypogonadism also causes azoospermia. It too may be congenital or acquired (Table 120.1). Patients present with azoospermia and low levels of FSH, LH, and serum testosterone. Congenital disease is often associated with anosmia (*Kallmann's syndrome*). Pituitary tumors account for much of the acquired disease; a *prolactinoma* may be responsible. Large sellar tumors can lead to panhypopituitarism, with features of hypothyroidism and adrenal insufficiency dominating the clinical picture. *Drugs* (including alcohol and marijuana) can interfere with hypothalamic-pituitary function.

Hypothalamic/pituitary
Prolactinoma
Idiopathic
Drugs (e.g., alcohol, marijuana)

Testicular
Klinefelter's syndrome
Sertoli cell–only syndrome
Irradiation
Adult mumps
Alkylating agents

Anatomic/functional
Obstruction of epididymis or vas
Impotence
Retrograde ejaculation
Infection
Antisperm antibodies
Idiopathic defects in sperm quantity or quality

Table 120.1. Important Causes of Male Infertility

Azoospermia in association with normal levels of LH, FSH, and testosterone characterize *retrograde ejaculation* (due to diabetes or drugs) and *obstruction* of the ejaculatory system. There may be *congenital obstruction* of the epididymis and vas deferens or the vas may be absent. Most other types of obstruction are more proximal, giving normal testicular size and normal semen fructose.

Oligospermic Etiologies. Patients with a large *varicocele* may present with the typical "bag of worms" appearance to the testicle, but at times the only manifestation is a faint pulsation along the spermatic vein on Valsalva or coughing. The varicocele may be unilateral (usually on the left) or bilateral. There is no correlation between size of the varicocele and degree of infertility. Testicular size may be reduced, even though the scrotal contents appear enlarged. The mechanism by which varicocele results in infertility remains undetermined; some even question the association, but repair of the varicocele by spermatic vein ligation often restores normal sperm quantity and function. Effects on fertility are less clear.

Another large group of oligospermic patients with normal LH and testosterone have no detectable pathology and are labeled *idiopathic*. The condition results in a quantitative abnormality of spermatogenesis without any identifiable anatomic or endocrinologic precipitant. FSH is normal unless the sperm count falls below 20 million/mL, in which case it may begin to rise. At times, the acquired forms of selective tubular damage (*chemotherapy, irradiation, adult mumps*) may leave the patient oligospermic rather than azoospermic. Testosterone and LH are normal, but thyroid-stimulating hormone is elevated.

In milder forms of acquired *hypothalamic-pituitary dysfunction*, some spermatogenesis may be preserved. FSH and LH are low to low normal and testosterone is low. Prolactin may be elevated due to a *microadenoma*. In *partial androgen resistance*, testosterone and LH are elevated, whereas FSH remains normal. Gynecomastia develops as a result of excess estradiol production by the testicle and peripheral conversion of testosterone.

Etiologies with Normal Sperm Counts. Most patients demonstrate abnormal sperm morphology or motility and suffer from many of the same conditions as those with oligospermia (e.g., varicocele). In addition, *genitourinary tract infection* may cause such qualitative sperm changes; leukocytes sometimes appear in the semen. *Antisperm antibodies* are noted in some patients, and an autoimmune mechanism may be operative in some instances, although the relationship between antibodies and infertility remains to be fully established.

Impotence or erectile dysfunction ranks as a leading, although frequently overlooked, etiology. Hormone concentrations and sperm parameters are usually normal in "functional" types (although depression and situational stress can transiently reduce sperm counts). In organic etiologies of impotence, these parameters reflect the underlying pathology (see Chapter 132 and Chapter 229). Anatomic anomalies, such as proximal location of the urinary meatus, may lead to infertility because of deposition of sperm and semen too far from the cervical os.

Women

Disorders of Ovulation are among the most frequent causes of failure to conceive, comprising 20% to 40% of cases in which a female factor is responsible for the

infertility. Anovulatory bleeding (irregular menses), amenorrhea, or infertility may be the presenting complaint. *Polycystic ovary syndrome* and other forms of *hypothalamic dysfunction* account for most cases (see Chapter 111 and Chapter 112). Pathophysiologically, the normal pattern of gonadotropin-releasing hormone (GnRH) release is disrupted, impairing the normal midcycle surge in LH. The result is failure to ovulate and inadequate corpus luteum formation. Treatment can restore fertility.

Premature ovarian failure may be autoimmune or idiopathic, but an important acquired source is *cancer therapy* in children and adolescents (see above). In the study noted above comparing survivors of childhood and adolescent cancers with their siblings, overall relative fertility for women was 85%, with radiation therapy below the diaphragm reducing it by 25% but alkylating therapy having relatively little effect.

Tubal Disorders account for about 25% of cases. *Pelvic inflammatory disease* (particularly indolent nongonococcal forms such as that due to *Chlamydia trachomatis*; see Chapter 116 and Chapter 117) is the leading cause of tubal damage. In a prospective study, 12% of those with a single episode of salpingitis had tubal occlusion; 35% of those with two infections had occlusion; and 75% of those with three or more had occlusion. Other pelvic and abdominal infections (such as a *ruptured appendix* in childhood) may lead to tubal adhesions. Infections associated with intrauterine devices are a problem. *Postpartum infection* has an unusually frequent association with tubal occlusion. Infections after induced abortion, particularly if inadequately treated (e.g., with inappropriately low doses of antibiotics), unrecognized, or not brought to medical attention, may lead to infertility.

Oil-based dyes used for uterotubograms (hysterosalpingograms) in some countries have also been associated with adhesions. Uncommon causes include *pelvic trauma* from vehicular accidents, *inflammatory bowel disease*, tuberculosis, and schistosomiasis. In general, processes that cause adhesions rather than tubal epithelial damage seem to have a better prognosis. *Endometriosis*, found in 8% to 15% of fertility clinic populations, may cause tubal obstruction and uterine disturbances.

Uterine Pathology represents about 5% of cases. *Congenital anomalies*, such as absence or duplication of the uterine fundus, often present as repeated pregnancy wastage. Complete duplication of cervix and uterus tends to diminish fertility but less so than anomalies causing distortion of a single uterine cavity. Septate and deeply arcuate uteri may be more useful after hysteroscopic or operative repair. Urinary tract anomalies are estimated to occur with 25% of congenitally abnormal uteri. They are found more frequently in the completely duplicated situation or when one side of the müllerian duct is missing.

Uterine Fibroids and Endometriosis may distort or obstruct the uterine cavity. Resection and reresection of fibroids have been surprisingly successful. The *forgotten intrauterine device* is occasionally a cause of infertility. The role of uterine glycosaminoglycan in stimulating conversion of sperm proacrosin to acrosin, a step necessary for sperm penetration of the zona pellucida, is an area of ongoing investigation.

Cervical Factors are increasingly appreciated sources of infertility. *Cervical incompetence* may lead to repeated abortion or later trimester pregnancy losses. The incompetence can result from inadequate innervation, disturbances in synthesis or breakdown of prostaglandin, or defects in muscle and collagen fibers. Incompetence of the cervix may also compromise its role in resisting the entry of infectious agents into the sterile uterine cavity.

The precise role of *cervical mucus* is still not well understood, but normal viscosity and ferning are essential to conception and represent evidence of adequate estrogen stimulation and response. The importance of cervical mucus *antibodies* andproteins as a cause of infertility continues to be a focus of much research.

Vaginal Factors are occasionally implicated. An intact or nearly *intact hymen*, a septum, or a constricting ring in the upper vagina can limit access to the cervix. Total absence of the vagina is only rarely associated with sufficient development of the cervix and uterus to allow fertility at all. As a site of *infection*, the vagina may prove to be an important cause of pregnancy wastage. *Trichomonas, Candida albicans, Chlamydia, Mycoplasma, Gardnerella*, streptococci, and gonococci are all associated with cervical and vaginal discharge (see Chapter 117). Their role in vaginally related obstructions to conception is not clear, although their role in pregnancy wastage is established. When these organisms lead to pelvic inflammatory disease, they become more clearly accountable for infertility.

Viral Infections of the Vulva and Labia, particularly herpes vaginalis and condyloma accuminata, are usually only temp-orary impediments to fertility (see Chapter 192). Vulvar surgery per se need not cause infertility. Similarly, paralysis or hemipelvectomy may or may not be blamed for infertility; much of the impediment derives from the social and emotional impact of these conditions.

Both Partners

Interpersonal problems (see Chapter 229) are an important etiologic factor, because they may lead to sexual dysfunction. The desire for children may not be shared equally by both partners. This may be overt, with one partner seeking medical assistance to persuade the other. More often, it is covert. There may be anxiety over how family responsibilities will interfere with career development, or one partner may not want to lose the economic and social freedom of a childless couple. Sometimes one partner may be concerned about sharing the other's affection with a child. Some may feel inadequate or unwilling to assume parental duties. Such concerns can lead to sexual inactivity. Transient situational problems arise. The young professional person may be under considerable job pressure; travel may interfere with optimal timing of intercourse for conception or lead to hypothalamic dysfunction. Acknowledged or unrecognized homosexual preference may also interfere with fertility.

Controversy surrounds the role of *genital* Mycoplasma *infection* in the genesis of infertility. In one study, if the husband was culture positive, treatment of the infertile couple for *Mycoplasma* led to a 60% pregnancy rate if the infection was eradicated versus a 5% rate when it was not. Other studies fail to show any association between the *Mycoplasma* infection and infertility.

DIFFERENTIAL DIAGNOSIS

In about a third of instances, a male factor is the predominant etiology. In another third, a female factor predominates. In the remainder, either the cause resides with both partners or the etiology is unknown. In most cases attributed to a male factor, there is either a quantitative or qualitative sperm defect of unknown etiology. Among female factors, ovulatory disturbances account for up to 40%, tubal disorders for 10% to 30%, cervical factors for 20%, and uterine factors for about 5%. Table 120.1 and Table 120.2 list some of the most important etiologies.

Hypothalamic/pituitary
  Hypothalamic dysfunction
  Polycystic ovary syndrome
  Prolactinoma
Ovarian
  Primary failure (e.g., premature menopause)
  Irradiation
Tubal
  Pelvic inflammatory disease
  Endometriosis
  Adhesions
Uterine
  Fibroids
  Scarring (Asherman's syndrome)
  Anatomic abnormalities
Cervical
  Poor mucus quality
  Infection
  Anatomic abnormalities

Table 120.2. Important Causes of Female Infertility

WORKUP

Initial Evaluation

The prognosis even for untreated couples is favorable (see below). An extensive "infertility workup" need not be undertaken on first visit, unless the couple is older

(mid to late 30s and upward), has been unable to conceive despite trying seriously for over a year, or has a similar good reason to hasten the pace of evaluation. Otherwise, a reasonable approach to the first visit is to limit the assessment to a careful general history and physical examination, checking for such important causes as endocrinopathy, tumor, genitourinary tract infection, anatomic disorder, and interpersonal problems.

In the Male. *History* should include inquiry into drug and medication use (marijuana, alcohol, antihypertensive agents), urethral discharge, headache and other symptoms of a pituitary tumor (see Chapter 100), past history of radiation therapy or cancer chemo-therapy, mumps, toxin exposure, and systemic illnesses (especially diabetes with associated retrograde ejaculation). A sexual history that reviews the marital relationship, sexual techniques, erectile function, and frequency of intercourse is also important.

Physical examination begins with noting general appearance and any signs of diminished androgenization (decreased body hair, gynecomastia, eunuchoid proportions). The scrotum is examined for testicular size, presence of a varicocele, hypospadias, and absent vas deferens. Soft small testes (less than 4 cm in longest diameter) are consistent with primary testicular failure and pituitary-hypothalamic insufficiency. A Valsalva maneuver performed while the patient is standing will help reveal a small varicocele. The urethra is observed for discharge, and the prostate and seminal vesicles are observed for tenderness and other signs of infection. If a pituitary condition is suspected, visual field testing by confrontation might reveal an important field defect; a normal study does not rule out a mass lesion. Testing deep tendon reflexes may uncover delay in relaxation suggestive of hypothyroidism (see Chapter 104).

In the Female. *History* focuses on the menstrual and reproductive history, including any abortions, complicated deliveries,curettages, menstrual irregularities, or episodes of amenorrhea. A life-long history of menstrual irregularities is suggestive of polycystic ovary syndrome, especially if accompanied by hirsutism and obesity. Any situational or emotional stress, marked weight loss, or excess exercise should be noted, because it can lead to hypothalamic dysfunction and impairment of ovulation (see Chapter 111 and Chapter 112). Similarly, checking for symptoms of hypothyroidism (see Chapter 104), hyperprolactinemia (see Chapter 100), Cushing's syndrome (see Chapter 100), and androgen excess (see Chapter 98) may yield clues of conditions that can impair hypothalamic function. Inquiry into headaches, visual field disturbances, galactorrhea, symptoms of pituitary insufficiency (see Chapter 100), and a history of postpartum hemorrhage helps to screen for a sella tursicaesion. Checking for a history or symptoms of pelvic inflammatory disease (vaginal discharge, pelvic pain, fever, dyspareunia) is also essential. Any malignant disease history is important to note, especially if treatment included irradiation or alkylating agents. One should also obtain a detailed psychosocial history that reviews pertinent details of the marital relationship and sexual activity. Loss of libido may signify psychosocial or hormonal dysfunction.

Physical examination focuses on checking for obesity, excessive weight loss, hirsutism, cushingoid appearance, stigmata of hypothyroidism (see Chapter 104), visual field disturbances, and goiter. Most important is a careful pelvic examination, taking special note of any ovarian, uterine, or adnexal masses, thickening, or tenderness. Examination of the cervix should include checking for erosions, discharge, polyps, masses, scarring, and pain on cervical motion. The hirsute patient is examined for clitoromegaly.

Both Partners. An empathic, supportive, nonjudgmental exploration of the marital relationship is essential; it is often best done by interviewing the couple together (to observe their interactions) and each partner separately.

Further Evaluation

Couples with no evidence of serious pathology on initial evaluation can be reassured and informed that more than half of such couples go on to conceive without the aid of treatment. Those who have been trying to conceive for less than 1 year can be advised to delay further evaluation until 12 months have passed, provided they are willing to do so and have no compelling reason for proceeding directly to more extensive testing. Couples who have failed to conceive after continuously trying for 12 months or who insist on further workup at the time of initial visit can undergo a set of basic laboratory studies to more fully define the problem and guide further evaluation and treatment.

In the Male. The first test to perform is a *semen analysis*, collecting two to three specimens over a 4- to 6-week period. Quantitative analysis includes number of sperm per milliliter of semen (counts more than 20 million/mL are normal) and semen volume (less than 1.5 mL may be inadequate to buffer vaginal acidity). Patients with normal counts should have qualitative studies of the sperm performed (motility, morphology, cervical mucus interaction), although these studies are often more useful for identifying the infertile individual than for defining a specific course of therapy (see below). In normal persons, the counts for motile forms and spermatozoa with oval heads are in excess of 50%.

Patients with azoospermia or oligospermia are candidates for serum gonadotropin (*LH and FSH*) and *testosterone* determinations, because of the possibility of an underlying disorder within the hypothalamic-pituitary-testicular axis. Proper sampling technique is important to avoid misleading results. One draws three serum samples 20 minutes apart and pools them. High concentrations of gonadotropins and low or low-normal testosterone suggest a primary gonadal problem. Both gonadotropins and testosterone being low characterize a pituitary-hypothalamic etiology. Normal FSH, testosterone, and testicular size in a patient with azoospermia suggests obstruction. Normal hormone and gonadotropin concentrations in the setting of oligospermia are characteristic of patients with varicocele or idiopathic disease. Small testes, gynecomastia, an elevated FSH, and a reduced testosterone suggest Klinefelter's syndrome. The diagnosis is confirmed by a *buccal smear* that shows the extra chromatin of a Barr body.

The patient with suspected pituitary disease needs a *prolactin level* and *computed tomography* (CT) of the sella turcica to search for a tumor. An elevated prolactin in the setting of a normal CT may be due to a drug-induced problem, but CT should be repeated in 6 months to be sure that an early tumor has not been missed.

The utility of more elaborate studies (e.g., antisperm antibodies, sperm-cervical mucus interaction, penetration testing) is best determined by the infertility specialist.

In the Female. The first task is to establish that ovulation is taking place. The time-tested approach is to use a *temperature chart*. Ovulation is accompanied by a rise in progesterone secretion, which leads to a 0.3° rise in basal body temperature after ovulation. Temperature is measured orally each morning before rising from bed. One uses a special thermometer graduated in tenths of degrees Fahrenheit. Absence of a rise indicates failure to ovulate. Alternatively, one can measure the *serum progesterone* on days 21 to 23 of the cycle. A level greater than 10 ng/mL indicates ovulation and a functioning corpus luteum. Endometrial biopsy may also be useful but is more expensive, more painful, and may remove the long-awaited pregnancy. If the patient is deemed anovulatory, further testing proceeds with measurement of *serum prolactin, FSH, and LH* (see Chapter 111 and Chapter 112).

A *postcoital examination* is used to assess cervical mucus function and the competency of the partner. An appointment is scheduled just before the time of ovulation, and the woman is asked to come within 2 to 12 hours of coitus. A specimen of cervical mucus is obtained from the endocervical canal. Five or more motile sperm found in the specimen confirms her partner's competence. Mucus is also examined for viscosity (stretching to 6 cm is normal) and "ferning," manifestations of estrogen effect.

If after the initial history, physical examination, postcoital test, and serum progesterone, it appears that tubal or uterine disease may be responsible for infertility, then *hysterosalpingography* and *laparoscopy* deserve consideration. Choice of test should be made by the gynecologist experienced in evaluationof infertility. Hysterosalpingoscopy involves injection of a contrast agent into the uterus by way of a cervical catheter. Pretreatment doxycycline antibiotic coverage is provided. Films reveal uterine and tubal anatomy. Laparoscopy requires general anesthesia but can detect adhesions, endometriosis, an unpalpable fibroid, and polycystic ovaries. Tubal patency and position may also be confirmed, often more accurately than by radiologic investigation. Not to be forgotten is the importance of negative findings.

PRINCIPLES OF MANAGEMENT AND INDICATIONS FOR REFERRAL

Studies from infertility clinics have shown that many couples go on to conceive without treatment (e.g., 44% of those with ovulation deficiency; 61% of those with endometriosis, tubal defects, or seminal deficiencies; and 96% of those with cervical factors or idiopathic infertility). A conservative approach of watchful waiting is reasonable in such cases, provided there is no evidence of tumor, infection, anatomic defect, or serious endocrinopathy. Counseling can be a very important adjunct (see below).

When the workup suggests causative organic pathology, an appropriate referral for confirmatory testing and design of a treatment program is indicated. The participation of the primary physician in the care of the couple should continue, but the subtleties of specialized care that some types of infertility treatment require argue for referral rather than for treatment by the primary physician. Successful referral depends to a large extent on proper patient selection.

Men. A neurologic or anatomic cause of *impotence*, a suspected acquired *obstructive defect*, and *varicocele* are indications for urologic consultation. Surgical ligation of a varicocele is commonly performed, but results are often disappointing even though sperm counts may rise. Treatment of obstruction requires a urologist skilled in microsurgical techniques, as does vasectomy reversal.

Hypothalamic-pituitary disorders have a high rate of success with treatment by the reproductive endocrinologist. Those with idiopathic hypogonadotropic disease often respond successfully to gonadotropin or GnRH administration. When prolactin levels are elevated and CT reveals a microadenoma, bromocriptine can often restore fertility. Larger pituitary adenomas may require neurosurgical intervention.

Idiopathic oligospermia (no evidence of a varicocele; normal LH, FSH, and testosterone) has no proven therapy. Clomiphene and other antiestrogens, GnRH factor, gonadotropins, and low doses of androgen have been tried but without confirmed long-term benefit. There is no evidence that vitamins (A, E, C), zinc, thyroid hormone, or a host of home remedies are at all useful in men with normospermia or oligospermia. Such patients should be referred to the reproductive endocrinologist for consultation.

Men who have quantitatively and qualitatively *normal sperm* and *normal LH, FSH,* and *testosterone* pose a challenge. When *antisperm antibodies* are found in high titers in the semen, their levels can be lowered with a course of high-dose corticosteroids. However, the efficacy of this therapy is controversial. Careful patient selection by referral to the reproductive specialist is essential. In vitro fertilization is an alternative.

Artificial insemination and other assisted reproductive technologies are available for patients with otherwise *refractory qualitative sperm defects*. Patients with retrograde ejaculation might also effect pregnancy with artificial insemination, using semen recovered in the urine.

Subclinical infection, especially with *Mycoplasma*, has been suggested as a cause of infertility. Culturing both partners and treating the couple if one partner is culture positive has produced inconsistent results. There are no known treatments for patients with gonadal failure or androgen insensitivity.

Women. Women with *hypothalamic dysfunction* have a good prognosis. Those with mild dysfunction are likely to resume ovulating without therapy and need only counseling at the time of initial evaluation. Those with moderate dysfunction often respond well to treatment, especially when FSH, thyroid function, and prolactin remain normal. Such persons have a 50% chance of conceiving with use of clomiphene, which is given for 3 to 5 days followed by a month of waiting for either pregnancy or an ovulatory period. Patients suffering from more severe hypothalamic dysfunction may fail clomiphene, but respond to synthetic GnRH therapy. GnRH is administered by parenteral pulse infusions, mimicking normal GnRH secretion. Careful dose adjustments are necessary to avoid multiple pregnancies. Only an experienced reproductive endocrinologist should prescribe such therapy. Those with a prolactin-secreting microadenoma require endocrinologic consultation. Bromocriptine may help restore fertility (see Chapter 100).

Gynecologic referral is indicated for patients with suspected *tubal scarring*. Microsurgical tubal reconstruction is required for successful repair, which leads to pregnancy in 10% to 60% of cases. In making the referral for tubal repair, it is important to select a gynecologist skilled in microsurgical techniques. Success rates vary considerably.

Women with *abnormal postcoital testing* may be candidates for intrauterine insemination if they are ovulating and the semen analysis is normal. Couples who have *failed other methods* may still be candidates for in vitro fertilization or gamete intrafallopian tube transfer. These are elaborate technologies that require the consultative and technical services of a specialized reproductive center. One must have adequate sperm, ovarian follicles, and a competent uterus to qualify for in vitro fertilization. These plus fallopian tube patency and accessibility are the minimum determinants for gamete intrafallopian tube transfer.

Couples. Infertility resulting from a *psychosocial problem* (e.g., lack of privacy, work exhaustion, marital discord) needs to be approached with careful and understanding explanation. Some individuals may attempt to view the situation as a medical problem when there is unlikely to be a strictly medical solution. Attention needs to be directed to the home environment, work situation, and marital relationship. When *sexual dysfunction* is detected, treatment is best directed toward it (see Chapter 229). However, artificial insemination is sometimes used when there is a strong desire to have a child as soon as possible.

The infertility evaluation may lead to reconsideration and redesign of treatment regimens for *underlying medical conditions* such as cancer and hypertension (see Chapter 26, Chapter 88, and Chapter 89).

PATIENT EDUCATION

Couples are eager for information about their chances of conceiving. At one end of the spectrum are men and women with permanent gonadal failure who have no chance of conceiving. At the other end are those with a transient functional deficit who are likely to conceive without any treatment other than reassurance and time. The couple that remains unsuccessful after a year of trying can be given some reassurance as they begin to undergo evaluation. Up to one fourth of such couples achieves pregnancy within 3 months. Published findings from infertility clinics show that, overall, 25% to 35% of couples achieve conception within 1 to 2 years of registration. The percentages continue to rise over the next 4 to 5 years.

There is a slight decrease in fecundity after 30 and a marked decrease after age 35. There appears to be little or no difference in prognosis between infertile couples who have conceived in the past and those who have never conceived. The prognosis for women who experience recurrent spontaneous abortions is better than the approximately 20% live-birth rate previously estimated. Patients with ovulatory problems do reasonably well; those with tubal problems have more difficulty. As noted earlier, rates for live births after tubal repair range from 10% to 60%, depending on the severity and site of the scarring, quality of semen, age of the women, and a host of other factors. Couples whose infertility involves multiple factors do less well than those in whom only one factor is identified.

Whenever an evaluation is normal, it is important to reassure patients about their normality, particularly if one harbors guilt or fear about an episode of infidelity, a previous abortion, an out-of-wedlock pregnancy, or some other potentially adverse event.

The investigation of infertility provides an opportunity to educate patients about normal human reproduction and prevention of sexually transmitted disease. Education for both partners about the menstrual cycles, the best time to attempt conception, and the frequency of coitus needed to achieve pregnancy can be very helpful, sometimes even curative. The importance of using a condom to prevent spread of sexually transmitted diseases that might lead to tubal scarring cannot be overemphasized to teenagers and other patients with multiple partners. Screening such persons for chlamydial infection and treating when present may help prevent tubal infertility (see Chapter 117). A review of sexual attitudes and concerns may also be of benefit. At times, the infertility evaluation encourages couples to take better care of themselves.

CHAPTER 121 APPROACH TO THE WOMAN WITH AN UNPLANNED PREGNANCY

More than half of the pregnancies that occur in the United States are unintended. An equal proportion of unintended pregnancies end in abortion and in birth. The woman who suspects an unplanned or unwanted pregnancy often calls on her primary care provider to confirm a diagnosis and formulate a care plan. To provide support and assistance, the physician first must accurately diagnose the pregnancy. He or she can then inform the patient about community services available for prenatal care, abortion, and adoption. If the physician feels his or her beliefs interfere with objective counseling, then referral to another provider is necessary. Awareness of the patient's social and cultural environment is essential to lending appropriate support.

CLINICAL PRESENTATIONS

Women presenting with unplanned pregnancies have highly variable experiences. Responses to the diagnosis, coping mechanisms, and capacity to take responsibility for decision making may differ greatly from woman to woman.

A pregnancy may be untimely or unwanted because of the severe hardship a child would create. A limited single or dual income may be insufficient to support either a first or additional child. A pregnancy may hinder opportunities for education and career advancement. These factors may conflict with the woman's desire for motherhood, creating great ambivalence. For many women, fear that an abortion will hinder future reproductive function adds to the concern. Some women who desire children may have a partner opposed to parenting or may need family or social support to raise a child alone. They may feel pressured to terminate the pregnancy yet be unwilling to do so.

The woman who desires pregnancy but suffers from a chronic or life-threatening illness such as diabetes, systemic lupus erythematosus, or cancer endures unique stress when she faces an unplanned pregnancy. The pregnancy may jeopardize her health and her ability to care for her family, and she may face conflicting opinions regarding termination. Additionally, the impact of pregnancy on certain disease processes is not well understood.

Many women of childbearing age are infected with HIV. The rate of transmission of the HIV to the fetus is estimated to be 25% to 50%. This raises concerns for the primary care physician who must consider the welfare of both the mother and the unborn child. It is unclear whether pregnancy adversely affects the HIV disease process in the mother. Additionally, the difficult dilemma of whether to carry a potentially infected fetus to term poses many ethical questions.

Substance abuse among pregnant women continues to rise. The most significant increase is seen with cocaine, but use of heroin, methadone, and amphetamines has also grown. Cocaine use has been associated with lower birth weight and preterm labor. Heroin use during pregnancy can lead to a withdrawal syndrome in the infant. In addition to toxic drug effects, poor pregnancy outcomes may result from transmission of disease from "dirty needles," hazardous behavior to support a drug habit, malnutrition, and poor prenatal care. Often there is evidence of polysubstance abuse with additive effects. Additionally, alcohol remains a significant problem during pregnancy. The fetal alcohol syndrome, manifested by intrauterine growth retardation, microcephaly, and developmental abnormalities, occurs in approximately 1 in 2,000 live births. Some substance abusers may respond to pregnancy with denial or indifference.

A woman with a severe poorly controlled psychiatric illness presents many concerns. Some evidence suggests that pregnant patients with psychiatric disorders may have worsening of their mental health during pregnancy. In addition, some studies indicate that patients with severe disorders may have increased birth complications resulting from poor prenatal care, concurrent substance abuse, increased incidence of homelessness, use of psychiatric medications during pregnancy, and unrecognized physical illness. The primary care physician may be asked to provide counseling and to act as a liaison between obstetric and psychiatric providers.

Some patients undergoing amniocentesis or chorionic villus sampling to identify genetic abnormalities do so on the assumption that they will consider an induced abortion. A patient may look to her primary care provider for guidance with this difficult decision-making process.

Almost 1 million adolescents in the United States become pregnant yearly. Consequences for the future of these teenagers may be immense. Pregnancy may lead to dropping out of school, limited job opportunities, and dependence on the welfare system. Adolescents may intentionally or unintentionally become pregnant for various reasons. They may exhibit risk-taking behavior in response to peer pressure, to experiment, or to test parental limits. Failure to properly use contraception may result from lack of adequate information or stem from the belief that "it will never happen to me." Some adolescents who feel deprived of love and security from parents or partners may see a child as a companion who will provide them with unconditional love. Often, teenagers present at a later gestational age because of denial or unawareness of how to get help. This delay may result in significant negative consequences with increased morbidity and mortality from the pregnancy or termination.

A number of presentations are particularly important because of their psychosocial circumstances. In both rural and urban areas, sexual abuse (including rape) persists to a greater extent than most professional people assume. It may occur between father and daughter, but frequently it involves another adult male in the household, such as uncle, older brother, or boyfriend. The victim may be repulsed at the thought of a baby inside her from such a traumatic experience and may not present for care until later in the pregnancy. In some states, the physician is mandated to report sexual abuse involving minors.

PRINCIPLES OF MANAGEMENT AND PATIENT EDUCATION

Diagnosis. Immunologic tests, including home pregnancy kits or office slide kits that measure human chorionic gonadotropin (hCG), are commonly used for first diagnosis of pregnancy. These use urine or serum, are accurate 4 to 14 days from a missed period, and can give false-positive results because of luteinizing hormone cross-reactivity. More sensitive and specific tests include the ELISA, using serum or urine, and serum radioimmunoassay tests. These detect lower hCG levels and appear positive earlier (12 days and 7 days postconception, respectively). They are specific for the b-hCG subunit and are not affected by luteinizing hormone cross-reactivity. The availability of monoclonal antibodies to the subunit has improved test accuracy. The half-life of hCG after delivery is 1.5 days, so failure to normalize after pregnancy termination indicates remaining tissue, as with incomplete abortion or gestational trophoblastic disease.

Counseling. Once a diagnosis of pregnancy is confirmed, a nonjudgmental supportive examination of the patient's feelings is needed. A thorough psychosocial history should be gathered so her options can be fully explored. Special attention to issues of rape and incest are necessary if this history is elicited or appears to be a possibility. Formal counseling is indicated in this instance. Community support groups may also be helpful.

Surgical Therapeutic Abortion. Abortion is one of the most common gynecologic procedures performed in the United States. Data regarding the use of abortion have remained fairly stable in recent decades. In 1990, the national abortion ratio (number of legal abortions per 1,000 live births) was 344 and the abortion rate (number of legal abortions per 1,000 women aged 15 to 44 years) was 24. In that year, about 55% of women undergoing pregnancy termination were younger than age 25, 79% were unmarried, and approximately 64% were white. Approximately 88% of abortions occur within the first 12 weeks of gestation, with half occurring within 8 weeks of gestation.

When performed appropriately, surgical pregnancy termination is safe, with less than one death per 100,000 procedures. In developed countries, legal first-trimester terminations result in lower death rates than those from pregnancy across all age groups. Termination is safest when performed earlier in gestation. Risk increases with gestational age, maternal age, and higher parity. With legalization of abortion in the United States, morbidity has decreased. There is increased physician training and expertise; increased use of the safer suction curettage procedure rather than sharp curettage, uterine instillation, and surgical procedures; and improved access, allowing earlier procedures. Service availability and practices regarding waiting periods, parental consent, and abortion funding all have an impact on a woman's obtaining services. Additional barriers to services include cost (earlier and nonhospital procedures are cheaper than second-trimester hospital procedures), harassment of patients at abortion facilities, and vandalism of facilities.

Preprocedure assessment includes determining any underlying medical problems that would necessitate an inpatient rather than outpatient procedure. Usual laboratory evaluation includes pregnancy testing, urinalysis, complete blood count, blood type and Rh factor determination, syphilis serologies, gonorrhea and

chlamydia testing, and Papanicolaou smear. Additional studies such as HIV testing and sonography can be considered. Contraception may also be addressed at this time, because oral contraceptives can be initiated the day after termination and intrauterine device placement can occur with the procedure. This addresses the concern about frequent no-show rates for follow-up appointments. Rh immune globulin should be given after the procedure to Rh-negative unsensitized individuals. Postabortion instructions include no intercourse, douching, or tampons for 1 to 2 weeks.

Local anesthesia is used for first-trimester procedures. Paracervical block using lidocaine, with or without epinephrine, and preoperative analgesics or sedatives are generally safe and inexpensive. General anesthesia is most often used for procedures done later in pregnancy.

First-trimester abortions are performed at 12 weeks gestation or sooner, and most in the United States are performed by suction curettage. Menstrual regulation, the least invasive procedure, is performed up to 2 weeks after a first missed period in an outpatient facility, without anesthesia. A flexible plastic catheter is inserted with no more difficulty than performing endometrial biopsy or intrauterine device placement, and suction is applied. Because the procedure is done so early in pregnancy, failure to aspirate all the tissue may occur, manifested by a persistent positive pregnancy test and absent postoperative bleeding. This may require a repeat procedure. Later first-trimester terminations involve suction curettage, commonly requiring cervical dilation. Intravaginal or oral administration of misoprostol has been shown to be effective in facilitating cervical dilation, especially in nulliparous women. Suction using a cannula removes the pregnancy. The complication rate is 2 per 1,000 procedures. A small percentage (3%) of pregnancy terminations use sharp curettage (the traditional dilation and curettage). These are most often later first-trimester procedures (10 to 12 weeks) or earlier second-trimester procedures.

Second-trimester terminations are mostly dilation and evacuation procedures involving placement of an osmotic dilator 6 to 12 hours before the procedure, which is either suction or sharp curettage. The complication rate for dilation and curettage is 7 per 1,000 procedures. From 16 weeks' gestation, induction terminations may be performed using intrauterine instillation of agents inducing labor. A small amount of amniotic fluid is removed and urea, prostaglandins, or rarely saline is introduced, resulting in labor and delivery over the next 12 to 24 hours. Intramuscular and vaginally-placed prostaglandin preparations are also used to induce labor. This is a hospital-based procedure, with a higher complication rate (up to 20% at some institutions) than earlier procedures and may take several days to complete. Complications from hypertonic saline inductions include disseminated intravascular coagulation, hypernatremia, and hemorrhage from retained tissue. Prostaglandins have side effects of nausea, vomiting, diarrhea, and fever.

Hysterotomy and *hysterectomy* are rarely performed second-trimester procedures (accounting for less than 0.05% of reported procedures). These have higher morbidity and mortality. Tubal sterilization can be done at the same time as hysterotomy. Hysterectomy is generally performed for an existing condition requiring hysterectomy with a coexisting pregnancy.

Nonsurgical Therapeutic Abortion. Extensive experience from other countries with mifepristone indicates that it provides a safe and effective alternative to surgical therapeutic abortionfor women who are no more than 7 weeks pregnant. Mifepristone, formerly known as RU-486, is a synthetic steroid that binds progesterone receptors, blocking normal activity and preventing implantation or inducing menstruation after implantation. Mifepristone is generally followed by progesterone administration. Effectiveness of this approach exceeds 95%. An alternative approach to medical abortion is the use of methotrexate, generally followed by misoprostol administered vaginally.

Abortion-related *complications* are affected by time of gestation, method of procedure, and coexisting complicating illnesses. Major complications of surgical abortion, including uterine perforation, hemorrhage, and infection, occur at a rate of 1 case per 1,000 procedures. The termination needs to be repeated 2.3 times per 1,000 abortions. Presentations suggestive of these complications include bleeding, fever, abdominal pain or cramping, and uterine tenderness. Minor complications, including infection, cervical stenosis, cervical tear, and bleeding or incomplete abortion requiring resuctioning, occur in 8 per 1,000 procedures. Complication rates increase with gestational age and are estimated as follows: at 8 weeks gestation, 2 per 1,000; at 14 weeks, 6 per 1,000; at more than 20 weeks, 15 per 1,000. Complications of medical abortions include bleeding and pain and gastrointestinal side effects.

A number of studies have examined women's preferences for either medical or surgical abortion. In one trial conducted in Scotland among women in the first 9 weeks of gestation, 20% of women preferred medical abortion, 26% preferred surgical evacuation, and 56% were sufficiently indifferent to permit randomization. Women in the eighth and ninth week were more likely to prefer the surgical approach. Short-term and long-term outcomes, including satisfaction, were comparable, highlighting the importance of the individual woman's preferences.

There are no conclusive data showing that serious emotional problems result after pregnancy termination in the United States. Existing data indicate that women generally experience relief and reduced anxiety and distress after pregnancy termination. Negative emotional reactions are more common among women with prior psychiatric illnesses, second-trimester terminations, terminations for medical or genetic reasons, or with significant ambivalence about the decision.

Women who have undergone a single first-trimester vacuum aspiration procedure are at no significant increased risk for infertility, miscarriage, ectopic pregnancy, stillbirth, or major pregnancy or delivery-associated complication. The effect of multiple abortions on future childbearing is uncertain; some evidence suggests a subsequent two- to threefold increased risk of pregnancy loss after two or more abortions. Second-trimester dilation and evacuation procedures are believed to be associated with development of an incompetent cervix, which can lead to spontaneous abortion, premature delivery, and low birth weight.

Illegal abortions occur rarely today. Reasons for this choice have included financial limitations, secrecy, geographic location, and knowledge deficits regarding legal termination or choosing an ethnically familiar provider. Complication rates are unknown but are thought to be higher than those of legal procedures. In 1989, 2 of 20 reported abortion-related deaths followed illegal procedures. Patients may present to hospital emergency rooms with hemorrhage and sepsis.

Adoption. Placing a child for adoption is an alternative for a woman who believes it is impossible to raise a child and who would prefer not to undergo an abortion. Women choosing this option often do so with the belief that their child will have a better upbringing than they can provide. Additionally, placement may allow a woman to defer or delay parenthood, complete her education, establish economic security, or pursue goals. Adoptions, however, have declined significantly over the past decades. Fewer than 3% of never-married women in recent years relinquished their infants. Societal acceptance of single motherhood, legalization of abortion, and establishment of programs offering financial assistance all contribute to this trend. If a woman decides to place her child for adoption, she may enlist a state-run or private agency. She should be encouraged to investigate an agency carefully to ensure that she is not pressured and that she agrees with its policies. Open adoption, where there is some future contact with the child, is becoming more common.

Keeping the Child. Keeping the child may emerge as a realistic option if a problematic social situation is amenable to change. Identification of social supports include extended family. Community agencies may facilitate this process. Adolescents need special counseling because teenage pregnancy is a serious problem resulting in poverty and child neglect.

Birth Control. Whether a patient chooses to proceed with or terminate a pregnancy, a discussion of future contraceptive options is essential (see Chapter 119).

Providing care to the woman faced with an unplanned and/or unwanted pregnancy is a challenge to the primary care provider. The provider must explore the patient's beliefs, fears, support network, and psychosocial history. Options must be explained thoroughly and without judgment. Only then can one formulate an appropriate care plan that incorporates the woman's personal circumstances and preferences.

CHAPTER 122 MANAGEMENT OF BREAST CANCER

ALBERT G. MULLEY, JR.

INTRODUCTION

Breast cancer is one of the most common malignancies in the United States. About 12% of American women will develop breast cancer during their lifetime, more than 170,000 cases per year. Unfortunately, despite the expanded therapeutic armamentarium for breast cancer, approximately 30% of women who develop the disease die from it.

Women with newly diagnosed breast cancer face a difficult and complex series of treatment decisions at a time when they may be least able to think rationally or bear the burden of decision-making responsibility. The breast cancer diagnosis evokes anger, a sense of isolation, irrational guilt, and, most of all, vulnerability. Clearly, this mix of emotions makes it difficult for the communication tasks necessary for the patient to be involved in decision making. Yet the most important determinants of the "right" decision for each patient are her attitudes toward the possible treatment outcomes and risks. New information about the relative effectiveness of alternative approaches to primary therapy and adjuvant therapy has added to the complexity of these decisions. The primary care physician can be a critically important source of empathy, support, and information about treatment options. After primary treatment, with or without subsequent adjuvant therapy, the primary care provider may be principally responsible for monitoring the patient's psychosocial adjustment to breast cancer and its treatment and for evidence of disease recurrence. Finally, the primary care role is critically important in decision making about treatment for the woman with advanced breast cancer.

CLINICAL PRESENTATION AND COURSE

The term "early-stage breast cancer" is generally applied to stage I and stage II tumors. *Stage I* disease is defined as a primary tumor of less than 2 cm in diameter with no axillary lymph node involvement (Table 122-1). Approximately 55% of patients with primary breast cancer now present with stage I disease, in part because of improved screening methods. *Stage II* disease is still considered a localized disease, but it does include involvement of axillary lymph nodes. About 25% of patients with *clinical* stage I disease turn out to have pathologic stage II disease on sampling of the axillary nodes. Interestingly, a similar percentage of patients with clinical stage II disease (palpable axillary lymph nodes) turn out to have no tumor in the nodes on pathologic examination. In *stage III* disease, there is extensive tumor (more than 5 cm) at the primary site, and lymph nodes are larger than 2 cm with or without fixation. In *stage IV* disease, there are distant metastases.

Stage	Tumor extent	10-Year disease-free survival (%)
I	Confined to breast	70–80
II	Involves the axillary nodes	20–40
III	Tumor >5 cm; nodes >2 cm; with or without fixation	<5
	Inflammatory	0

Table 122-1. Curability of Breast Cancer by Stage

Because of greater use of mammographic screening, cases are increasingly identified with small lesions, including those without evidence of invasion. Noninvasive cancer, or carcinoma in situ (CIS), is characterized as ductal or lobular based on histology and location, cytologic features, and growth patterns. These two lesions behave very differently. With ductal CIS (DCIS), mastectomy results in cure for 98% to 99% of women. Similar rates can be achieved with lumpectomy without subsequent radiation if the surgical margins are adequate. One reason for the very good prognosis after therapy is the indolent course for many cases of DCIS. Much remains uncertain about the natural history, but there is evidence that many women with DCIS lesions would not progress to invasive disease if left untreated. DCIS now accounts for 12% of all newly diagnosed breast cancers in the United States and 30% of cancers detected by mammography. With more than 10,000 mastectomies performed each year for DCIS, it is obvious that more information and education about the clinical significance of DCIS are needed. Lobular CIS has very different treatment implications. It is not clear whether it is indeed a premalignant lesion or simply a marker for increased risk of invasive disease elsewhere in the breast(s). The incidence of invasive cancer in women with lobular CIS is about 1% per year.

Prognosis. For women with early-stage breast cancer, the prognosis is largely determined by the size of the tumor and the number of positive nodes. For women with negative nodes, 5-year cumulative recurrence rates for women with tumors smaller than 1 cm, 1 to 2 cm, and 2 to 5 cm in diameter are 10%, 20%, and 30%, respectively. Among women with one to three positive nodes, 40% have a recurrence within 5 years. For women with 4 to 10 nodes positive, the 5-year recurrence rate is 60% to 70%. For women with more than 10 nodes positive, or with stage III disease, long-term survival is less than 5%. Inflammatory breast cancer has a worse prognosis than noninflammatory lesions.

In addition to the stage of tumor and tumor size, *estrogen receptor* and *progesterone receptor* status affect the prognosis. Patients with stage I or stage II disease whose tumors have estrogen or progesterone receptors, or both, have a better prognosis than those with the same stage of disease whose tumors are receptor negative.

Breast cancer may metastasize to almost any site in the body, but five general categories have been distinguished by Smalley et al., which are correlated with predictable response to therapy and prognosis (Table 122-2). It is evident that even in patients with metastatic disease, median survival may exceed 3 years, and there does not have to be significant change in quality of life when palliative radiation and chemotherapy or hormonal therapy are used throughout that period (see below). Today, more than 50% of patients with metastatic breast cancer may respond to therapy, but only a small portion (perhaps fewer than 10%) show complete regression. The median duration of response is approximately 12 to 18 months.

Pattern	Incidence (%)	Median time (mos)	
		Relapse	Survival
Multiple metastases	19	9	4
Pulmonary	12	36	18
Bone	26	15	29+
Effusions[a]	16	39	44
Skin and subcutaneous[b]	26	15	27+

[a] + Minor skin nodules.
[b] + Minor bone metastases.

Table 122-2. Patterns of Recurrence and Survival in Breast Cancer

The clinical course of breast cancer is unique in that metastatic lesions may develop after a long period of freedom from disease, even after as long as 20 years. Thus, 5 years without evidence of metastatic spread does not indicate cure.

PRINCIPLES OF MANAGEMENT

The therapeutic options for women diagnosed by an incisional or excisional biopsy have expanded in recent years, accompanied by greater patient participation in choice of therapy. It is no longer justified to perform a biopsy and immediate total mastectomy under the same anesthesia. Patients should be fully informed of the diagnosis, promptly staged, and advised of the therapeutic options.

Updated: 08/13/03

Staging. As in most cancers, accurate staging is essential to planning safe and effective treatment. Confirmation of early-stage disease is especially important. Traditionally, patients with no clinical evidence of metastasis underwent full *axillary lymph node dissection* to rule out regional metastasis. Although accurate and capable of reducing mortality by 5% by properly identifying extent of disease and helping to select appropriate therapy, it is a morbid procedure that often results in axillary pain, disfigurement, tightness and limitation of movement, and troublesome chronic lymphedema of the affected limb. Sentinel node biopsy is a more limited procedure, usually involving injection of radionuclide tracer plus scintigraphic scanning to identify the draining lymph node that is then resected and examined pathologically. In some instances blue dye is used to help identify the sentinel node. Should the sentinel node be found positive for malignancy, the remainder of the axillary nodes are then resected for examination. The accuracy of the procedure is over 95%, with a false-negative rate of approximately 5% to 8%. Large-scale studies are underway to determine if there is any loss of long-term survival benefit by substituting sentinel node biopsy for traditional axillary node dissection. Available data from relatively small-scale studies find no loss of survival benefit, but more data are needed for definitive determination. Radionuclide bone scan is another important staging modality for breast cancer, especially in persons with positive lymph nodes. CT scanning may be used for suspected distant metastasis in such areas as liver, brain, and lung.

Updated: 08/13/03

Primary Treatment of Early-Stage Breast Cancer. Most women with early-stage breast cancer have a choice of surgical treatments. Multiple randomized trials have demonstrated that survival is the same with either *mastectomy* or *breast-conserving surgery* ("lumpectomy" or "quadrantectomy") *followed by radiation*. There are some relative contraindications to breast-conserving surgery, including tumors that are large relative to breast size, cancer that is near or involves the nipple, and tumors with extensive intraductal components within or adjacent to the primary tumor. Also, women with large breasts may fare worse cosmetically with radiation therapy. Chemotherapy has been used before surgery to reduce tumor size and make breast conserving an option for more women with large tumors relative to their breast size. Termed *neoadjuvant chemotherapy*, this approach has been used increasingly in recent years. Radiation therapy after the breast-conserving option is essential. Without it, there is a 40% rate of ipsilateral breast recurrence after breast-conserving surgery. Even with radiation therapy, ipsilateral recurrences do occur, at a rate of 1% to 2% per year. These can usually be treated with mastectomy and, as noted, do not result in decreased survival for women who opt for the breast-conserving approach.

Mastectomy is preferred by some women who do not want to live with the anxiety associated with the possibility of having to deal with an ipsilateral recurrence in the breast that they chose to keep. Others prefer mastectomy simply because it does not usually involve subsequent radiation and it thereby lets them put primary therapy behind them more quickly. However, some recent studies suggest that women who are at high risk of recurrence because of a tumor larger than 4 cm or the presence of more than four positive nodes benefit from radiation therapy after mastectomy. After mastectomy, some women opt for breast reconstruction, whereas other feel no need for surgery for cosmetic purposes.

Adjuvant Therapy of Breast Cancer. Adjuvant therapy is administered to decrease the likelihood of, or delay, cancer recurrence and death. The most commonly used regimens are cyclophosphamide, methotrexate, and fluorouracil and other regimens that include adriamycin. Recent studies indicate that newer agents provide additional benefit. The antiestrogen tamoxifen has become the standard hormonal therapy.

The effectiveness of adjuvant therapy in decreasing rates of recurrence and breast cancer death among node-positive women has been proven for some time. More recent evidence indicates that adjuvant therapy is as effective in node-negative women. That is, the relative risk reduction afforded by either chemotherapy or hormonal therapy is the same in node-positive and node-negative women. However, the absolute risk difference is much smaller for node-negative women because their baseline risk is lower. For example, women with two positive nodes and women with negative nodes and tumors less than 1 cm might receive the same 30% risk-reduction benefit from adjuvant chemotherapy or hormonal therapy. For the former, that means a reduction from 40% to 28% or an increase in disease-free survival from 60% to 72%. For the node-negative woman, the same proportional benefit means a reduction from 10% to 7% or an increase in disease-free survival from 90% to 93%. The significant morbidity associated with adjuvant therapy may or may not be justified, depending on the absolute benefit and the woman's attitudes toward the alliterative outcomes.

Adjuvant chemotherapy has been the standard of care for premenopausal women with positive nodes, regardless of hormone receptor status, and tamoxifen has been the standard for postmenopausal women with positive nodes, particularly those with positive hormone receptor levels. Ongoing analysis by the Early Breast Cancer Trialists' Collaborating Group of individual patient experiences for tens of thousands of women who have participated in scores of randomized trials continues to refine our understanding of adjuvant therapy effects. Tamoxifen is effective regardless of age or menopausal status in women who are estrogen-receptor or progesterone-receptor positive. The effects of chemotherapy and tamoxifen are greater than either intervention alone for these women. The relatively nontoxic response has led to increasing use of tamoxifen among node-negative women who are receptor positive. Treatment of node-negative women who are receptor negative is more controversial. The source of the controversy is the question of whether the risk-reduction benefits are sufficiently great to justify the significant morbidity associated with adjuvant chemotherapy. Women who choose this option should have a clear understanding of the benefits and realistic expectations of side effects, including nausea and vomiting, alopecia, and premature menopause.

The inclusion of a *bisphosphonate* in the adjuvant regimen has recently gained favor. The antiosteolytic effect of bisphosphonates has been shown to significantly reduce the incidence of bone pain, pathologic fractures, and hypercalcemia in women with breast cancer and bone metastases. And recently, the adjuvant use of the bisphosphonate clodronate in women at high risk for distant metastases has been shown to reduce the incidence of bony and visceral metastases by 50%.

Monitoring. After primary therapy, women with breast cancer should be seen at regular intervals. Psychosocial adjustments and clinical status need careful attention. A mammogram should be obtained annually. Follow-up examination of the bones should be undertaken only in patients who develop symptoms of bone pain. The crucial concern in monitoring patients with breast cancer is the increased risk of a second primary tumor, which may also be curable. The identification of early metastatic disease is less consequential, because systemic therapy should be used only for patients with either rapidly growing tumor or symptomatic disease.

Treatment of Advanced Disease. Stage III breast cancer is an inoperable local disease confined to the skin, breast, or lymph nodes. It may be treated either with systemic therapy (either hormonal or chemotherapy) to determine the effectiveness of the systemic treatment and to reduce the bulk of tumor or with local therapy, which may be either mastectomy followed by radiation therapy or radiation therapy alone. The median length of survival after effective treatment is 18 to 24 months.

The management of stage IV (metastatic) breast cancer is determined in part by sites of metastases, menopausal status, and hormone receptor status. The decision to treat and the timing of therapy depend on the presence or absence of symptoms and the growth rate of the tumor. There are three categories of systemic therapy for advanced breast cancer: hormone therapy, chemotherapy, and combination therapy. Radiation therapy is also very effective for palliation, and, as noted, bisphosphonate therapy reduces the incidence of complications associated with bony metastases.

Hormone therapy can be very effective for tumors that have high concentration of estrogen receptor protein in the cytoplasm. Tumors with progesterone receptors are also more likely to be hormonally responsive. The sites of disease most often responsive to hormones are pulmonary nodules, pleural effusions, and osseous lesions. There is a much lower likelihood of response to hormonal manipulation for patients with hepatic metastases, lymphangitic pulmonary involvement, brain metastases, or skin lesions. Hormone management also depends on menopausal status. The least responsive group is perimenopausal. After an initial response to hormonal therapy, a relapse usually occurs, but a subsequent secondary response to an alternative hormonal manipulation is not uncommon. For the most part, such secondary responses are short lived and are not of the quality of the initial response. It is important to recognize that the effect of hormonal therapy on tumor bulk may not be

observed for 1 or 2 months, even though the agent may begin working immediately. Relief of bone pain is much more rapidly achieved.

Hormonal therapy occasionally results in exacerbation of bone pain or tumor growth. The mechanism is not known. In a small percentage of these patients, the opposite hormonal maneuver (i.e., ablation or supplementation) may induce an antitumor effect. In some institutions, patients are monitored in the hospital for a 10-day period to determine whether or not tumor stimulation and serious hypercalcemia occur.

The development of drugs for use in place of adrenalectomy has eased the burden of treatment for patients with advanced disease. *Tamoxifen*, a competitive inhibitor of endogenous estrogen, binds to estrogen receptors and achieves an antitumor effect by an unknown mechanism. The drug has a low rate of toxicity and a response rate comparable with that of other forms of hormone therapy. As a result, tamoxifen is the usual first-line hormonal therapy.

Chemotherapy should be considered for patients with advanced disease after hormonal manipulations have failed or when they are deemed inappropriate (e.g., in receptor-negative patients). However, the likelihood of response is reduced when the tumor has proven resistant to other forms of treatment. The chemotherapeutic regimens most commonly used to manage advanced disease include the same regimens commonly used for adjuvant therapy. As with adjuvant therapy, combinations of hormonal manipulations and multidrug programs have been advocated on the basis of a possible synergistic interaction.

Breast cancer is particularly sensitive to radiation therapy. Metastatic bony lesions are present in more than 60% of patients with breast cancer, and lytic lesions are often associated with pain. Local radiation therapy at the relatively low doses of 2,000 to 3,500 rads may relieve pain, although persistent structural defects as a consequence of cortical bony erosion may necessitate orthopedic support and even internal fixation for weight-bearing bone structures. Another important role for radiation therapy is in palliation of patients who develop metastatic brain lesions, which occur in more than 10% of patients.

Autologous bone marrow transplantation in conjunction with high-dose chemotherapy has been used extensively in the United States among women deemed at high risk of distant metastases and death, usually because of extensive lymph node involvement. However, it should be thought of as an investigative approach because of unproven benefits. A recent trial with median follow-up of more than 4 years did not show a survival benefit for the high-dose approach.

PATIENT EDUCATION

Whether or not a woman has had a role in decision making about breast cancer treatment can be an important determinant of her psychosocial adjustment. Many women find reasons to blame themselves or others because of things they might have done, or might not have done, to prevent the disease. Some focus on stressful experiences and believe that they played a causative role, or that they will increase risk of recurrence and/or progression. They should be reassured that there is good evidence that this is not the case. The primary care provider is well positioned to provide empathetic support and vital information about the benefit and harm of alternative treatment options. **Updated: 7/10/02**

CHAPTER 123 MANAGEMENT OF THE WOMAN WITH GENITAL TRACT CANCER

Cancers of the genital tract account for about 20% of cancers in women and 10% of cancer deaths. They range from the readily detectable and curable carcinoma of the cervix to the very problematic ovarian carcinoma, with its tendency to remain inconspicuous until very late. Endometrial carcinoma has come to be one of the most common genital cancers of the postmenopausal years. Cervical cancer is now predominantly a disease of younger women.

Treatment of the woman with genital tract cancer is usually the province of the oncologist and gynecologist, but the primary physician remains an important part of the collaborative effort. Patient counseling, monitoring, and management of ongoing medical problems are among the important responsibilities.

CARCINOMA OF THE CERVIX

The incidence of invasive cervical carcinoma peaks between the ages of 48 and 55. The peak for carcinoma in situ is between ages 25 and 40. Most women with the disease present in their twenties and thirties thanks to early detection from use of the Papanicolaou (Pap) smear (see Chapter 107). Among proven risk factors are early sexual intercourse, multiple sexual partners, and infection with human papillomavirus (particularly types 16 and 18).

Principles of Management

Diagnosis. Postcoital bleeding should raise suspicion for the diagnosis. In most cases of early disease, the patient is asymptomatic and, as noted above, detection is by screening *Pap test* (see Chapter 107). Diagnosis requires biopsy confirmation of a sufficiently abnormal Pap test or a grossly suspicious-looking lesion. Patients with only mild atypia on the Pap smear (also referred to as reactive or reparative change) can be followed without biopsy but require repeat Pap testing (usually in 3 to 6 months) to be sure there is no progression to the more serious dysplasia. If there is ongoing infection, it should be treated before the Pap smear is repeated. Patients with dysplasia seen on Pap smear are at greater risk and should be referred to the gynecologist for *colposcopy* and *biopsy*. If colposcopic examination fails to identify the area for biopsy, cervical conization is required.

Staging. Clinical staging is based on findings from biopsy, physical examination, and radiologic study. An estimate of extent of local disease can be made by *pelvic examination*, carefully palpating to see if there is lateral extension to the vagina or pelvic wall. Palpating lymph nodes may detect a distant nodal metastasis, but clinical staging for involvement of pelvic nodes and the more distant paraaortic ones requires *lymphangiography* and/or *computed tomography* (CT). The latter has been especially helpful in assessment of paraaortic nodes. Studies of *magnetic resonance imaging* suggest some usefulness in delineating local extension.

Stage of disease is designated by the TMN system (Table 123.1). Prognosis worsens with advancing stage of local disease, development of regional and distant nodal metastases (especially paraaortic nodes), and histologic grade. Risk of nodal metastasis rises with growth of tumor to greater than 4 cm, lymphovascular invasion, invasion deep into the cervical stroma, and histologic grade.

Table 123.1. Staging of Cervical Cancer

Treatment and Prognosis. Early stages of carcinoma of the cervix are curable. Patients sometimes ask the opinion of their primary physician regarding the choices of therapy for early stage disease. Consequently, these choices are worth reviewing here.

For *stage 0 disease*, the treatment of choice has been *conization*. In instances where the lesion is readily visible by colposcopy and the patient can be counted on to come for regular follow-up, outpatient *cryotherapy* or *laser ablation* can serve as an alternative to conization. *Hysterectomy* is reserved for those who have intraepithelial neoplasia at the margins of the cone biopsy and do not care for future childbearing. Cure is in excess of 99%.

Stage IA1 is treated with *vaginal hysterectomy* when childbearing is not an issue. When it is desired, *conization* and close follow-up are the alternative if the cone margins are free of tumor. Five-year survival is over 90%. There is debate regarding the best approach to *stage IA2* disease. If invasion is greater than 3 mm or there is lymphovascular invasion, then these patients are usually treated like stage IB. If invasion is less than 3 mm and there is no lymphovascular involvement, then they are treated like IA1. *Intracavitary irradiation* is another curative option.

Stages IB and IIA are treated by *radical hysterectomy* plus *pelvic lymphadenectomy* or by definitive *irradiation*. Surgery is preferred in young women, because the ovarian function can be spared and the vagina is more pliable than after irradiation. Also, radiation effects on bowel and other adjacent structures are avoided. Radiation therapy spares the need for an extensive surgical procedure and its attendant complications. With either procedure, 5-year survival is equally good, with rates averaging about 85% for patients with no pelvic node disease. If there is involvement of pelvic nodes, 5-year survival falls to about 50%.

Stages IIB and beyond are treated with *irradiation*. Five-year survival averages about 60% for patients with IIB disease and falls to about 35% for stage IIIB and to 20% for stage IV.

The high likelihood of nodal metastasis associated with advancing stages of local disease markedly lowers the chances of cure. Clinically inapparent involvement of paraaortic nodes is a particularly difficult problem, leading some to advocate surgical sampling. Prophylactic radiation to the area does not seem to improve survival.

Patient Education

Young patients need to know that carcinoma of the cervix is potentially curable and that early disease can be successfully treated without compromising childbearing capacity. Such knowledge ensures that the young woman with carcinoma in situ or severe dysplasia will not refuse timely treatment out of fear. Older patients presenting with more invasive disease can still obtain some comfort from knowing the prognosis remains very favorable for most stages of this disease.

CARCINOMA OF ENDOMETRIUM

This disease continues to be the most common female genital cancer, accounting for about half of all new cases (about 33,000 per year). It predominantly strikes

postmenopausal women. Peak incidence is between ages 55 and 60. Only 5% of cases occur in women under the age of 40. Risk factors include obesity, nulliparity, late menopause, and prolonged unopposed estrogen stimulation of the uterus (either from replacement therapy or polycystic ovary syndrome; see Chapter 111). Uninterrupted estrogen stimulation in the absence of progestin risks induction of cystic and adenomatous hyperplasia, which are considered premalignant changes. Obesity may contribute by the ability of adipose tissue to convert circulating androstenedione into estrogen. Postmenopausal bleeding (defined as uterine bleeding occurring 6 months after the onset of menopause) may be the only early clue to the development of this tumor. Occasionally, a mass is felt on routine pelvic examination.

Principles of Management

Diagnosis. Suspicion of the diagnosis mandates gynecologic referral for *fractional curettage*. When there is confusion as to whether a pelvic mass is ovarian or uterine, ordering a *pelvic ultrasound* examination can help make the distinction noninvasively, but the test is insufficient for definitive diagnosis of an intrauterine lesion. Biopsy by way of curettage is required.

Staging and Prognosis. Prognosis is a function of the extent of disease and of histologic type. The gynecologist will attempt to determine if the problem is confined to the uterine corpus or extends into the cervix and beyond. A careful *pelvic examination*, *CT*, *and chest x-ray* comprise the clinical staging process. Surgical staging is based on findings at the time of hysterectomy. Histologic grade, depth of myometrial penetration, and lymph node metastases influence prognosis in patients with early-stage disease. Overall survival is about 80% for those with stage I disease (confined to the corpus), 50% for stage II (involves corpus and the cervix), 27% for stage III (spread beyond the uterus but within the pelvis), and 9% for stage IV (invades bladder or rectum, extends beyond the pelvis).

Treatment. Patients with the *premalignant* change of adenomatous hyperplasia are usually advised to undergo *hysterectomy* because of the risk of developing cancer. However, a second option is *progestin therapy* followed by repeat curettage. Patients with *stage I or stage II* disease are curable when treated with *hysterectomy/bilateral salpingo-oophorectomy plus irradiation*. The addition of radiation therapy is especially useful in stage II disease. The precise type of radiation therapy depends on histologic type and degree of spread. Intracavitary and external beam treatments are considered. The treatment of *stage III* disease is individualized, determined by findings on laparotomy. Patients with more advanced disease are inoperable and treated with radiation, progestins, or chemotherapy for palliation.

Patient Education

Patients who are considering estrogen therapy for treatment of postmenopausal osteoporosis need to consider the risk of developing endometrial cancer. Although patients who do develop cancer from estrogen therapy are often detected early at a curable phase of illness, the disease still represents a serious consequence of an elective form of therapy. Adding a progestin to the estrogen program helps prevent unopposed endometrial proliferation and development of cystic hyperplasia (see Chapter 117 and Chapter 158).

OVARIAN CARCINOMA

Ovarian cancer ranks fourth in cancer deaths among women and leads all gynecologic cancers. Incidence increases with age, beginning shortly after menarche and continuing through the eighth decade. Risk heightens among women in their 40s, especially among those who are nulliparous. Up to 10% of cases are *familial*, with many of these demonstrating germ-line mutations of the *BRCA1* gene on chromosome 17 and to lesser degree mutations in the related *BRCA2* gene. It is believed that these genes function as tumor suppressor genes and that mutations at this site account for the greatly increased risk of ovarian cancer in the hereditary form of the disease. Mutations in these genes have also been identified in families with increased risk of breast cancer.

Women in families with a history of ovarian cancer have a lifetime risk of the malignancy that ranges from 20% to 40%. BRCA mutations are rare in the sporadic form of the disease, and risk is minuscule in family members with sporadic disease compared with that of women with a positive family history. Although risk of developing the disease is greatly increased in hereditary ovarian carcinoma, the prognosis appears much more favorable. Among patients with advanced disease (the most common stage at presentation), those with the hereditary form that includes mutation of BRCA1 survive nearly three times as long as those with sporadic disease, making mutation at BRCA1 the single most important determinant of prognosis.

Screening remains inadequate, despite the advent of transvaginal ultrasound for detection of ovarian masses and monoclonal antibody techniques for detection of the tumor-associated antigen CA-125 (see Chapter 108). *Genetic testing* for BRCA mutations holds considerable promise, but the implications for management must be more fully defined before meaningful guidelines can be constructed. Possible uses might include testing of women from families with a strongly positive history of ovarian cancer if they are contemplating prophylactic removal of both ovaries or other forms of prophylactic therapy. Study results could help inform the decision.

Clinical Presentation is typically late, because the disease is usually silent in its early stages. Over 80% of ovarian tumors derive from the epithelial surface of the ovary, disseminating silently by surface shedding or lymph node invasion. Initial symptoms when they do occur may be extremely vague, such as nonspecific gastrointestinal complaints that seem to persist in the absence of objective evidence for bowel disease. In later stages, the disease may be manifested by an abdominal or pelvic mass or development of ascites. Almost 70% of patients have already reached advanced-stage disease at the time of initial presentation.

Diagnosis

Because the disease is so silent or nonspecific in its presentation, a high index of suspicion is required. Family history should be checked carefully for ovarian cancer. Peri- and postmenopausal women with unexplained pelvic or abdominal complaints should have a thorough *pelvic examination* with emphasis on careful palpation of the adnexae for a mass. Ability to palpate the ovary in a postmenopausal woman is suspicious of pathologic enlargement, because the ovary normally involutes to less than 2 cm in size.

A *transvaginal ultrasound* can help confirm the presence of an ovarian mass and is superior to transabdominal study. The finding of a simple cyst less than 4 cm is unlikely to represent cancer but warrants further observation, especially in postmenopausal women who do not have functioning ovarian cysts. In women of reproductive age, ovarian enlargement is common and usually due to functioning follicular or corpus luteum cysts. These typically regress within one to three menstrual cycles. Finding a complex cyst increases the risk of malignancy to about 10% and necessitates *surgical exploration*, as does discovery of a solid mass. Spread to the opposite ovary occurs in up to 15% of cases, so the finding of bilateral disease should increase rather than decrease suspicion. *CT* delineates pelvic and abdominal masses, liver and pulmonary metastasis, and retroperitoneal node involvement. It can be used to assess the ovary when pelvic ultrasound study is obscured by bowel gas.

As just noted, suspicious cases require surgical exploration. Laparoscopy is not a substitute, because laparoscopically guided needle aspiration or biopsy risks spilling malignant cells into the peritoneum and washings are of insufficient sensitivity.

Use of the tumor marker *CA-125* to achieve earlier detection of ovarian cancer has proven disappointing, perhaps because only 50% of women with clinically detectable disease have elevated levels of the marker. In addition, many women with positive studies prove to already have advanced disease, because the frequency of marker elevation increases with tumor stage and bulk. Nonetheless, a markedly elevated CA-125 in a patient with a suspicious adnexal mass only increases the importance of proceeding with surgical exploration. A negative study does not obviate the need to refer for consideration of exploration. Combining CA-125 with transvaginal ultrasound appears to have little impact on survival when used as a screening technique in the general population. Its efficacy in persons with hereditary disease may be better, but the effect on survival remains unknown (see Chapter 108).

Principles of Management

Prophylaxis. Because ovarian carcinoma is hard to detect in its early stages, much attention has been directed toward prophylactic approaches to disease. The prime candidates for consideration of prophylaxis are women at very high risk (i.e., those with a family history of hereditary disease and mutation of the BRCA genes). Options include *regular screening* by CA-125 and ultrasound (see above), *prophylactic oophorectomy*, and *oral contraceptive therapy*. Because data on efficacy and relative benefit are sparse (no randomized trials), the options need to be reviewed with each woman at high risk to help her reach a personally acceptable decision.

Prophylactic Oophorectomy can be accomplished laparoscopically as an ambulatory surgical procedure with minimal adverse effects. It is a reasonable consideration for women with a family history of hereditary disease and BRCA mutations who have completed childbearing. Such persons have a 20% to 40% chance

of getting the disease and might be willing to undergo surgery. However, there is still a small risk (1% to 2%) of the tumor arising from a primary peritoneal site in high-risk persons with hereditary disease. Hormone replacement therapy would usually be prescribed after surgery to obviate the consequences of a surgical menopause; however, such therapy increases the relative risk of breast cancer by about 20%—a concern in this population already at increased risk for breast cancer by virtue of the *BRCA1* mutation.

Oral Contraceptive Therapy. Epidemiologic observations demonstrate that the risk of ovarian cancer in unselected populations of women is reduced by approximately 50% when there is a history of long-term oral contraceptive use. A retrospective analysis of women with the BRCA mutations and a positive family history shows a similar reduction in risk with 6 or more years of oral contraceptive use. However, women with BRCA mutations are also at increased risk of breast cancer, and estrogen therapy does modestly increase the relative risk of breast cancer in unselected populations. There are no data on breast cancer risk when oral contraceptive therapy is used as prophylaxis for hereditary ovarian cancer. Many women with known hereditary predisposition may well be inclined to opt for the risk-reduction benefits afforded by oral contraceptive use during their childbearing years, after which prophylactic oophorectomy may become an acceptable strategy for some women. Those opting for estrogen therapy will require close monitoring and regular mammographic screening for breast cancer.

Staging and Monitoring. Staging is performed predominantly by surgical exploration. Precise staging necessitates a meticulous *laparotomy* to assess the diaphragmatic surface and the omentum and other intraabdominal sites to which spread is common. Disease limited to the ovaries is considered stage I; if confined to the pelvis, it is considered stage II. Stage III designates involvement of regional nodes or disseminated peritoneal seeding with spread to the upper abdomen. Stage IV signifies distant or visceral metastasis. Ascites and bulky peritoneal tumor are frequent manifestations of advanced-stage disease. About 75% of patients present with stage III or IV disease. In the near future, staging is likely to include genetic testing for BRCA1 status, because of its important contribution to prognosis. BRCA1 status could become extremely important if it is found to predict responses to treatment modalities.

The disease most commonly recurs within the abdominal cavity. Monitoring techniques include *CA-125 levels*, *laparoscopic examination*, *ultrasonography*, *and second-look surgery*. Miliary implants on the serosal surface may go undetected by imaging studies. Elevations in CA-125 are associated with residual tumor at the time of second-look surgery.

Treatment Modalities. Although the tumor is responsive to cancer treatment measures, its bulk and spread limit the results. Cure is still limited. In advanced stages of the disease, prognosis correlates with amount of residual disease after initial surgery. Those with less than 2 cm of residual disease do better than those with greater amounts of tumor remaining. Consequently, treatment often begins with "*debulking*" or tumor removal. *Omentectomy* and *total abdominal hysterectomy* and *bilateral salpingo-oophorectomy* are performed, in addition to the reduction of tumor masses throughout the abdominal cavity. This is believed to lessen the host-tumor burden and increase the effectiveness of ancillary or adjunctive therapeutic modalities, such as radiation or chemotherapy.

A major advance in *chemotherapy* has been achieved with the *combination regimen of cisplatin and paclitaxe*. Complete clinical response has been achieved in over 70% of persons with advanced stage disease (stage III or IV with residual tumor after surgery). Median survival in responding patients has increased to 38 months, a marked improvement from the 12 to 24 months achieved with older regimens. In patients appearing to respond to chemotherapy, a *second-look operation* is performed to remove residual disease, check response, and, at times, place intraperitoneal catheters for *intraperitoneal infusion* therapy with cisplatin. The regression of disease, confirmed by second-look operations, suggests that multidrug therapies should be the standard approach to ovarian cancer.

Radiation therapy to the pelvis or to the abdomen (for patients with disease that extends beyond the pelvis) has been advocated as a routine adjunct to surgery in patients with advanced stage disease, although impact on survival appears minimal. The rationale for abdominal and pelvic irradiation is based on the fact that ovarian tumors frequently cause recurrent ascites and bowel obstruction, leading to progressive inanition.

Survival. As noted above, median survival has increased dramatically. More than two thirds of patients used to die within a year. Now over two thirds of women who present with advanced disease can expect a complete clinical response to combination chemotherapy and a median survival of 38 months. Prognosis correlates with amount of residual tumor after initial surgery, stage of disease, tumor grade, age, histologic type, and BRCA1 gene status. Those with stage I or II disease, less than 2 cm of residual disease, grade I tumor, and mucinous histology have the best chance of achieving complete remission and long-term survival from postoperative therapy. Relatively young age at time of diagnosis and mutation of the BRCA1 gene are among the most powerful determinants of favorable prognosis. Median survival of those who have a mutation of BRCA1 is over 6 years.

Patient Education

Patients with ovarian cancer have a long and difficult clinical course. Mortality rates are high, and tumor bulk leads to considerable morbidity. Women with this disease and their families need all the support, interest, and comprehensive care that one can muster (see Chapter 87). With the advent of improved chemotherapy regimens, some hope for prolongation of survival can now be offered to those with advanced disease. Careful counseling, perhaps in conjunction with genetic testing for BRCA1 status, is essential for women with a family history of ovarian carcinoma.

CARCINOMA OF THE VULVA

Being a disease of a readily visible area, carcinoma of the vulva lends itself to early detection and treatment. Associations between the disease and low socioeconomic class and infection with herpes simplex virus and human papillomavirus have been observed. The median age for initial presentation of carcinoma in situ is 44; for invasive disease it is 61, suggesting a slowlyprogressive course. Presentations include a mass or growth, vulvar pruritus, and bleeding. About 20% are asymptomatic. Lesions may be flat and raised or verrucal. Coloration ranges from white (leukoplakia) to brown (hyperpigmentation) to red. The term *Bowen's disease* refers to the hyperpigmented variety, and Paget's disease refers to the leukoplakial form. The best means of early diagnosis is a high index of suspicion. Surgical excision is the treatment of choice. More conservative approaches are now being used to decrease short- and long-term morbidity without sacrificing chance for cure. Cure rates in excess of 90% are achievable for localized disease less than 2 cm in greatest dimension. Radiation therapy is used for nonresectable disease.

CARCINOMA OF THE VAGINA

This is a relatively rare disease. Cancer found in the vagina is more likely to represent spread of disease from the cervix. Primary vaginal carcinomas are mostly squamous cell lesions, although those related to diethylstilbestrol exposure are of the clear cell variety. Prior irradiation may be a predisposing factor. Most lesions appear on the posterior wall and in the upper third of the vaginal vault. The tumor spreads directly and by lymphatic channels. It may present as an ulcerated lesion or as an exophytic mass extending into the vaginal vault. Preinvasive disease is asymptomatic. Invasive disease may present as postmenopausal or postcoital bleeding. Careful inspection of the posterior and distal aspects of the vagina is important in locating the lesion. Diagnosis is made by biopsy. Carcinoma *in situ* can be treated with local excision. Laser techniques are popular. Invasive disease is treated with radiation.

PART 9 GENITOURINARY PROBLEMS

CHAPTER 124 SCREENING FOR SYPHILIS

BENJAMIN DAVIS AND HARVEY B. SIMON

The prevalence of syphilis in the United States began to decline with the introduction of penicillin therapy in the 1940s, falling to about 7,000 cases in 1956. Since then, reported cases of syphilis have increased. In the 1970s, much of the increase was a consequence of infection in homosexual men. The AIDS epidemic produced changes in sexual behavior that have reduced the incidence of syphilis in homosexual men; however, syphilis has increased dramatically in African-Americans, Hispanics, and inner-city residents. This trend peaked in 1990, when more than 50,000 cases of primary and secondary syphilis were reported, representing a 9% increase in just 1 year. Since then, the reported cases of syphilis have declined to a new low in 1997.

If a patient is not identified and treated during the primary or secondary stages of the disease, the infection becomes latent and is identifiable only by means of laboratory tests until late, often irreversible, clinical manifestations appear. The prevention of destructive cardiovascular and neurologic lesions by means of appropriate screening for latent syphilis is an important task for the primary physician. Because false-positive results are common and are potentially traumatic for the patient, it is critical that the sensitivity and specificity of the various serologic tests be understood.

EPIDEMIOLOGY AND RISK FACTORS

With the exception of infection in utero or, rarely, by means of blood transfusion, syphilis is transmitted exclusively by *direct sexual contact* with infectious lesions. It follows that risk increases with sexual activity. Because syphilis is readily treated with antibiotics, it is less common in populations with access to medical care. The reported incidence of syphilis in nonwhites in the United States is much higher than in whites. Rates are highest in urban areas. It must be remembered, however, when incidence rates in different populations are compared, that case reporting has been shown to be more complete in public clinics than among private practitioners.

The age-specific incidence rates parallel those of gonorrhea, with the peak incidence for both diseases occurring between ages 20 and 25. A diagnosis of gonorrhea, nongonorrheal urethritis, HIV infection, or another sexually transmitted disease should be considered a risk factor for syphilis. Drug abuse has become an important risk factor. Male homosexuals are also at high risk.

The importance of an accurate sexual history in determining the risk for syphilis is obvious. Patients with early syphilis report an average of three recent sexual contacts. The probability that syphilis will develop in a known contact following a single exposure has been shown to be approximately 30%.

NATURAL HISTORY OF SYPHILIS AND EFFECTIVENESS OF THERAPY

Treponema pallidum enters the bloodstream within a few hours after inoculation through intact mucous membranes or abraded skin. A primary lesion occurs at the site of the inoculation between 10 and 90 days after contact. The incubation period depends on the size of the inoculum but is usually less than 3 weeks. The painless chancre usually resolves within 4 to 6 weeks, ending the *primary stage*. The *secondary stage* is usually heralded by a maculopapular rash that appears approximately 6 weeks after the primary lesion has healed. When the rash subsides, after 2 to 6 weeks, untreated syphilis enters the *latent stage* (arbitrarily divided into *early latent* for the first year and *late latent* thereafter). If untreated, patients with secondary syphilis may relapse clinically during early latency.

Because anorectal or vaginal chancres are not likely to be brought to medical attention, primary syphilis is often not diagnosed among homosexual men or among women. Whereas more than 40% of syphilis cases are detected in the primary stage among male heterosexuals, only 23% and 11%, respectively, are detected in the primary stage among male homosexuals and among females.

Natural history studies from Oslo and Tuskegee indicate that clinically manifest tertiary disease develops in approximately one third of persons with untreated syphilis, and that evidence of cardiovascular syphilis can be found in more than half at autopsy. In the retrospective Oslo study, 10% of patients had clinically evident cardiovascular syphilis, 7% had neurosyphilis, and 16% had gummatous disease. The incidence of cardiovascular syphilis was higher and that of neurosyphilis was lower in the prospective Tuskegee study.

Factors that influence the progression to clinical tertiary disease are incompletely understood. Congenital syphilis or disease contracted before age 15 does not predispose to cardiovascular tertiary disease. In general, late complications seem more likely to occur among untreated men than among untreated women.

The antibiotic regimens recommended in Chapter 141 are highly effective in eradicating early syphilis. If the response to therapy is appropriately monitored by following the quantitative VDRL or RPR titer, the risk for late complications is virtually eliminated. Antibiotic treatment of late syphilis has less predictable results. Improvement among patients with general paresis has been reported in 40% to 80% of cases. Not surprisingly, structural cardiovascular changes caused by syphilis are not reversed by antibiotic treatment.

SCREENING AND DIAGNOSTIC TESTS

Two groups of serologic tests can be used to diagnose syphilis: nontreponemal tests and treponemal tests.

Nontreponemal Tests, first introduced by Wasserman in 1906, use *cardiolipin* antigens extracted from mammalian tissues. These tests depend on cross-reactivity with antibodies against *T. pallidum*. The *rapid plasma reagin* (RPR) test, *Venereal Disease Research Laboratory* (VDRL) test, and *automated reagin test* (ART) are among the most widely used. Their advantages include low cost, simplicity, and automated processing for mass screening. Many of the results can be quantified to allow serologic monitoring of response to therapy.

Nontreponemal tests are well suited for *screening* because they are highly sensitive. Virtually all patients with secondary syphilis are seropositive. Most with primary disease become seropositive within a week of the appearance of symptoms, but in a minority, detectable antibodies fail to develop in early infection. Patients with concomitant HIV and *T. pallidum* infection usually have positive findings on serologic testing for syphilis (titers are often high). Even without treatment, 25% of patients with syphilis become seronegative in late latent disease.

A disadvantage of nontreponemal tests is that their specificity is only about 70%. *Acute false-positive reactions*, which spontaneously revert to negative within 6 months, may follow many bacterial and viral infections. *Chronic false-positive reactions* occur in patients with elevated serum globulins. Such reactions are particularly common in IV drug abusers (about 25%), patients with systemic lupus (15%), and healthy elderly persons (10%). Chronic false-positive tests also occur in patients with chronic liver disease, other connective tissue diseases, myeloma, and other advanced malignancies.

Treponemal Tests. All patients with positive nontreponemal test results should be retested with specific treponemal antigens. Although these tests are more sensitive and specific than the nontreponemal tests, they are better suited for diagnostic confirmation than for screening. The *microhemagglutination–T. pallidum test* (MHA–TP) is now the most widely used. Others include the *fluorescent treponemal antibody–absorbed test* (FTA-ABS), the *hemagglutination treponemal test* for

syphilis (HATTS), and the now rarely performed *T. pallidum immobilization test* (TPI).

In general, the results of treponemal tests become positive earlier than do the results of nontreponemal tests, and they tend to remain positive throughout life. However, it has been noted that in about 13% of patients receiving prompt treatment for primary syphilis, MHATP test results become negative within 3 years of therapy.

CONCLUSIONS AND RECOMMENDATIONS

- After decades of decline, syphilis is becoming more common, especially among IV drug abusers, the urban poor, and HIV-infected persons.
- Screening for latent disease is simple, and the late manifestations of syphilis are entirely preventable if treatment is instituted early.
- Many patients have been screened routinely at the time of marriage, during prenatal care, before giving blood, or on hospital admission. Frequent screening is unnecessary, but the nonreactivity of sexually active persons, particularly those with multiple sex partners, should be documented at approximately 5-year intervals.
- Special indications for screening include exposure to or infection with other sexually transmitted diseases, pregnancy, IV drug abuse, and HIV infection.
- All patients with syphilis should be counseled about HIV infection and advised to accept HIV testing.
- Nontreponemal tests such as the RPR or VDRL are appropriate for screening because of their sensitivity and simplicity. MHATP or other treponemal tests should be reserved for confirming a diagnosis suspected on the basis of clinical presentation or positive nontreponemal test results.

CHAPTER 125 SCREENING FOR CHLAMYDIAL INFECTION

BENJAMIN DAVIS

INTRODUCTION

Chlamydia trachomatis is responsible for close to 4 million cases of genitourinary tract infection each year in the United States. Transmission is by sexual contact. Because symptoms may be absent, mild, or nonspecific, treatment is often delayed or missed. Undetected or untreated infection can lead to pelvic inflammatory disease, with such consequences as tubal scarring, infertility, and ectopic pregnancy. More than 50,000 women are left sterile each year. The estimated direct and indirect costs of such adverse outcomes is in excess of $2.4 billion per year. Screening for chlamydial infection should be a consideration in the provision of routine primary care to women. Key issues are who should be screened and with what method(s).

EPIDEMIOLOGY AND RISK FACTORS

Chlamydial infection is a sexually transmitted disease (STD) present in epidemic proportions. Its prevalence varies by clinical setting. Among women seen in primary care practice, the prevalence is 3% to 5%. In family planning clinics, the prevalence increases to 9%; in STD clinics, the rate rises to 17% to 28%. Prevalence is very high among adolescents (18%), and one study of college campus women found 50% to be infected. Among female military recruits, the prevalence of chlamydial infection was 9%; the rate for the youngest recruits, 17 years of age, was 12%. Between 1987 and 1995, the reported rates of chlamydial infection increased by 281%. Although much of this rise is accounted for by increased screening, chlamydial infection is still very prevalent in the United States.

Women are at greater risk for contracting *C. trachomatis* infection than are men, and they also suffer more serious consequences. The risk in a single act of unprotected intercourse with an infected partner is 40% for women and 20% for men. The increased risk for women reflects the fact that they receive an ejaculate of infected secretions from their partner's genital tract. Men do not receive such a large inoculum unless they have an intact foreskin, which can serve as a reservoir for the woman's infected cervical secretions.

Among women with documented urogenital infection, the cervix is infected in 75% and the urethra in 50%. Endometritis can be demonstrated in about 33%; it is often clinically silent, but infection may spread to the tubes. In studies of salpingitis, *Chlamydiae* is recovered from the tubes in up to 50% of subjects. Vaginal infection is rare.

Chlamydiae may also colonize the pharynx and rectum in women engaging in oral and anal sex, respectively. Among those attending an STD clinic, the rate for oral recovery of organisms was 3.2%; the rectal colonization rate was 5.2%. Rectal involvement has been noted even in the absence of rectal intercourse.

In men, the urethra is the predominant site of infection, with more than 82% having a symptomatic or visible urethral discharge. In 1% to 2% of infected men, the infection ascends to the epididymis to produce acute scrotal pain and discomfort. Homosexual men demonstrate even higher rates of oral and anal recovery of organisms. Lymphogranuloma strains are often present.

Age is a powerful predictor of infection. Women *younger than 21 years* are at the greatest risk. Other important risk factors include having had a *new partner* in the last 2 months, *more than one partner* in the last 6 months, or a *partner known to have other partners*. Nonetheless, even among women who are monogamous or who have been sexually inactive in the last 2 months, prevalence can be as high as 7% to 10%.

Other significant predictors of chlamydial infection identified by multivariate analysis include *African-American race*, *low level of education*, *unprotected intercourse*, *mucopurulent cervical discharge*, and *induced mucosal bleeding* on swabbing of the cervix. Among patients with *gonococcal infection*, 30% to 50% have concurrent chlamydial disease. In a large surveillance study of urban residents under the age of 45 years, the rate for either infection was 15% in black women, 6.4% in black men, 2.8% in white men, and 1.3% in white women. The risk of *C. trachomatis* was highest in the 18-20 group (8.0%), but *N. gonorrhoeae* infection was unexpectedly high in the 31 to 35 group (10.2%). **Updated: 5/6/02**

SCREENING

Screening women at risk for the disease is essential because infection is so frequently asymptomatic despite being associated with extensive inflammation of the female genital tract. The rising rate of chlamydial infection in the past decade surely reflects, in part, wider acceptance and implementation of screening programs. However, when family planning clinics (where chlamydial screening is universal) are analyzed, the rate of chlamydial infection has actually *declined* from 9% to 3% in the past decade. This very likely reflects the impact that screening programs have had on the incidence of untreated disease, and quite possibly a reduction in infertility caused by chlamydial infection. In fact, a randomized controlled trial of screening of asymptomatic women enrolled in a health maintenance Organization demonstrated a 50% reduction in subsequent pelvic inflammatory disease.

DIAGNOSIS

Clinical Recognition

In women, clinical recognition can be difficult because most patients are asymptomatic or have only minor symptoms. Although vaginal discharge, bleeding, lower abdominal discomfort, and dysuria may accompany infection, these symptoms are nonspecific and require a detailed workup in their own right (see Chapter 111, Chapter 116, Chapter 117, and Chapter 133). The only features of the history that reliably suggest the problem are the risk factors identified above.

In the absence of definitive symptoms, physical findings take on additional importance. *Mucopurulent discharge*, *cervical ectopy*, *edema* in the area of ectopy, and easily *induced mucosal bleeding* have proved predictive of *C. trachomatis* infection, as has the presence of more than 10 neutrophils per high-power field. *Uterine* or *adnexal tenderness* in a patient with a mucopurulent cervical discharge is suggestive of chlamydial pelvic inflammatory disease (see Chapter 116 and Chapter 117).

In men, nongonococcal *urethritis* is the most common presentation, with dysuria, penile discharge, and the presence of more than five neutrophils per high-power field (see Chapter 136). About a third of men with chlamydial urethritis have no symptoms or signs, although pyuria may be noted. A small number experience acute testicular pain from an ascending epididymitis (see Chapter 131).

Diagnostic Tests

Culture. Culture is the gold standard for identification. However, because *chlamydiae* are obligate intracellular organisms, cell culture techniques similar to those used for viruses are required to isolate and identify them. Such cultures are technically difficult and expensive, take up to a week, and require refrigeration of the specimen and transport to the laboratory within 24 hours.

Modifications in traditional cell culture techniques have simplified isolation of the organism. Cell monolayers set up in microtiter plates are helpful in settings where titers are likely to be high (e.g., STD clinics). Fluorescein-conjugated monoclonal antibodies are useful for identifying chlamydial inclusions in infected monolayers. Combining both advances provides a 14% increase in diagnostic yield and sensitivity, makes second-pass testing unnecessary, and shortens test time to 3 days.

Antigen Detection. Antigen detection techniques were developed to overcome the difficulties and limitations posed by culture. *Direct immunofluorescence* staining of smears, with the use of monoclonal antibodies, and *enzyme-linked immunosorbent assay* (ELISA) of antigen eluted from swabs are commercially available. When culture is used as the gold standard, the sensitivity of the direct immunofluorescent technique in women ranges from 77% in intermediate-prevalence populations to 90% in high-prevalence ones. Specificity is above 95% in both. The ELISA has a sensitivity of 85% to 89% and a specificity in excess of 95%. Cost-effectiveness studies indicate that screening for *Chlamydia* with antigen detection techniques becomes cost-effective when the pretest probability of disease exceeds 7%. Prescreening the urine for white blood cells can facilitate identifying asymptomatic men for testing.

DNA Detection. DNA detection techniques represent a further advance in diagnosis and have made detection possible by sampling of urine in addition to the traditional urethral or cervical swab. When a polymerase chain reaction or ligase chain reaction is used to detect minute quantities of chlamydial DNA, sensitivity rises into the 90% range and specificity approaches 100%. The convenience of an accurate urine test for *Chlamydia* makes the polymerase chain reaction and ligase chain reaction ideal for screening high-risk, asymptomatic patients.

EFFECTIVENESS OF TREATMENT

Several effective treatment regimens are available for chlamydial urogenital tract infection (see Chapter 117, Chapter 135, and Chapter 141). For urethritis and cervicitis without evidence of pelvic inflammatory disease, the treatment of choice is a *single 1-g oral dose of azithromycin*. The cost is comparable to that of 1 week of *doxycycline* (100 mg twice daily) or *tetracycline* (500 mg four times daily), and ensured compliance is a major benefit. If the patient is pregnant or unable to take tetracycline or azithromycin, then 500 mg of *erythromycin* base four times daily for 7 days is recommended.

CONCLUSIONS AND RECOMMENDATIONS

•Screening for chlamydial genitourinary infection is definitely worthwhile, but universal screening is not recommended in most primary care practices because the prevalence of asymptomatic infection in this setting is likely to be below the threshold that makes universal screening cost-effective.
•In settings where prevalence is very high (e.g., >10%), universal screening deserves consideration.
•Antigen testing becomes cost-effective among patients whose pretest risk is above 7%. Culturing becomes cost-effective among patients whose pretest risk is above 14%. DNA-based testing with polymerase chain reaction amplification lowers the prevalence threshold for cost-effective screening.
•A policy of selective screening is recommended based on a clinical estimate of the risk for chlamydial infection.
•Because the prevalence of chlamydial infection among sexually active girls and women *under the age of 21* is high and because the risk for sterility resulting from subclinical infection is also very high, annual screening of such persons with or without symptoms has been recommended.
•The Centers for Disease Control and Prevention has recommended annual screening for women *ages 20 to 24* years if either of the major risk factors for chlamydial infection is present: *lack of barrier contraception, or new or multiple partners in the preceding 3 months*. Women *older than 24 years* who have both these risk factors should also be screened.
•Those at high risk for *Chlamydia* infection should also be screened for gonorrhea (see Chapter 137), because they are at increased risk for other common STDs. **Updated: 5/6/02**
•All men presenting with a urethral discharge and all women with mucopurulent cervicitis should be screened for chlamydial infection.
•Partner notification and treatment, either by patient referral or provider referral, is a critical step in interrupting the cycle of reinfection by asymptomatic partners.
•Although antigen testing of a cervical or urethral swab is the least expensive screening method, DNA-based polymerase chain reaction technology is recommended as the testing method of choice, especially in settings of lower prevalence, because its sensitivity is superior and it allows testing of urine in addition to cervical specimens, which lowers the prevalence threshold at which screening is cost-effective.
•All young women coming for routine gynecologic care who do not desire pregnancy should be urged to insist on condom use during intercourse.

CHAPTER 126 SCREENING FOR PROSTATE CANCER

MICHAEL J. BARRY, JOHN D. GOODSON

INTRODUCTION

Prostate cancer is a common cause of morbidity and mortality among older men in the United States. The lifetime probability of a man having clinical prostate cancer diagnosed in the "PSA era" is between 10% and 20%, but the probability of death from prostate cancer is stable, at approximately 3%. This ratio of cumulative incidence to mortality indicates that most patients in whom prostate cancer is diagnosed die of something else.

Patients and clinicians face a great deal of uncertainty in making clinical decisions about the early detection and treatment of prostate cancer. These tumors are exceedingly common and have the potential to cause significant morbidity and mortality. They also have a variable, often indolent course and a higher prevalence in elderly men whose health is often more limited by other diseases. The clinician should be aware of the unpredictable natural history of the disease and the limitations of current knowledge about the benefits of therapy when considering the use of screening tests for prostate cancer.

EPIDEMIOLOGY AND RISK FACTORS

The incidence of prostate cancer increases with age. Age-specific prevalence rates derived from autopsy studies are about 15% for men in their sixth decade, 25% for those in their seventh, and 40% or higher for men older than 70. The incidence of prostate cancer rose dramatically in the United States with increasing use of the prostate-specific antigen (PSA) test after about 1990, and it is now falling. Mortality from prostate cancer, however, has been relatively stable (Fig. 126-1). African-Americans have a twofold to threefold higher incidence of prostate cancer. A brother or father with prostate cancer increases risk twofold. A diet high in fat (particularly red meat) may also be a risk factor, and there is some suggestion that selenium, vitamin E, and tomato products (lycopenes) are protective. The role of selenium and Vitamin E in primary prevention of prostate cancer is currently being investigated. The 5-alpha-reductase inhibitor, finasteride, has been shown to decrease the period prevalence of prostate cancer, but it increases the proportion of cancers that are high grade, actually increasing the absolute risk of developing a prostate cancer that is more likely to affect survival. Evidence linking prostate cancer with prior vasectomy has been equivocal. No strong evidence has linked prostatitis or benign prostatic hyperplasia (BPH) to the development of prostate cancer.

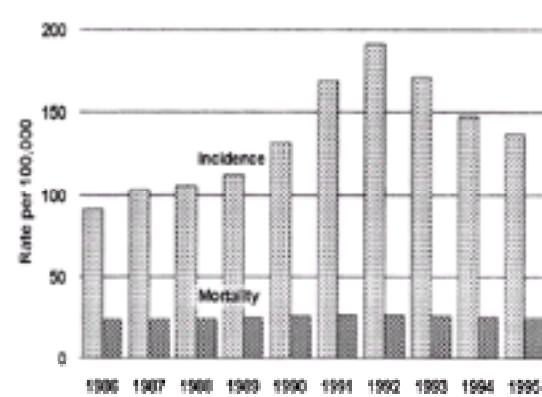
Updated: 07/24/03


Figure 126-1. Mortality and incidence of prostate cancer.

NATURAL HISTORY OF DISEASE AND EFFECTIVENESS OF THERAPY

Clinical Presentation and Course. The biologic behavior of prostate cancer can vary, making individual cases unpredictable. Early prostate cancers are asymptomatic; older men not infrequently have concurrent lower urinary tract symptoms caused by BPH. Early prostate cancers may be discovered through screening activities or diagnosed incidentally when men undergo prostatectomy for BPH. Advanced cancers may present with obstructive symptoms, bleeding, and pelvic or bone pain.

The prognosis of prostate cancer depends as much on the degree of histologic differentiation of the tumor as on the extent of the disease, at least before detectable metastases are evident. Histologically, prostate cancers are often heterogeneous. Pathologists commonly assign a *Gleason score* of 1 to 5 to the most common and next most common histologic patterns, and add the two scores to obtain a Gleason sum ranging from 2 to 10. Cancers with Gleason sums of 2 to 4 are considered well differentiated, 5 to 7 moderately differentiated, and 8 to 10 poorly differentiated (although cancers with sums of 7 in fact behave in an intermediate fashion between moderate and poorly differentiated cancers). Most cancers discovered by screening are Gleason 5 to 7.

Clinically localized prostate cancers generally have doubling times measured in years. The prognosis of prostate cancers depends on tumor factors such as grade, and patient factors such as age. Table 126-1 provides estimates of the 15-year probability of being alive, dying of other causes, or dying of prostate cancer for different combinations of these factors in the absence of initial attempts at curative therapy with surgery or radiation. These data were generated from men in whom cancer was diagnosed in the pre-PSA era. Men with cancer diagnosed in the PSA era will generally do even better because the lead time afforded by early detection through PSA measurement appears to be at least 5 years, on average.

Table 126-1. Estimated Percentage of Patients with Putatively Localized Prostate Cancer Managed Conservatively, by Age and Gleason Score at Diagnosis, with Each Outcome after 15 Years

Effectiveness of Therapy. The variability in the natural history of this disease complicates an assessment of therapeutic efficacy. Some have argued that early and aggressive intervention [surgical extirpation of involved tissue (radical prostatectomy), radiation therapy (either external beam radiotherapy or implantation of radioactive seeds, also called interstitial radiotherapy or brachytherapy), or both] may improve survival for patients in whom the tumor appears to be localized to the gland. However, current practices have evolved in the absence of evidence for a mortality benefit from randomized clinical trials. A recent randomized trial of radical prostatectomy compared to watchful waiting was conducted among Scandinavian men younger than age 75 with well-differentiated and moderately differentiated prostate cancer. Over a 6-year period, it did show a 50% reduction in prostate cancer–specifc mortality, but there was no significant difference in overall mortality, underscoring the usual slow progression of prostate cancer, often in older men who face multiple competing risks for illness and death. In very old patients, many specialists withhold treatment until symptoms appear. A recent trend has developed toward more aggressive therapy in younger patients and older patients without coincident disease. This strategy may eventually prove beneficial, but it presents a higher immediate risk to the patient, including a small but finite risk of mortality and high rates of both erectile dysfunction and urinary incontinence. Some argue that smaller, well-differentiated or moderately differentiated cancers are unlikely to need treatment because of their good prognosis, whereas larger, more poorly differentiated tumors are unlikely to benefit from curative treatment. In this context, it is important to recognize that men who participated in the Scandinavian trial were, for the most part, diagnosed after presentation with symptoms, a nodule, or disease that was otherwise clinically evident. Another trial of radical prostatectomy among American men, many of whom had their cancers detected after PSA screening, is in progress, as are trials of screening in both the United States and Europe. In the meantime, nonexperimental comparisons of treatment outcome from the pre-PSA era suggest a small advantage for more aggressive treatment of moderate and poorly differentiated cancers (Table 126-2), although these advantages may simply represent biases resulting from case selection.

	TEN-YEAR CANCER-SPECIFIC SURVIVAL	
	NO.	PERCENTAGE (95% CI)
Grade 1		
Prostatectomy	3,854	94 (91–95)
Radiotherapy	4,065	90 (87–92)
Conservative	9,304	93 (91–94)
Grade 2		
Prostatectomy	14,237	87 (85–89)
Radiotherapy	7,939	76 (72–79)
Conservative	6,198	77 (74–80)
Grade 3		
Prostatectomy	5,133	67 (62–71)
Radiotherapy	2,596	53 (47–58)
Conservative	2,236	46 (40–51)

CI, confidence interval.

Table 126-2. Ten-Year Disease-Specific Survivial in Patients with Clinically Localized Prostate Cancer by Intention to Treat

SCREENING AND DIAGNOSTIC TESTS

Digital Rectal Examination. Digital rectal examination (DRE) for evidence of either prostate or rectal cancer is a time-honored screening maneuver. Many clinicians believe a curled lateral decubitus position, with the legs drawn to the chest, and a standing position, with toes together and heels apart and the patient leaning over an examination table, to be the two best. Symmetric enlargement and firmness may be seen with BPH. Asymmetric areas of firmness or frank nodules are suggestive, and a stony hard, asymmetric prostate is highly suggestive, of malignancy. Fixation to adjacent tissue and a loss of the lateral prostate sulcus suggest local spread. Interobserver agreement regarding suggestive DRE findings is poor, even among urologists.

Test Characteristics. Test characteristics of the DRE are poor for the earliest stages of prostate cancer. Compared with a multimodal screening battery including both transrectal ultrasonography (TRUS) and PSA determination, DRE has an estimated *sensitivity* of 60% to 70%. The *positive predictive value* (see Chapter 2) for a suspected abnormality detected on DRE is between 20% and 40%; however, cancer is often found by random biopsies in areas separate from the palpable abnormality. As many as 60% to 70% of the cancers detected initially by rectal examination are later found to have spread beyond the capsule of the gland. It has been estimated that abnormal findings on DRE double the odds of intracapsular cancer but increase the odds of extracapsular disease threefold to ninefold. Two case–control studies have evaluated whether DRE is associated with reduced mortality from prostate cancer, with conflicting results.

Prostate-Specific Antigen. Prostate-specific antigen is a unique glycoprotein produced by both benign and malignant prostate epithelial tissue. Measurement of PSA can clearly find more cancers than DRE alone. Because a number of assays are commercially available, physicians should know which assay is used by their local laboratory. Elevations can be seen after cystoscopy, acute urinary retention, or prostate trauma (such as a needle biopsy or prostatectomy), or with infection (especially prostatitis). DRE does not raise the PSA level; however, ejaculation may cause minor increases for a day or two. BPH can also produce modest PSA elevations, and separating BPH from early prostate cancer is a major clinical problem with PSA screening.

Test Characteristics. The true *sensitivity* and *specificity* of PSA measurement are unknown, as generally only men with suggestive results undergo biopsy. Gann and colleagues indirectly estimated the sensitivity of PSA to detect cancers ultimately destined to present clinically at 50% to 75%, with a specificity of about 90%; specificity deteriorates among older men or men with symptoms suggesting BPH. The predictive value of an elevated PSA level (above 4 ng/mL) for prostate cancer is about 30%, regardless of age (rising prevalence cancels the effect of decreasing specificity with age).

Prostate-Specific Antigen Derivatives. Prostate-specific antigen derivatives such as an *age-specific biopsy threshold* and *PSA rates of change over time* (i.e., the *"PSA velocity"*) have been proposed to separate men with early prostate cancer from those with BPH more effectively. Some aggressive urologists have begun to perform biopsies in all men with PSA levels above 2.5 ng/mL, finding cancer in 10% to 20% of men with levels of 2.6 to 4.0 ng/mL. Increases in PSA of more than 0.75 ng/mL yearly suggest cancer, but these must be based on at least three annual samples. Most recently, measurements of circulating *free PSA* (not bound to macromolecules) have been suggested for the same reason; men with higher ratios of free to total PSA are less likely to have prostate cancer. Some experts have suggested that in men with mildly elevated PSA levels (in the range of 4.0 to 10.0 ng/mL), biopsies need not be performed if free PSA comprises more than 25% of total PSA. However, the probability of prostate cancer in men with these ratios still appears to be about 10%. Given the lack of evidence regarding the benefit of screening with total PSA, no one of these modifications can be recommended over another. Similarly, recommendations for annual PSA screening are arbitrary.

Outcomes. No randomized trials have documented a *mortality* reduction from PSA screening. A recently published trial revealed no reduction in prostate cancer mortality among residents of Montreal randomized to screening; however, only a small percentage of men accepted the screening invitation. Among these men, mortality was lower, but self-selection for testing may have been an important source of bias. Advocates of PSA screening point out that there is also *no* convincing evidence that early detection programs do not reduce prostate cancer mortality. As a result, groups like the American College of Physicians recommend presenting the potential benefits and known risks of PSA screening to patients, and helping them reach an informed decision about whether or not to undergo PSA testing. At minimum, patients undergoing PSA screening should be informed that false-positive and false-negative PSA test and biopsy results can occur, and that no one knows whether regular PSA screening will reduce the risk of death from prostate cancer. However, even advocates of early detection and aggressive treatment doubt its value, at least in terms of reducing mortality, in men who have less than a 10-year life expectancy, or who are about age 75 or older with average comorbidity.

Transrectal Ultrasonography. Transrectal ultrasonography of the prostate is no longer widely promoted as a primary screening test because of poor sensitivity and specificity. It is, however, used to evaluate abnormalities found on DRE and PSA screening and to guide transrectal biopsy by identifying suspect hypoechoic areas. The yield from biopsy depends on the number of samples obtained. When the results of a rectal examination and PSA measurement are both negative, the positive predictive value of ultrasonography drops to 5% or less. Because of the limited sensitivity of TRUS, urologists usually systematically obtain six or more biopsy specimens from men with an elevated PSA level when no hypoechoic areas are seen.

CONCLUSIONS AND RECOMMENDATIONS

- Evidence regarding DRE screening for prostate cancer is conflicting. Many clinicians, however, simply consider the DRE an extension of a thorough physical examination of older male patients.
- If a prostatic abnormality on DRE is identified in a younger patient or an older patient without significant comorbid disease who would be eligible for curative treatment, a urologic referral for biopsy should be made. A normal PSA result does not exclude cancer in the presence of a palpable abnormality.
- PSA measurement can be considered at the age of 50 (and perhaps at age 40 among men at higher-than-average risk, such as those with a positive family

history). However, because there is no evidence that such screening reduces long-term mortality, screening is optional. Patients should understand the pros and cons of screening before undergoing the test.

- When to proceed to biopsy is controversial; a PSA threshold of 4.0 ng/mL is commonly used.
- Screening periodicity has not been established, but repeating the PSA measurement at 1- to 2-year intervals is probably reasonable (the longer interval should be used when the initial PSA level is lower). Early detection efforts are not indicated for men with a life expectancy of less than 10 years.
- Routine TRUS is no longer recommended as a primary screening test; its main role is in the evaluation of abnormalities found on DRE or PSA measurement.

CHAPTER 127 SCREENING FOR ASYMPTOMATIC BACTERIURIA AND URINARY TRACT INFECTION

Efforts to detect and treat asymptomatic bacteriuria are based on the assumption that treatment reduces the likelihood of subsequent morbidity from symptomatic infection, sepsis, or chronic renal disease. The risk for such complications depends on the clinical situation, including the age and sex of the patient. For some, risk is well defined and treatment is indicated; for most, however, the most significant morbidity may be related to the side effects of inappropriate treatment. It is therefore critical that the physician appreciate the implications of bacteriuria in different settings.

EPIDEMIOLOGY AND RISK FACTORS

The prevalence of bacteriuria depends on age and sex. Among neonates, positive cultures are found in about 1% of both boys and girls. During school age, the prevalence among boys is as low as 0.03%, in comparison with 1% to 2% among girls. The prevalence among women increases by 1% of the population per decade; throughout the childbearing years, the prevalence is 2% to 4%, and by age 50, it has reached 5% to 10%. Elderly men are almost as likely to have bacteriuria as women because of the high incidence of prostate and other urologic disease and subsequent instrumentation in this group. Prevalence in these older age groups reaches 15%.

The greater susceptibility of younger women and girls can be explained anatomically in that a short urethra allows easier access to the bladder, so that colonization by perineal organisms is facilitated. Risk increases with local trauma associated with sexual activity and relaxation of the pelvic supporting structures with age. Anatomic changes may also explain the higher prevalence of bacteriuria (4% to 7%) among pregnant women. Alternatively, because users of birth control pills also have an increased risk, the higher prevalence may also reflect estrogen-mediated dilation of the urethra.

The prevalence of bacteriuria is even higher in diabetic women. The relative risk for bacteriuria among women with diabetes, in comparison with nondiabetic women, is approximately 3. The risk among diabetic men is not increased.

It must be kept in mind that prevalence figures indicate the extent of bacteriuria at a single point in time. Because risk factors are shared by many and bacteriuria frequently resolves spontaneously as well as after therapy, the cumulative prevalence of bacteriuria is higher. By age 30, approximately 25% of women have experienced symptoms consistent with urinary tract infection.

Structural abnormalities (including obstruction of the urethra or ureters), significant vesicourethral reflux, neurologic lesions, and the presence of foreign bodies are important additional risk factors for bacteriuria.

NATURAL HISTORY OF ASYMPTOMATIC BACTERIURIA AND EFFECTIVENESS OF THERAPY

Asymptomatic and symptomatic urinary tract infections have the same epidemiologic correlates. Asymptomatic infections can become symptomatic; bacteriuria can persist after symptoms have resolved. Ninety percent of women with bacteriuria have had symptoms some time in the past, nearly 70% within the preceding year. Although both asymptomatic and symptomatic infections can resolve spontaneously, the urine is more likely to become sterile after treatment. Approximately 80% of women with bacteriuria have sterile urine after appropriate antibiotic treatment. However, follow-up studies indicate that only 55% of those treated will have sterile urine at the end of 1 year. Sterile urine developed spontaneously in fully 36% of untreated bacteriuric women during the same period. Significantly, women who had recurrences of infection after treatment were more likely to have associated symptoms than those who had persistent or relapsing bacteriuria. Symptomatic infection recurs within 3 years in 40% of women.

The importance of chronic or recurrent bacteriuria as a cause of chronic renal failure has been deemphasized as diverse noninfectious etiologies for the pathologic findings of interstitial nephritis have been recognized. Patients with bacteriuria are more likely to be hypertensive. They are also more likely to have identifiable abnormalities on intravenous pyelogram, including small kidneys, delayed excretion, caliceal dilation and blunting, ureteral reflux, stones, and other obstructive lesions. However, chronic renal failure rarely occurs as a complication of urinary tract infection in the absence of structural abnormalities. Evidence indicates that such abnormalities predispose patients to both chronic renal failure and recurrent infection. Definitive studies that address this important question have not yet been performed.

In addition to symptomatic urinary tract infection and chronic renal disease, the clinician must also be concerned with the possibility that chronic asymptomatic infection is a potential source of disseminated infection, such as endocarditis. This danger is particularly likely in the male patient with prostate disease and infection who requires instrumentation. Bacteremia has been documented in as many as 50% of male patients whose urine is infected at the time of the procedure; it is relatively rare when the urine is sterile. In elderly populations, asymptomatic bacteriuria has been associated with increased mortality. Obviously, such increased rates may be a consequence of either bacteriuria or other factors that increase the risk for both bacteriuria and death. Recent evidence suggests the latter; studies among among elderly women and men have found no difference between patients with and without bacteriuria when comorbidity such as cancer was controlled.

Special risks are associated with bacteriuria during pregnancy. Asymptomatic bacteriuria, defined by repeated recovery of more than 10^5 colony-forming units per milliliter in voided urine or suprapubic aspirates positive for bacteria, occurs in approximately 5% of pregnancies. In one study, the risk for onset of bacteriuria was greatest between weeks 9 and 17 of gestation. Among women with bacteriuria identified early in pregnancy, the incidence of acute pyelonephritis without prophylactic treatment is 40%. Women with bacteriuria are nearly twice as likely to deliver low-birth-weight infants, and the relative risk for perinatal mortality in their infants has been estimated at 1.6. Randomized trials of treatment of asymptomatic bacteriuria during pregnancy have demonstrated efficacy in reducing the incidence of pyelonephritis and delivery of low-birth-weight infants.

SCREENING AND DIAGNOSTIC TESTS

Asymptomatic bacteriuria is a laboratory diagnosis that requires careful definition. Because voided urine is easily contaminated by urethral and (in women) perineal flora during micturition, clean voided urine must be cultured quantitatively. The probability of infection when a specimen contains 10^5 colony-forming units per milliliter is nearly 100% for male patients but only 80% for female patients. The finding of two such positive cultures in a female patient increases the probability of infection to 95%. False-negative findings are more likely if the patient is undergoing vigorous diuresis, if the urine is unusually acidic (pH 5.5), or if the specimen has inadvertently been contaminated with antibacterial detergents. Spurious positive cultures are more common because of unclean collection technique, contaminated collection equipment, or failure to culture the urine promptly.

Collection of a single urine specimen with 10^5 colony-forming units per milliliter during urethral catheterization has a predictive value of infection of 95%. Catheterization should be limited to patients requiring relief of obstruction or those who absolutely cannot cooperate with collection techniques. The risk of introducing infection during catheterization may be as high as 5%. The risk of inducing bacteremia in men with an infected urinary tract approaches 50%. When suprapubic percutaneous bladder aspiration is performed, either in young children or in adults with confusing problems that must be resolved, infection can be presumed if growth of any bacteria other than skin contaminants occurs.

Nonquantitative approaches to diagnosis include microscopic examination for bacteria and clinical tests of bacterial activity, such as the reduction of nitrate to nitrite. Dipstick nitrite testing for bacteriuria has been shown to have a sensitivity of better than 90%, but specificity is limited and variable, ranging from 35% to 85% in different studies. This variation may be explained by differences in the prevalence of bacteria that do not reduce nitrates and variation in the time interval between collection and testing of urine. Dipstick tests for leukocyte esterase activity as a marker of pyuria are more sensitive but less specific. Reported sensitivity of the leukocyte esterase dipstick test for bacteriuria ranges from 72% to 97%; the reported range for specificity is 64% to 82%. Dipstick tests have been shown to be less sensitive when the prior probability of infection is low based on clinical findings. These and other nonspecific signs of urinary tract inflammation, such as the presence of microscopic pyuria or hematuria and the presence of proteinuria, may be helpful in making a presumptive diagnosis in the symptomatic patient. They may also

indicate the need for urine culture when incidental abnormalities are detected in the asymtomatic patient. Confirmation of infection with quantitative culture technology should precede a therapeutic decision in the absence of symptoms.

CONCLUSIONS AND RECOMMENDATIONS

- Bacteriuria, both symptomatic and asymptomatic, is a common phenomenon with well-defined risk factors.
- Treatment is moderately effective in the short run, but because of high rates of spontaneous recurrence and resolution, the likelihood that bacteriuria will be noted with longer follow-up is not significantly influenced by short-term therapy.
- Symptomatic infections are generally not prevented by the treatment of asymptomatic bacteriuria in nonpregnant women.
- Although an association exists between bacteriuria and renal abnormalities, there is no evidence that this is an etiologic relationship. Furthermore, there is no evidence that treatment of infection in the absence of urinary tract abnormalities prevents progressive renal disease.
- Screening for asymptomatic bacteriuria is recommended only in selected high-risk populations, including (a) pregnant women; (b) elderly men with clinical prostatism or other urologic abnormalities, before and after required instrumentation; (c) all patients recently catheterized; and (d) patients with known renal calculi or other structural abnormalities of the urinary tract.
- Screening with reagent strips is not sufficiently sensitive to be used among patients who are at high risk and likely to benefit from detection and treatment. Screening of pregnant women should include urine culture.

CHAPTER 128 SCREENING FOR CANCERS OF THE LOWER URINARY TRACT

Lower urinary tract cancers include tumors of the renal pelves, ureters, bladder, and urethra. These lesions can logically be considered together because of their similar cell types—more than 95% consist of transitional cells, squamous cells, or a combination of the two—and because of common epidemiologic correlates.

Cancer of the lower urinary tract is viewed by many primary physicians as a relatively benign tumor that principally affects the elderly. Nevertheless, more than 50,000 new cases occur each year in the United States, and 11,000 deaths per year can be attributed to bladder cancer. The lifetime probability of incurring cancer of the bladder is approximately 3% for white men and 1% for white women. The probability of dying of bladder cancer, however, is approximately 1% and 0.3% for white men and white women, respectively.

Risk factors, including a strong association with occupational exposure, have been well defined. A weaker association with tobacco use has more recently been demonstrated. A prospective study of fluid intake and development of bladder cancer during 10 years suggests that a high intake of fluids decreases risk. Screening tests are available. Although the natural history of bladder cancer is still insufficiently understood to allow specific screening recommendations, the physician should understand the epidemiology of these tumors and the potential costs and benefits of various screening practices.

EPIDEMIOLOGY AND RISK FACTORS

Cancer of the lower urinary tract is a tumor of older age groups; in the United States, the mean age at the time of diagnosis is 68 years. The incidence increases at a constant rate during adult life, varying from 1 in 100,000 per year at age 20 to 200 in 100,000 per year at age 80 for white men. Women have approximately one-third the risk of men. In the United States, whites are twice as likely to have bladder tumors as nonwhites. Urban dwellers, too, have consistently been shown to have a higher incidence of lower urinary tract tumors than do people who live in rural or suburban areas.

The most notable risk factor for the development of lower urinary tract cancers is *occupational exposure* to aromatic amines, first noted in England in 1895. Subsequently, dyestuff workers were shown to have a 10- to 50-fold increased risk for bladder carcinoma. Compounds most closely associated with bladder carcinogenesis include 2-naphthylamine and benzidine. Recent case–control studies indicate excess risk among men who work with dyestuffs, rubber, leather, paints, and organic chemicals. It has been estimated that these occupational exposures are responsible for 18% of bladder cancer cases. As little as 2 years' exposure may be sufficient to increase the risk, but the time between exposure and subsequent cancer may be as long as 45 years.

Smoking has been implicated as a risk factor for bladder cancer in many studies, most of which indicate that smokers have a twofold increase in risk in comparison with nonsmokers. Other suggested risk factors include pelvic irradiation, which was used in the past for dysfunctional bleeding, and abuse of phenacetin-containing analgesics. Early case–control studies suggested an association with coffee consumption, but the weight of evidence does not support a significant increase in risk.

Because direct contact of the bladder urothelium with carcinogens excreted in the urine may contribute to bladder cancer, it has been hypothesized that a high consumption of fluids could reduce risk by diluting the urine or reducing contact time. Evidence has been inconsistent, but the largest prospective study suggests that men in the highest quintile of fluid consumption face about half the risk of those in the lowest quintile. Case–control and cohort studies also suggest that long-term use of diuretics may increase the risk for bladder cancer by as much as twofold.

NATURAL HISTORY OF LOWER URINARY TRACT CANCERS AND EFFECTIVENESS OF THERAPY

The natural history of lower urinary tract tumors is not well defined. The prognosis at the time of diagnosis depends on both clinical stage, defined by depth of penetration and extent of metastases, and histologic grade of the tumor. Depth of penetration and histologic grade are often closely correlated. Urothelial tumors are grossly subdivided into papilloma, papillary carcinoma, and transitional cell carcinoma. These gross morphologic distinctions have histologic counterparts that are highly predictive of 5-year survival. Grade 1 papillary carcinoma (papilloma) has a 5-year cure or clinical control rate of approximately 95%. Grade 2 papillary carcinoma (papillary carcinoma) has a 5-year survival rate of only 25%. The outlook for grade 3 papillary and infiltrating carcinoma (transitional cell carcinoma) is worse. The prognosis for patients with squamous carcinoma is also very poor unless the tumor is well differentiated. Clinical staging systems that distinguish between levels of tumor penetration of the bladder have also been shown to have good prognostic value. Overall, about 50% of patients with treated bladder cancer survive for 5 years. However, multiple synchronous and asynchronous tumors are the rule in lower urinary tract cancer and contribute to morbidity and eventual mortality.

Hematuria is the most common presentation of lower urinary tract cancer. Other symptoms suggestive of cystitis may also occur. Although it has been claimed that 75% of tumors promptly diagnosed after a first episode of hematuria are localized, few data on this subject are available. The likelihood that screening tests, including urinalysis and urinary cytology, would significantly advance the time of diagnosis is likewise unproven. A progression from urothelial atypia to sessile carcinoma in situ or papilloma to higher-grade malignancy has been postulated. Studies of the natural history of urothelial carcinoma in situ indicate that the majority of lesions progress to more malignant forms. Although early lesions are much less likely to be detected cytologically, 3.7% of detected tumors were *in situ* in one study. The usual synchronous and asynchronous multiplicity of such tumors makes it difficult to assess the benefits of early detection.

SCREENING TESTS

Efforts to screen for asymptomatic bladder cancer have focused on the detection of asymptomatic hematuria with urine dipsticks and urine cytology. Studies of dipstick urinalysis have been conducted in older men at increased risk for bladder cancer. Daily screening for 2 weeks or 10 serial screens conducted on a daily or weekly basis have produced at least one positive screen result in about 205 men. The predictive values positive for any urologic malignancy (bladder, prostate, or renal) in these two studies were 6% and 8%. One-time screening in general outpatient populations has a significantly lower yield and predictive value. In one such study, dipstick screening of more than 20,000 patients disclosed only one bladder cancer and two cancers of the prostate. In a second study, only 2% of patients with a positive screen result had any significant urologic disease. The predictive value for urologic cancer diagnosed anytime in the ensuing 3 years was 0.5%.

Urinary cytology is less sensitive but more specific than hematuria on dipstick as a screening test for lower urinary tract cancers. Reported rates of the sensitivity of cytology in detecting bladder carcinoma vary from 50% to 90%. Studies have consistently demonstrated that sensitivity increases with the grade of malignancy. Although invasive transitional cell carcinoma can regularly be detected with a sensitivity of 90% or greater, sensitivity rates for papillomas and papillary carcinomas range from zero to 50%.

Studies of cytologic screening of high-risk populations have been conducted. In one such study, screening of 285 exposed workers produced positive results in 31, 10 of whom had the diagnosis of cancer confirmed at cystoscopy. Within 4 years, 11 additional tumors developed among the 21 cytology-positive, cystoscopy-negative patients. Cystoscopy was also performed in the 254 workers with negative cytologic findings; only one case of bladder cancer was diagnosed on that examination. In general, the specificity of urinary cytology depends on the skill of the cytologist. False-positive rates as low as 1% and as high as 20% have been reported.

The value of other urinary sediment abnormalities, particularly hematuria, has not been well defined. In one study of cytologic detection, hematuria was absent in 50% of true-positive cytologic diagnoses.

Cystoscopy and radiographic procedures cannot be considered screening tools. They should be reserved for patients who present with symptoms suggestive of urinary cancer or who have positive findings on cytology. Frequent follow-up cystoscopy is also part of the postoperative care of the patient with bladder cancer.

CONCLUSIONS AND RECOMMENDATIONS

- Lower urinary tract cancer is associated with significant morbidity and mortality.

- Risks of occupational exposure to dyestuffs, rubber, leather and leather products, paint, and organic chemicals have been well defined. Smoking is also associated with a significant increase in risk.
- High levels of fluid intake may reduce the risk for bladder cancer.
- Urinary cytology is an imperfect but useful screening test for high-risk groups.
- There is no evidence that screening significantly advances the time of diagnosis in an individual case or that early treatment influences the outcome. Nevertheless, because of the relatively high specificity and lack of morbidity associated with cytologic screening, identification of patients at high risk because of occupational exposure, with subsequent yearly cytologic screening, may be indicated in the occupational health setting. Screening of asymptomatic smokers without risk of occupational exposure is not recommended.

CHAPTER 129 EVALUATION OF THE PATIENT WITH HEMATURIA

LESLIE S.-T. FANG

Virtually every disease of the genitourinary tract can produce hematuria. The primary physician may encounter a patient with gross hematuria or may find microscopic hematuria on routine examination of the urine. Sometimes, the cause is a harmless condition, especially when asymptomatic microscopic hematuria occurs in an otherwise healthy, young patient. At other times, hematuria may be the only symptom of genitourinary neoplasia. Its presence demands careful consideration and often a thorough investigation to ascertain the underlying cause. One needs to be able to initiate an effective workup and decide how comprehensive and invasive it ought to be; this includes deciding when referral for urologic evaluation or renal biopsy is necessary.

PATHOPHYSIOLOGY AND CLINICAL PRESENTATION

Normally, fewer than 1,000 red blood cells are excreted in the urine each minute. Microscopic hematuria ensues if the rate of excretion rises to 3,000 to 4,000 red blood cells per minute; two to three red blood cell per high-power field will appear on microscopic examination of the urine. If the excretion rate exceeds 1 million red blood cells per minute, macroscopic or gross hematuria will result. Definitions of clinically significant hematuria are somewhat arbitrary; however, more than eight red blood cells per high-power field is considered a reasonable cutoff for separating the likelihood of a benign cause from that of potentially serious disease.

Any intrinsic lesion within the genitourinary tract involving the kidneys, ureter, bladder, prostate, or urethra can produce hematuria. Hematuria may also result from periurethral problems in the pelvis or colon, systemic diseases, bleeding diatheses, and the use of certain drugs (e.g., cyclophosphamide).

Symptoms associated with hematuria may provide important clues to etiology. The flank pain of renal colic is usually secondary to renal calculi but may occasionally be associated with the passage of clots. Frequency, dysuria, urgency, and suprapubic pain occur with inflammatory lesions of the lower urinary tract. Dull flank pain with fever and chills may accompany pyelonephritis (see Chapter 133).

Occasionally, complaints such as fever, rash, or joint pains may indicate an underlying systemic disease. Uncommonly, hematuria occurs without any associated symptoms, although the majority of cases have a definable cause. When a thorough workup fails to reveal one, the patient is said to have "essential hematuria." Renal biopsy of such patients often shows minimal glomerular or interstitial disease. The long-term prognosis of these patients is excellent.

DIFFERENTIAL DIAGNOSIS

Intrinsic genitourinary lesions involving the kidneys, ureters, bladder, prostate, and urethra can all produce hematuria (Table 129.1 and Table 129.2). Gross hematuria is most commonly associated with infections and neoplasms. Microscopic hematuria is most commonly associated with infection and benign prostatic hypertrophy. The prevalence of serious underlying disease (e.g., cancer, polycystic disease) in community-based study of asymptomatic microscopic hematuria is 0.1%, in comparison with 10% in referred populations. Even among high-risk groups (e.g., older men), the prevalence in community-based study is only 5%.

Essential hematuria	44.0

From Greene LF, O'Shaughnessy EJ Jr, Hendricks ED. Study of 500 patients with asymptomatic microhematuria. JAMA 1956;161:610, with permission.

Table 129.2. Diagnosis in 500 Referred Cases of Asymptomatic Microscopic Hematuria

Rarely, periureteral inflammatory lesions in the appendix, colon, or pelvic structures produce microscopic hematuria. On occasion, a systemic illness such as lupus erythematosus, bacterial endocarditis, or rheumatic fever is the source of hematuria. Blood dyscrasias (e.g., hemophilia, sickle cell disease, polycythemia vera, and leukemia) and hemorrhagic disorders (e.g., thrombocytopenic purpura and various coagulation defects) can be responsible for red cells in the urine.

Drugs such as anticoagulants, salicylates, methenamine preparations, and sulfonamides have been known to cause hematuria. Cyclophosphamide can induce hemorrhagic cystitis or microscopic hematuria (see Chapter 88). Hematuria in a patient on anticoagulants requires evaluation because an underlying urologic lesion is often found (see Chapter 83).

Fever, strenuous exercise, and long-distance running are among the harmless causes of microscopic hematuria in otherwise healthy patients.

Conditions occasionally mistaken for hematuria include menstrual bleeding and the intake of substances that can darken the urine, such as beets, rhubarb, and the drugs phenazopyridine (Pyridium) and rifampin.

WORKUP

The appropriate workup depends on whether the patient has macroscopic hematuria or asymptomatic microscopic hematuria, on the age and sex of the patient, and on the mode of clinical presentation. As indicated in the previous section, the likelihood of finding a significant genitourinary tract disease is higher in patients with macroscopic hematuria, particularly in older men. Asymptomatic microscopic hematuria in young adults, on the other hand, carries a much lower risk. Evidence from five population-based studies indicates that 1% to 5% of children and adults will show evidence of microhematuria on routine urinalysis and that fewer than 2% of these patients will have a serious and treatable urinary tract disease. However, the incidence of urinary tract cancers rises dramatically with age and is more than twice as high in men as in women. An investigation of microscopic hematuria in the older male patient should therefore be pursued.

History is of paramount importance in narrowing the scope of the workup. A history of trauma ought to direct attention to possible renal, ureteral, or urethral injury. Massive hematuria is usually associated with bladder neoplasm, benign prostatic hyperplasia, or trauma. The passage of large, bulky clots implicates the bladder as the source, whereas long, shoestring-shaped clots suggest a ureteral origin. A past history of analgesic excess makes analgesic nephropathy a possibility. A prior history of nephritis requires consideration of chronic nephritis as the basis of the hematuria. A family history of renal diseases may suggest polycystic kidney disease or hereditary nephritis. Benign familial hematuria has been described and is inherited in a pattern consistent with autosomal dominant transmission; checking for hematuria in relatives may avoid an extensive workup in otherwise healthy-appearing patients. Harmless, self-limited forms of microscopic hematuria are suggested by a recent history of strenuous exercise, long-distance running, or a minor febrile illness.

Physical Examination should include observation of any fever, hypertension, rash, purpura, petechiae, friction rub, heart murmur, or joint swelling. The presence of hypertension suggests renal parenchymal disease. The abdomen has to be examined carefully for enlargement of one or both kidneys, liver, or spleen. Thorough examination of the prostate in the male patient and the pelvis in the female patient is essential.

Laboratory Testing. A repeated urinalysis is worthwhile in patients suspected of having a self-limited or trivial cause for their hematuria, such as low-grade infection, a menstrual period, or vigorous exercise. An entirely normal result of a repeated study in a healthy young person requires no further investigation other than a follow-up urinalysis in a month or two. However, in an older patient, whose risk for malignancy is much greater, an abnormal number of red blood cells on urinalysis should be taken seriously, even if a second urine specimen is clear. A urinary tract malignancy may present in just this manner. The urine sediment should be carefully examined. The presence of white cells and bacteria favors a diagnosis of cystitis; casts of white cells imply the presence of pyelonephritis or interstitial nephritis. Red cell casts strongly suggest glomerulonephritis. The presence of dysmorphic red cells under phase contrast microscopy is also highly suggestive of a glomerular origin of the red cells. A urine specimen should be sent for routine culture when pyuria is noted (see Chapter 133). Culture for urine acid-fast bacillus needs to be obtained if sterile pyuria and hematuria persist.

The need for further workup is determined by the probability of important underlying pathology. For example, a patient over age 50 is at increased risk for urinary tract cancer; it must be ruled out. On the other hand, an otherwise healthy young patient with an unremarkable history, normal findings on physical examination, and an otherwise benign urinary sediment need not undergo invasive testing because the likelihood of malignancy or other serious pathology is low. In a major population study, the frequency of clinically significant microscopic hematuria was 2.3%, with only 0.5% of patients having bladder or renal cell carcinoma; malignant lesions were found almost exclusively in patients over age 50.

The *three-glass test* (see Chapter 139) can be performed to attempt to identify the site of the bleeding. Initial hematuria is usually associated with anterior urethral lesions, such as stenosis and urethritis. Terminal hematuria usually arises from a lesion in the posterior urethra, bladder neck, or trigone. Total hematuria is associated with lesions at the level of the bladder or above.

Renal function is checked when renal parenchymal disease is suspected. In patients with proteinuria, a *24-hour urine collection for creatinine and protein determinations* should be performed to assess renal function and assess the degree of proteinuria quantitatively. Heavy proteinuria (>3 g/24 h) is usually associated with glomerular lesions (see Chapter 130). In the presence of renal colic, the urine should be strained to detect calculi or papillae. Three first-void morning urine specimens are sent for *cytology* in patients over the age of 40 with hematuria because they are at increased risk for a neoplasm. Normal findings on cytology do not rule out a malignancy (see Chapter 128); cystoscopy is indicated if suspicion remains. *Flat plate and upright films* of the abdomen are obtained and carefully examined to ascertain renal size and detect the presence of calcification.

If these tests fail to define the origin of the hematuria, an *intravenous pyelogram with tomograms* should be performed. Renal and ureteral abnormalities can be defined accurately. A *postvoid film* should be obtained to assess the amount of postvoid residual urine, which can be used to estimate the degree of bladder neck obstruction. *Ultrasonography, computed tomography* of the body, and *magnetic resonance imaging* are useful to differentiate a solid mass from a cystic lesion if the differentiation cannot be made on nephrotomograms. *Renal angiography* is reserved for evaluation of possible renal trauma, suspected renal masses, and possible arteriovenous malformations.

If clinical evidence of glomerular disease (red cell casts, dysmorphic red cells, heavy proteinuria) is present, *immunologic studies* should be performed and a renal biopsy should be considered. The immunologic tests of diagnostic use include the following: antinuclear antibody (ANA), anti-DNA antibody, and complement levels [C3, C4, and CH50 (hemolytic complement)] for the diagnosis of systemic lupus erythematosus (see Chapter 130); antistreptolysin-O (ASLO) titer and antihyaluronidase, antistreptokinase, and complement levels for the diagnosis of poststreptococcal glomerulonephritis; serum and urine immunoelectrophoresis for the diagnosis of multiple myeloma; serum immunoglobulin A level for patients suspected of having Berger's disease (IgA nephropathy) or Henoch-Schönlein purpura; serum antiglomerular basement membrane antibody levels for patients suspected of having Goodpasture's syndrome; and antineutrophil cytoplasmic antibody (ANCA) levels for pauciimmune glomerulonephritis.

INDICATIONS FOR REFERRAL

In a patient over age 50, if a distinct lesion is still not defined or a bladder lesion is suspected, it is necessary to proceed to *cystoscopy* (see Chapter 128). The procedure is particularly useful during periods of active bleeding. Careful examination of the ureteral orifices for bleeding and biopsy of suspected lesions are essential.

Patients with evidence of glomerulonephritis should be referred to a nephrologist for consideration of *renal biopsy*, which is indicated only to establish a diagnosis that will affect the selection of therapy (see Chapter 130) and should be reserved for patients with clinical evidence of glomerular disease. Rarely, renal biopsy may be indicated if the preceding studies have not led to a diagnosis.

PATIENT EDUCATION

It is essential to impress on the older patient the necessity of a complete evaluation of hematuria. The high incidence of potentially curable neoplasms in patients over age 50 (see Chapter 143) makes thorough investigation in this group mandatory.

CHAPTER 130 EVALUATION OF THE PATIENT WITH PROTEINURIA

LESLIE S.-T. FANG

Normal persons excrete less than 150 mg of urinary protein each day; the mean is 40 to 50 mg. Excretion in excess of 150 mg/24 h is classified as clinically significant proteinuria. Causes range from benign conditions, such as exercise and orthostatic proteinuria, to glomerulonephritis with rapidly deteriorating renal function. Office evaluation is frequently prompted by an incidental finding of proteinuria on routine urinalysis. The objective of the outpatient workup is to establish the presence of significant proteinuria, search noninvasively for treatable underlying conditions, and select patients who require referral for renal biopsy.

PATHOPHYSIOLOGY AND CLINICAL PRESENTATION

Small amounts of protein (2 to 8 mg/100 mL) are normally found in the urine of healthy persons, but at a concentration below that detectable by routine methods. Two thirds of this protein is low-molecular-weight globulin of serum origin; the remainder is albumin and nonserum protein.

Significant proteinuria can occur through a number of mechanisms:

1. Increased glomerular permeability
2. Increased production of abnormal proteins small enough to pass freely through the glomerulus (e.g., Bence Jones protein)
3. Decreased tubular reabsorption (e.g., because of interstitial nephritis)
4. Lower urinary tract disease, including infection
5. Fever, heavy exertion, congestive heart failure, postural changes, and surgical trauma—all believed to affect renal blood flow

Clinical Presentations

Proteinuria can present as an isolated asymptomatic finding on urinalysis, as edema of unknown cause, or as part of the clinical picture in a patient with known renal or systemic disease.

Isolated Proteinuria. Asymptomatic patients excreting less than 1 g of protein daily and appearing otherwise healthy, with no other evidence of renal dysfunction or systemic disease, are considered to have isolated proteinuria. The urine sediment is normal. Two varieties have been described: benign, transient proteinuria and persistent, isolated proteinuria.

Benign forms are characterized by their transient nature. A *functional* variety has been observed in the context of emotional or physical stress, an acute illness, or even a bout of congestive heart failure. The proteinuria is believed to reflect physiologic changes in renal hemodynamics. Although all forms of proteinuria worsen with standing, some persons experience proteinuria only on standing; it is absent when they are recumbent. The condition is common in persons under the age of 30 (especially males) and is labeled *orthostatic proteinuria*. In many persons, the postural proteinuria resolves after a few years; in others, it remains. Long-term (20-year) follow-up studies show no development of progressive renal impairment.

Other forms of benign disease in young people include *idiopathic transient proteinuria*, characterized by an occasional positive result on dipstick testing that is unrelated to posture or stress, and *intermittent proteinuria*, in which about half of dipstick test results are positive for albumin. The former is considered a physiologic variant of normal. The latter is sometimes associated with minor abnormalities on renal biopsy, but progressive disease is rare and the condition is usually self-limited. Intermittent proteinuria in older persons carries a slightly higher risk for renal impairment.

Persistent isolated proteinuria carries a worse prognosis, although the urine sediment and renal function are entirely normal. The condition is most common in healthy young men. Mild forms of glomerular and tubular injury have been found among these patients. Long-term follow-up studies of patients with persistent isolated proteinuria reveal a 40% chance for the development of renal insufficiency, usually secondary to glomerular disease. In some instances, nephrotic syndrome may ensue. However, even when persistent and accompanied by minor glomerular changes on biopsy, the condition has an excellent prognosis provided no associated abnormalities of the urine sediment are present.

Proteinuria in the Setting of Renal or Systemic Disease. Albuminuria in excess of 1 g/24 h suggests significant renal impairment. When it exceeds 3 g/24 h, underlying *glomerular disease* is likely; lesser amounts are consistent with either glomerular or tubular dysfunction. Early in the course of glomerular injury, *microalbuminuria* (urine albumin concentration >20 mg/dL) appears. *Obstruction* and *reflux* are important treatable causes of tubular protein leakage. Glomerular injury may be caused by intrinsic renal disease or a systemic process (e.g., diabetes, systemic lupus).

Nephrotic syndrome is said to be present when more than 3.5 g of protein is excreted in 24 h and the serum albumin falls to less than 3.0 g/dL. Such heavy proteinuria usually indicates significant glomerular disease (either primary or secondary to systemic illness), but it may occur with severe tubular injury. If the serum albumin concentration drops to less than 2 g/dL, then plasma oncotic pressure may fall sufficiently to cause *edema*, typically beginning in the medial aspect of the ankles; on occasion, however, periorbital puffiness may be the principal manifestation. *Hypercholesterolemia* is a common accompaniment reflecting increased hepatic synthesis of low-density lipoprotein (LDL) and very low-density lipoprotein (VLDL) cholesterol. *Lipiduria* is a diagnostic feature of the urine sediment. A *hypercoagulable* state may ensue, believed linked to reductions in protein S (an inhibitor of thrombosis). Venous thromboembolism occurs in about 20% of cases. The source of embolization may be a clinically silent *renal vein thrombosis*. The risk for *bacterial infection* is increased in those with marked urinary loss of immunoglobulins. Excessive urinary loss of vitamin D may develop, causing *hypocalcemia* and secondary hyperparathyroidism. Other presenting symptoms reflect associated renal dysfunction or underlying systemic diseases.

DIFFERENTIAL DIAGNOSIS

Asymptomatic Proteinuria. Proteinuria without other abnormalities in an asymptomatic patient can be transient or persistent (Table 130.1). *Transient* forms include functional, orthostatic, idiopathic, and intermittent varieties. *Persistent isolated proteinuria* suggests underlying glomerular or tubular disease.

Asymptomatic–Transient
   Exercise
   Upright posture
   Lower urinary tract disease (e.g. infection)
   Fever (occasionally)
   Congestive heart failure (occasionally)
Asymptomatic–Persistent
   Idiopathic
   Fixed postural type
   Mild glomerular injury
   Mild tubular injury
Symptomatic
   Glomerular disease
   Severe tubular disease (see Table 130.3)

Table 130.1. Differential Diagnosis of Proteinuria

Symptomatic Proteinuria. As noted above, heavy proteinuria resulting in nephrotic syndrome is usually the result of either intrinsic or secondary glomerular disease (Table 130.2), but occasionally severe tubular injury is responsible (Table 130.3). About 50% to 75% of cases are associated with intrinsic glomerular disease; the remainder are associated with systemic illnesses that cause glomerular injury (e.g., long-standing diabetes mellitus, systemic lupus, amyloidosis). In adults, *membranous nephropathy* is the most common histologic abnormality seen on the biopsy specimens of patients with nephrotic syndrome. It may be idiopathic or secondary to systemic lupus, hepatitis B, cancer (breast, lung, colon), or medication (gold, penicillamine, captopril). It accounts for close to 50% of patients with idiopathic disease. *Minimal-change disease* is the glomerulopathy most common in children but is also seen in patients with Hodgkin's disease and hypersensitivity reactions to drugs such as NSAIDs. *Focal* and *segmental glomerulosclerosis* is the pathologic picture in about 25% of cases of intrinsic renal disease but is also a feature of HIV infection and IV heroin abuse. *Membranoproliferative glomerulonephritis* accounts for about 15% of patients with idiopathic disease and also occurs in the setting of infection, non-Hodgkin's lymphoma, cryoglobulinemia, and some forms of systemic lupus.

Table 130.2. Important Glomerular Causes of Nephrotic Syndrome

Table 130.3. Tubular Disorders Associated with Proteinuria

WORKUP

Confirming Proteinuria and Its Significance

Repeat *urinalysis* that includes examination of the *urine sediment* should be the initial step when proteinuria is detected by *dipstick* in a routine random urine sample. The dipstick test is specific for albumin and can detect concentrations in excess of 30 mg/dL. A single negative test result does not rule out significant proteinuria because protein excretion may be intermittent (e.g., orthostatic proteinuria), or a protein other than albumin (e.g., light chains in myeloma) can be excreted. Orthostatic proteinuria can be differentiated from more serious types by collecting a urine sample from the patient on arising and another after the patient has been continuously upright for 2 hours. False-positive dipstick reactions can be seen in patients who are dehydrated, have gross hematuria, or are receiving large doses of nafcillin or a cepha-losporin. The specific gravity should be noted along with the test results.

Detection of microalbuminuria (urine albumin concentration >20 mg/dL) is becoming increasingly important in the management of diabetes (see Chapter 102) and other conditions in which early treatment of glomerular impairment can reduce the risk for progression to renal failure. *Radioimmunoassay* is the most sensitive and specific mode of detecting microalbuminuria, but the procedure is costly and not widely available. Combined testing with a *dipstick* (e.g., Chemstrip) plus *sulfosalicylic acid* provides a high degree of sensitivity (95%) and can function well as a low-cost *screening* procedure. However, specificity is low (64%), and false-positives occur frequently with such testing. When the result will affect management, samples that test positive by screening methods can be subjected to radioimmunoassay.

Sediment examination is critical and should be performed on a freshly collected specimen. Red cell casts indicate glomerulonephritis (although the absence of erythrocytes on one sample does not rule out glomerulonephritis). White cell casts are found in pyelonephritis and interstitial nephritis. Oval fat bodies are a consequence of lipiduria in patients with nephrotic syndrome.

A confirmed urinalysis for protein should be followed by a *24-hour urine collection* to quantify the proteinuria. In addition to the urinary *albumin*, the urine *creatinine* should also be noted. The latter determination enables assessment of adequacy of collection. Depending on muscle mass, the total 24-hour urine creatinine level should be 15 to 24 mg/kg. In conjunction with a serum creatinine measurement, the urine creatinine determination can also be used to calculate the *creatinine clearance*. Recent reports indicate some progress in developing quantitative estimates of heavy proteinuria with use of a spot urine sample. For now, 24-hour collection remains necessary.

Once significant proteinuria has been established, the evaluation turns to determining whether the patient is asymptomatic or symptomatic and, if asymptomatic, whether the proteinuria is transient or persistent. If the patient is asymptomatic, several urinalyses are performed (as described above). If the proteinuria is found to be transient (especially if orthostatic or exercise-induced), then it is likely to be benign, usually occurring in young adults with no underlying renal disease. Invasive procedures and extensive workup are unnecessary. On the other hand, persistent asymptomatic proteinuria is associated with a high incidence of renal disease and warrants the same investigation as that performed in patients with symptomatic proteinuria. For such patients, a careful history and physical examination are required, followed by selected laboratory testing.

History and Physical Examination

History should begin by focusing on risk factors for glomerular disease. These include long-standing diabetes, systemic lupus, paraproteinemia, infectious disease (HIV infection, malaria, syphilis, endocarditis), medications (gold, penicillamine, NSAIDs, antibiotics, high-dose angiotensin-converting enzyme inhibitors), hepatitis B, toxin exposure (heavy metals, heroin), allergen exposure (bee sting, serum sickness), and malignancy (lymphoma, Hodgkin's disease, cancer of breast, lung, or colon). Risk factors for tubular disorders also should be sought, including analgesic abuse (especially with phenacetin-containing compounds), heavy metal exposure, family history of proteinuria, and history of pyelonephritis.

Physical Examination begins with a careful blood pressure determination.

Hypertension is a poor prognostic sign, raising the specter of significant renal impairment. The patient is also checked for vasculitic skin changes, other rashes,

retinopathy, lymphadenopathy, signs of right-sided heart failure and constrictive physiology, abdominal masses, organomegaly, stool positive for occult blood on guaiac testing, prostatic enlargement, peripheral edema, and joint inflammation.

Laboratory Studies

Several laboratory studies are helpful regardless of etiology:

- The *creatinine clearance* is the best determination of renal function, as it approximates the glomerular filtration rate. A serum creatinine and a 24-hour urine collection for urinary creatinine levels are simultaneously obtained. Random measurements of *blood urea nitrogen* or serum *creatinine* are less accurate than a clearance determination but are useful for following the patient once the creatinine clearance is known.
- The *complete blood cell count* will identify any anemia resulting from severe subacute or chronic renal insufficiency. Anemia is also present at some point in all cases of myeloma.
- The *serum albumin level* is worth monitoring because it correlates inversely with the severity of proteinuria.
- The *protein selectivity index* is useful for diagnosis and therapy in patients with nephrotic syndrome. Proteinuria is considered selective when the urine contains large amounts of proteins of low molecular weight. A high degree of selectivity in patients with nephrotic syndrome suggests minimal-change disease, which is responsive to corticosteroids (see below).
- Radiographic examination of the *kidneys, ureters, and bladder* can be used to judge kidney size, which may help to elucidate etiology (e.g., small, shrunken kidneys suggest significant chronic bilateral disease). *Renal ultrasonography* may be more accurate and informative, as it can detect cystic disease, mass lesions, and obstruction. *IV pyelography* is indicated when chronic pyelonephritis is under consideration. It also provides an estimate of individual kidney function, based on how well each concentrates and excretes the contrast material. However, when creatinine clearance is reduced by more than 75%, the kidneys may not concentrate the contrast medium sufficiently for visualization. Contrast-induced acute renal failure is a risk in patients with preexisting renal disease, especially those with diabetes or multiple myeloma.

Additional studies may prove useful when based on clinical findings, although they are not always necessary. The patient with long-standing diabetes mellitus accompanied by retinopathy, significant proteinuria, and azotemia is almost certain to have diabetic glomerulosclerosis and requires little additional workup other than exclusion of concurrent urinary tract infection or obstruction. On the other hand, in a young woman with polyarthritis, red cell casts, and heavy proteinuria, the ANA, anti-ds (double-stranded) DNA, and serum C3 and C4 complement levels should be determined. Hepatitis serology and cryoprotein determinations are useful in the patient with a history of jaundice, hepatitis B, or its risk factors. Serum and urine electrophoresis is indicated when myeloma is under consideration (elderly patient with elevated globulins, unexplained anemia). Although occult malignancy is occasionally a possible cause, a search beyond careful breast, lymph node, abdominal, and rectal examination, chest radiography, mammogram, and stool guaiac testing has not been shown to be of sufficient yield to warrant more extensive testing. Extensive testing for all possible causes of proteinuria is unlikely to be of much diagnostic value when the pretest probabilities of the conditions being tested for are low. Such indiscriminate testing is more likely to yield false-positive results (see Chapter 2).

Kidney biopsy deserves consideration when treatable disease remains a possibility but the cause continues to be elusive despite careful and thorough clinical and laboratory evaluations (see below).

INDICATIONS FOR REFERRAL

A referral for consideration of renal biopsy is indicated if the result will have important therapeutic or prognostic implications. Most causes of glomerulonephritis do not respond to therapy; thus, biopsy is of academic interest only. However, at times, it will be clinically impossible to rule out a treatable form of glomerulonephritis, and either a biopsy or an empiric course of therapy may be indicated. The advice of an experienced nephrologist is essential.

Referral is also indicated when a cause (e.g., membranous disease) potentially responsive to immunosuppressive therapy is suspected clinically. Because the morbidity associated with therapy can be high, consultation is indicated for optimal design of the treatment regimen.

PRINCIPLES OF MANAGEMENT AND PATIENT EDUCATION

Asymptomatic Proteinuria. *Transient proteinuria* is, by and large, benign. Patients should be reassured; therapy is not warranted. Patients with idiopathic and fixed orthostatic forms of proteinuria that occur as isolated findings without other associated abnormalities have been found to have an excellent prognosis in prospective studies with 5 to 20 years of follow-up.

Asymptomatic patients with *persistent isolated proteinuria* can also be followed expectantly. However, they are at greater risk for eventual development of renal impairment and should be carefully followed with annual checks of blood pressure, urine, blood urea nitrogen, and creatinine. Referral to a nephrologist for consideration of renal biopsy and treatment is indicated if the urine sediment becomes abnormal or the blood pressure begins to rise.

Symptomatic Proteinuria/Nephrotic Syndrome. Marked proteinuria associated with systemic diseases such as multiple myeloma, diabetes, or systemic lupus erythematosus is best countered by treating the underlying disease. In addition, *angiotensin-converting enzyme inhibitors* (see Chapter 26) help reduce albumin loss and preserve renal function, presumably by limiting hyperfiltration. The edema of nephrotic syndrome is aggravated by sodium retention, which can be countered by *sodium restriction* and the judicious use of loop and distally acting diuretics. Modest *dietary protein restriction* (approximately 1.0 g/kg daily) may be of benefit in slowing the course of patients with progressive renal disease. Patients for whom protein restriction is prescribed require close nutritional follow-up to ensure adequate nitrogen balance. Onset of hypercholesterolemia is initially treated with a *diet low in saturated fat and cholesterol*, but use of a lipid-lowering agent (e.g., a statin) may be necessary. If severe hypocalcemia or renal failure develops, *1,25-dihydroxyvitamin D* plus *calcium* supplementation can limit onset of secondary hyperparathyroidism (see Chapter 142). Because of an increased risk for infection, all nephrotic patients should receive the *pneumococcal* and *influenza vaccines*.

In idiopathic nephrotic syndrome, therapy also depends on the renal pathology defined by biopsy. Minimal-change disease responds to *corticosteroids* and *immunosuppressive agents*, which can enhance the already favorable rate of remission. Most patients with focal and segmental glomerulosclerosis are resistant to steroid therapy and experience renal insufficiency within 5 years of diagnosis. Some patients with idiopathic membranous nephropathy respond to high-dose, alternate-day corticosteroids with partial or complete remission of proteinuria. However, 40% undergo spontaneous remission, and steroid treatment overall confers no additional improvement in long-term renal survival. Adding an alkylating agent to the steroid regimen does little to improve outcome. Membranoproliferative disease is progressive, ending in renal failure in about 50% of cases. Treatment appears to have little impact on renal survival.

CHAPTER 131 EVALUATION OF SCROTAL PAIN, MASSES, AND SWELLING

A mass, generalized enlargement, or acute pain involving the scrotum may be noted by the patient or discovered incidentally on physical examination. Patients with scrotal complaints are often concerned about loss of sexual function and the possibility of cancer. The primary physician needs to be able to recognize torsion and epididymitis promptly and to differentiate benign masses from those suggestive of testicular malignancy, which require referral for urologic evaluation.

PATHOPHYSIOLOGY AND CLINICAL PRESENTATION

Testicular Cancer. Almost all testicular neoplasms are malignant and of germ cell origin. Fortunately, these tumors are uncommon, accounting for fewer than 1% of all deaths from neoplasms in men. However, testicular cancers are the most common malignancy in male patients ages 15 to 35, with an estimated incidence of 3 in 100,000. Incidence is increased in those with an undescended testicle and remains high even if orchiopexy is performed or the testicle is removed; the risk seems to be genetically determined. Peak incidence occurs between ages 20 and 40. In patients over age 60, testicular lymphoma is the most common testicular malignancy.

Typically, the tumor presents as a hard, heavy, firm, nontender testicular mass that does not transilluminate, but sometimes it is smooth or even resilient in nature, so that it is mistaken for a benign lesion even though it blocks transmission of light. Although these lesions are usually painless, about 20% cause some discomfort in the scrotum, and frank pain may be reported and tenderness noted, especially if hemorrhage into the tumor is present. Metastasis to the retroperitoneum may cause vague pain in the back or abdomen. Spread to the chest can lead to dyspnea, cough, or hemoptysis. A palpable left supraclavicular node or epigastric mass may be noted. On occasion, extensive metastasis occurs with little evidence of the primary tumor. The metastatic lesion may be histologically different from the primary lesion. A few of these malignancies produce chorionic gonadotropin or estrogen and are associated with gynecomastia (see Chapter 99).

Nonmalignant Testicular Disease. *Testicular torsion* presents with acute pain and a firm tender mass in a young patient. The intense pain may be associated with nausea and vomiting and may be confused with an abdominal process. The condition is mostly one of adolescent boys and young men. A history of recurrent episodes of testicular pain is often present. The testicle dangles within an abnormally enlarged tunica, likened to the clapper of a bell. An attack can come on during sleep; there need not be a history of antecedent trauma. *Testicular trauma* produces acute testicular pain and swelling similar to that associated with torsion or infection. It does not predispose to cancer. *Mumps orchitis* is usually seen 7 to 10 days after parotitis; most often, it is unilateral and accompanied by fever, swelling, pain, and tenderness. On occasion, parotitis is absent. The condition is more common in adults than in children.

Cystic and Vascular Scrotal Masses. Cystic masses containing fluid or sperm often develop spontaneously. They are slow-growing and usually painless, and they may be large and fluctuant. *Hydroceles* are cystic accumulations of clear or straw-colored fluid within the tunica vaginalis or processus vaginalis. *Epididymal cysts* are common and benign. *Spermatoceles* are intrascrotal cysts containing sperm that derive from the small tubules of the epididymis. The space between the testicle and tunica vaginalis may also fill with fluid secondary to impaired drainage or inflammation.

Varicoceles arise from incompetent venous valves. They occur on the left in 97% of cases because the left spermatic vein empties directly into the renal vein and considerable hydrostatic pressure is transmitted into the scrotum when the valves are incompetent and the patient stands. A right-sided varicocele may occur in the context of venous obstruction or renal carcinoma. Varicoceles have a "bag of worms" appearance and are usually nontender; they decrease in size when the patient is recumbent.

Epididymitis. In men under age 35, epididymitis may occur as a consequence of gonococcal or chlamydial infection. *Ureaplasma* infection has also been implicated. Being a sexually transmitted disease, it may be accompanied by symptoms of urethritis (dysuria, discharge). In older men, the cause is more likely to be prostatitis, recent urinary instrumentation, or a structural lesion. Epididymitis can occur with carcinoma of the testes. Initially, tenderness and swelling are confined to the epididymis, but as the condition progresses, the inflammation may spread to the adjacent testicle, making for a large, ill-defined, tender scrotal mass.

Nontesticular Intrascrotal Malignancies are rare and usually firm, and they do not transilluminate, which differentiates them from benign extratesticular scrotal pathology.

Inguinal Herniation can lead to scrotal enlargement and discomfort as bowel tracks through the inguinal canal and pushes down into the scrotum.

Referred Pain. Extrascrotal sources can cause scrotal pain by stimulating one of the nerves (genitofemoral, iliofemoral, or posterior scrotal) supplying the scrotum. Scrotal examination is unremarkable.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis can be considered in terms of the clinical presentation. A clearly extratesticular, soft scrotal mass that transilluminates may be represent a hydrocele, spermatocele, epididymal cyst, or even generalized edema. A "bag of worms" presentation is characteristic of a varicocele. A tender, inflamed extratesticular mass is likely early epididymitis. Acutely painful testicular swelling may represent epididymitis, orchitis, torsion of the spermatic cord, trauma, or hemorrhage into a testicular cancer. A firm, nontender, testicular nodule that does not transilluminate represents carcinoma until proven otherwise. A malignancy also has to be considered in the setting of a nontransilluminating extratesticular nodule, although benign etiologies are more common.

An extrascrotal source is suggested by pain in the absence of scrotal pathology. Causes include abdominal aortic aneurysm, ureteral colic, retrocecal appendix, retroperitoneal cancer, and prostatitis.

WORKUP

Because testicular cancer and testicular torsion are serious but potentially curable diseases, they are prime, must-not-miss considerations in young men who present with a complaint referable to the scrotum or testicles. Epididymitis is similarly curable and important to recognize because it may represent sexually transmitted disease.

History should include inquiry into the acuteness of symptoms, duration, clinical course, tenderness, recent trauma, urethral discharge, dysuria, fever, inguinal herniation, and concurrent infection (e.g., mumps, gonorrhea, prostatitis). A complaint of scrotal heaviness is common but nonspecific, found in conditions ranging from tumor to hydrocele and epididymitis. The patient's age is worth noting because testicular cancer is a disease of men under the age of 40 and torsion is most common among adolescents and young men. A history of an undescended testicle raises the possibility of testicular cancer. Vague abdominal, back, or chest complaints should not be dismissed because they may herald the onset of metastatic testicular cancer. Recurrent episodes in a young person suggest torsion (see below). Concurrent flank pain, abdominal pain, prostatitis, or known extratesticular cancer suggests an extrascrotal source, especially in the absence of scrotal pathology on physical examination.

Physical Examination. The key elements of the examination are careful palpation of the scrotal contents and transillumination of any palpated mass. One should try to assess whether a lesion is cystic or solid, testicular or nontesticular. During inspection, the examiner should note any erythema, masses, hernias, or varices. To palpate the scrotal contents properly, one stands to the side and uses both hands, one to support the testicle and the other to feel and identify each structure, beginning with the uninvolved side. The head of the epididymis is usually situated above the testis; the body and tail run posteriorly. All are separately palpable from the testis. The normal testicle is freely movable and uniform in consistency. It is checked for abnormalities that may provide clues to disease on the involved side, such as horizontally oriented "bell clapper" mobility in a person at risk for torsion. The scrotal structures are identified and examined for tenderness, warmth, swelling, and nodularity. If a mass or nodule is found, one attempts to determine if it is testicular or extratesticular and if it feels solid or cystic. The inguinal canal is examined

for a hernia.

Transillumination with a penlight in a darkened room is necessary to help determine whether the lesion is cystic or solid. Cystic lesions allow transmission of light in most instances, although a bloody exudate may not. A mass that appears extratesticular and cystic is most likely benign and either a spermatocele, a cyst of the epididymis, or hydrocele. If it is hard, does not transilluminate, or is reported to be steadily growing, tumor must be considered, and urologic evaluation is necessary even if the mass appears to be extratesticular.

In patients suspected of having a testicular tumor, a careful check of the supraclavicular lymph nodes, chest, and abdomen is needed because more than 50% present with metastatic disease. In addition, the breasts are examined for gynecomastia. (Inguinal adenopathy does not suggest testicular cancer because the testicular lymphatics drain into the paraaortic nodes. Scrotal nontesticular lymphatics drain into the inguinal nodes.)

A tender scrotum in the absence of a mass, redness, increased warmth, or swelling should trigger a look for extrascrotal pathology. Careful examination of the abdomen for signs of appendicitis, aneurysm, and inguinal hernia is warranted, as is a check of the prostate and flanks for tenderness.

Laboratory Studies. When a mass is noted or uncertainty persists, *testicular ultrasonography* is helpful in determining whether the lesion is testicular or extratesticular, solid or cystic. Measurement of human chorionic gonadotropin and a- *fetoprotein* levels is more useful for monitoring testicular cancer than for diagnosis (see Chapter 143), but a marked elevation in either is suggestive. Unfortunately, sensitivity is low; a negative study does not rule out cancer. If metastatic disease is suspected, *chest radiography* and *abdominal computed tomography* are performed as part of the staging process.

A *urinalysis* is helpful for detection of pyuria or bacteriuria in cases suggestive of an infectious process. Semen analysis should be performed only when infertility is a concurrent complaint. A right-sided varicocele or suddenly appearing left-sided varicocele requires further evaluation because of the possibility of venous obstruction or renal carcinoma. In such cases, an *IV pyelogram* or *renal ultrasonography* is indicated.

When extrascrotal pathology is suspected, appropriate direction of the workup is required (see Chapter 58 and Chapter 139).

Approach to the Patient with Acute Pain and Swelling. An acutely painful, swollen testicle requires urgent assessment because if torsion of the testes is present, permanent damage may occur if treatment is not initiated within 4 hours of onset. Acute epididymitis and torsion are the two dominant considerations. Hemorrhage into a testicular cancer is a third. In an older man with concurrent prostatitis or a younger one with urethritis (see Chapter 136), epididymitis is the more likely cause of the problem. The presence of a urethral discharge, tender prostate, pyuria, or bacteriuria further supports the diagnosis of epididymitis. A firm, tender mass of acute onset in an afebrile young man with a history of prior episodes must be considered to represent torsion until proven otherwise. The diagnosis is further supported by finding a testicle with a horizontal lie on the uninvolved side. Urgent urologic consultation is necessary to determine whether the scrotum should be explored. Sometimes, it can be difficult to distinguish torsion from acute epididymitis on clinical grounds, and urgent surgical exploration is mandatory.

PATIENT EDUCATION AND INDICATIONS FOR REFERRAL

It has been suggested that teaching testicular self-examination might help shorten or eliminate the delay in presentation common in patients with testicular carcinoma. The patient with a clearly extratesticular, transilluminating scrotal lesion can be reassured that cancer is virtually ruled out and that no further evaluation for cancer is necessary other than a periodic follow-up examination. On the other hand, the person with a solid testicular mass needs prompt referral to the urologist, regardless of whether the mass is tender. Testicular cancer confined to the testicle is almost 100% curable by orchiectomy alone (see Chapter 143).

As noted above, referral to a urologist should be swift in cases of suspected torsion because surgical exploration must not be delayed if a viable testicle is to be preserved. Patients in whom testicular cancer is strongly suspected are also likely to require surgical evaluation, although whenever a testicular malignancy is suspected, exploration should be conducted through an inguinal incision. Transscrotal biopsy may cause spillage of tumor into the scrotum and areas of lymphatic drainage. Any mass that cannot be confidently defined as cystic and separate from the testicle should be subjected to a urologist's examination.

A patient with varicocele should be referred if it does not deflate when he lies down, is painful, or is associated with infertility, although conception is often not achieved after correction of the varicocele (see Chapter 120). Referral to a general surgeon is needed for the patient with a poorly reducible hernia.

Most hydroceles and cystic lesions do not require surgical therapy, but the patient should be instructed to return if the enlargement becomes uncomfortable or interferes with intercourse. The patient should understand that surgery is an option that will not threaten virility or fertility. Patients may want a hydrocele removed for cosmetic reasons or for relief of discomfort. Aspiration of a hydrocele is to be avoided. Patients with inguinal hernias that are at risk of causing bowel strangulation should be advised to have them repaired (see Chapter 67).

CHAPTER 132 MEDICAL EVALUATION AND MANAGEMENT OF ERECTILE DYSFUNCTION

ALBERT G. MULLEY, JR., ALLAN H. GOROLL

INTRODUCTION

Most normal men have occasional episodes of erectile failure, especially at times of stress, fatigue, or distraction. Only when the rate of failure approaches 25% is it proper to invoke the clinical diagnosis of impotence or erectile dysfunction, defined as the repeated inability to achieve or sustain an erection sufficient to engage in sexual intercourse. The condition is estimated to affect up to 10% of men at any given point in time; prevalence increases among older men. Other forms of male sexual dysfunction, including premature ejaculation, which is more common among younger men, are addressed in Chapter 229.

In recent years, the primary physician has taken a more active role in the evaluation and management of sexual problems, helped by a better understanding of sexual pathophysiology and more open discussions of sexual problems. Men with erectile dysfunction who suspect their problem may have an organic basis (e.g., diabetics, those taking medications, and the elderly) are especially insistent on a medical evaluation before they are willing to consider psychological issues. It is estimated that up to 50% of erectile dysfunction is organic in origin, a number that is bound to increase as the mean age of the population rises. Nonetheless, the workup of erectile dysfunction requires thorough investigation from both medical and psychological perspectives (see Chapter 229), and it often begins with a visit to the primary physician.

Many treatments require subspecialty consultation and intervention, but a substantial number of patients appreciate an opportunity to review possible treatments with their primary physician, which necessitates an understanding of the advantages and limitations of available therapeutic options.

NORMAL AND PATHOLOGIC PHYSIOLOGY AND CLINICAL PRESENTATIONS

A working knowledge of both normal and abnormal erectile function is essential to conducting a proper evaluation.

Normal Physiology

Erection is predominantly a hemodynamic process, mediated by neurogenic, endothelial, endocrinologic, and cortical (psychogenic) influences. It begins when blood flow increases into the large, vascular corpora cavernosa, which comprise much of the penile shaft. Flow varies according to the contractile state of smooth muscle lining the corporal arterioles and sinusoids. In the flaccid state, corporal smooth-muscle tone is high, and arterial flow into the penis is minimal. In addition, venous outflow is facilitated by copious arteriovenous shunts. On sexual stimulation, the smooth muscle relaxes, arterioles dilate, and blood flows in, engorging the corporal sinusoidal spaces. This engorgement and its restriction by the bandlike tunica albuginea compress the venous plexuses and arteriovenous shunts, impairing venous outflow. The net effect is a strong erection in which systemic arterial pressure may be approached. Detumescence occurs when smooth-muscle tone returns, blocking arterial inflow and opening venous channels. *Cyclic guanosine monophosphate (GMP)* is essential to achieving smooth-muscle relaxation in the corpus cavernosum.

Mediators. In the flaccid state, penile vascular smooth-muscle contraction is maintained by sympathetic a- *adrenergic* tone, which results in *norepinephrine* release. The vasodilation of erection can be triggered by *parasympathetic* stimulation, which releases *acetylcholine*, and by *nonautonomic* neurotransmission, which is believed to involve vasoactive intestinal peptide. Vascular endothelial cells contribute to relaxation by releasing *endothelium-derived relaxing factor*, a locally active vasodilator. *Prostaglandins* produced by corporal tissue are also capable of inducing both contraction and relaxation of smooth muscle and may play a regulatory role. *Nitric oxide* is released by cavernous nerves and endothelial cells in response to sexual stimulation. Nitric oxide, in turn, stimulates the formation of *cyclic GMP*, which causes cavernosal smooth-muscle relaxation. Although *androgens* have a clear effect on sexual development, behavior, and libido, their influence on erectile capacity is less well defined. Erection can occur with visual stimuli, even if circulating testosterone levels fall to castration levels. However, nocturnal erections are lost.

Control Centers. Erections may be triggered by psychic (cortical) stimulation or reflexively by tactile stimulation of the genitals. In most instances, both are operable and synergistic. A host of erotic stimuli can elicit cortical and subcortical responses, which are transmitted to the medial anterior hypothalamus, integrated, and projected down into the spinal reflex centers. There they modulate sympathetic and parasympathetic outflow to corporal smooth muscle.

There are two spinal reflex centers. The *sympathetic* reflex center is situated in the *thoracolumbar* region. It controls adrenergic tone and sustains the vasoconstriction of the flaccid state. The *parasympathetic* reflex center occupies the *midsacral* region and effects vasodilation. Tactile stimulation of the genitals produces afferent impulses carried by the internal pudendal nerve, which has synapses in the reflex erectile center (sacral cord segments 2 through 4). From there, efferent impulses pass over the pelvic nerves (nervi erigentes) to the parasympathetic plexuses innervating the corpora cavernosa.

Pathophysiology and Clinical Presentations

Impairment of any element of the erectile apparatus or its control can lead to erectile dysfunction. Included among the major organic causes are injury to the reflex centers in the spinal cord, severance of cortical input, injury to peripheral nerves, diabetes-induced autonomic and endothelial dysfunction, and medication-induced disruption of autonomic function.

Spinal Cord Injury. The location of the injury and its severity determine the degree of sexual dysfunction. Even if the cord is functionally severed, some erectile capacity is likely to be maintained if the thoracic and sacral reflex centers are left intact. Also, less severe injury is associated with a greater likelihood of erection remaining possible. About 60% of paraplegics regain the capacity for penile erection 1 to 24 months after injury. The percentage of erections is higher if the injury is above T-11, lower if below. More than 75% of all persons with cord injuries demonstrate some erectile capacity, but only 25% are able to engage successfully in intercourse. The erection is reflexive in nature, requiring constant penile stimulation to be maintained. Erections are totally abolished when local destruction of spinal segments *S-2* to *S-4* or their roots is complete. Again, the higher the location of the lesion, the better the chances of a good erection.

Ejaculation is rare when the lower thoracic and upper lumbar segments (approximately to L-3) of the cord are so extensively damaged that the nearby sympathetic components are destroyed. Sexual sensation is abolished with transection anywhere above the sacral level. After tactile stimulation, a paraplegic must look to confirm that reflex erection has occurred. Ejaculation can be documented only by feeling wetness with the fingers. Orgasm can be recognized only by feeling for perineal muscle contractions.

Herniated intervertebral disks and metastatic cancer of the vertebral column, especially between T-10 and L-5, which cause local swelling and destruction of spinal cord tissue, may produce a similar clinical picture.

Surgical Procedures. Erectile dysfunction results from transection of autonomic fibers. In simple prostatectomy, whether transurethral, suprapubic, or retropubic, erectile dysfunction is only occasional and is a function of age, prior potency, extent of surgical dissection, and psychological expectations. However, in up to 80% of patients undergoing simple prostatectomy, regardless of the type of procedure performed, some degree of retrograde ejaculation will develop as a result of surgical destruction of the internal sphincter mechanism at the bladder neck. The surgically destroyed or neurologically incompetent internal sphincter allows retrograde flow of seminal fluid into the bladder, producing a dry emission. Normal ejaculation will not occur under these circumstances because the external sphincter tightens to retain urine. Simple perineal prostatectomy is associated with a much higher incidence of erectile dysfunction because of unavoidable direct dissection of parasympathetic fibers along the posterior capsule.

Open *perineal biopsy* and posterior urethral reconstruction can result in erectile dysfunction; transperineal or transrectal needle biopsy of the prostate does not.

Radical prostate, bladder, or *colorectal surgery* can produce erectile dysfunction as a result of surgical damage to the pelvic autonomic nerves, notably the nervi erigentes as they course through the perirectal retroperitoneal tissues. Improved understanding of the course of these autonomic fibers has led to revised surgical techniques that spare them and lower the risk for erectile dysfunction. Good results have been achieved in younger patients undergoing radical prostatectomy. After radical *retroperitoneal lymph node dissection* for testicular tumors, ejaculatory failure may develop in young men as a result of bilateral resection of the paraaortic sympathetic ganglia, but erectile dysfunction rarely develops. *Bilateral sympathectomy* of lumbar ganglia at L-1 will inhibit ejaculatory capacity, but not orgasmic sensation, in more than half of cases.

Diabetes Mellitus. Erectile dysfunction may be the presenting symptom and is reported in up to 50% of men with the disease. Parasympathetically mediated smooth-muscle relaxation becomes defective, although sympathetic tone remains normal. Cholinergic transmission in corporal smooth muscle declines because of decreased synthesis of acetylcholine. In addition, endothelium-derived relaxing factor becomes deficient. Occlusive disease of larger vessels plays a much less important role than was previously thought, although the presence of hemodynamically significant atheromatous plaques may slow the onset of erection.

The risk for erectile dysfunction appears to parallel the duration and severity of diabetes. With conventional means of achieving glucose control, the majority of diabetic men experience some degree of erectile dysfunction, with fewer than 10% achieving restoration of normal function. Aggressive control of type I diabetes has effected a marked reduction in the risk for development of autonomic neuropathy. Whether initiating tight control in an already impotent diabetic will restore erectile capacity remains to be determined. The forerunner of erectile dysfunction in the diabetic is most often retrograde ejaculation. The presence of dry orgasm or milky postcoital urine augurs a loss of erectile function within a year.

Other Endocrine Diseases. The common denominator of most other endocrinopathies causing erectile dysfunction is decreased libido and a decline in serum testosterone. *Hypogonadism*, whether a result of chromosomal, pituitary, or testicular disorders, involves nondevelopment or regression of the secondary male sex characteristics, along with feeble libido and waning potency. When the cause is testicular failure, gonadotropin levels will be very high; when a pituitary or hypothalamic cause is present, gonadotropin levels will be low. *Hyperprolactinemia* is an important source of pituitary-derived erectile dysfunction. Serum testosterone levels fall as gonadotropins decline, although erectile dysfunction seems more closely related to the degree of prolactin elevation. Reduction in prolactin restores erectile function. Hyperprolactinemia may be idiopathic, the result of a functioning pituitary adenoma, or a consequence of *hypothyroidism* (stimulated by high levels of thyroid-stimulating hormone; see Chapter 100).

Addison's disease tends to lead to loss of libido and erectile dysfunction. *Cushing's syndrome*, except when associated with adrenal carcinoma, impairs libido and potency after an initial period (weeks or months) of marked increase. *Acromegaly* leads to early impairment of potency and premature extinction of function. The decline in function is frequently preceded by a hyperlibidinal period.

Drugs. Although it is a common observation that drugs can interfere with sexual functioning, the precise mechanisms remain incompletely understood. Drug effects are often unpredictable and may vary from patient to patient and with dosage and duration. Most are reversible by reducing or discontinuing the medication.

Antihypertensives are frequently to blame (see Chapter 26), with methyldopa, clonidine, b-blockers, reserpine, and diuretics leading the list. Most of these are centrally acting agents, which are believed to interfere with neurotransmitter activity. Erectile dysfunction has also been observed in patients taking antihypertensives with peripheral activity (e.g., hydralazine, thiazides, prazosin). On theoretical grounds, one might expect peripheral vasodilators and a-blockers to facilitate trabecular smooth-muscle relaxation, but clinically these antihypertensives are more likely to be the cause rather than the cure. However, agents with peripheral a-agonist activity (e.g., clonidine) can worsen erectile dysfunction by increasing trabecular smooth-muscle tone. In patients with underlying vascular insufficiency, antihypertensives may contribute to erectile dysfunction by lowering perfusion pressure. Ganglionic blockers may inhibit parasympathetic activity from the sacral segments of the cord or sympathetic activity from the sympathetic chain. Although most antihypertensives have been implicated, the calcium channel blockers and angiotensin-converting enzyme inhibitors appear to interfere least with sexual function.

Psychotropic agents may also be responsible for unpredictable forms of sexual dysfunction. The *phenothiazines* suppress central sympathetic activity. They are capable of producing such side effects as decreased libido, impaired ejaculation, erectile dysfunction, and retrograde ejaculation. The anticholinergic effects of *tricyclic antidepressants* may interfere with erection, although sexual function often improves after drug treatment of depression (see Chapter 227). The serotonin reuptake inhibitors *fluoxetine* and *sertraline* have also been found to impair sexual functioning. Large doses of alcohol can acutely depress the sexual reflexes to the point of abolishing them. Chronic alcoholism leads to nerve damage, liver failure, and high levels of circulating estrogens (see Chapter 71). *Exogenous estrogen* therapy may have a similar effect of diminishing the libido.

Drug abuse involving barbiturates, heroin, morphine, or methadone can result in major disturbances of sexual potency. Most cases are reversible. Marijuana, amyl nitrite, hashish, and lysergic acid diethylamide may heighten the perception of the sexual experience but do not specifically increase or decrease potency. Amphetamines, in moderate users, may increase libido and delay orgasm, thus prolonging the sexual act; however, erectile dysfunction often occurs with long-term, heavy use. Cocaine increases both male and female sexual excitability, but side reactions, including a flight of ideas, may interfere with sustained sexual performance. Episodes of painful priapism may develop in chronic abusers.

Prostatic Disease. Erectile dysfunction may be the first symptom of *prostate cancer*. Advancing centrifugal growth of neoplastic tissue in the posterior lobe of the prostate may induce local swelling and destruction of the parasympathetic fibers that run along the posterolateral aspect of the prostate. *Prostatitis* may cause painful ejaculations and even hematospermia. Premature ejaculation and postcoital fatigue occur, but erectile dysfunction is not characteristic. *Benign prostatic hypertrophy* does not interfere with sexual functioning.

Compulsive vesiculoprostatitis represents a chronic congestive syndrome. It occurs in the context of habitual self-inhibited masturbation, lifelong limitation of sexual activities, chronic coitus interruptus with a sexually inert partner, or habitually hastened intercourse fraught with anxiety related to threatened interruptions. The onset is gradual and progressive weakening of erectile strength may occur, although complete erectile dysfunction is not a primary feature. Other symptoms of this psychosomatic syndrome may include sacroiliac ache, irritating sensations in the glans penis, urinary urgency and frequency, minor weakness of the urinary stream, overflow prostatorrhea (especially after straining), and sometimes hematospermia.

Injury to the Penis or Urethra. *Pelvic fracture*, resulting from a crash injury in which the posterior urethra is ruptured, causes erectile dysfunction in 25% to 30% of cases. Nonperformance may result from painful intromission associated with *Peyronie's disease, balanitis*, acute *gonorrhea, herpes genitalis*, or *phimosis*. Hypospadias with a chordee of the shaft can preclude intercourse. With *priapism*, erection may be only partial and insufficient for intercourse because irreversible fibrosis of the corpora cavernosa has occurred. A large hernia or hydrocele may mechanically interfere with coitus, although potency should remain intact.

Vascular Disease. *Arterial insufficiency* is usually listed as a leading cause of erectile dysfunction in older men. Unexplained, progressive slowing of erection followed by decreased rigidity can be among the first symptoms of aortoiliac vascular disease when plaque obstructs the iliac arteries immediately distal to the aortic bifurcation. Erectile dysfunction develops in almost 40% of men with stenosis and nearly 75% of those with occlusion. Symptoms of claudication in association with erectile dysfunction, aortic or femoral bruits, and diminished peripheral pulses describe Leriche's syndrome. In some cases, the patient has the ability to initiate an erection but cannot maintain it. Patients with hypertension, diabetes, and hypercholesterolemia, or who smoke, are at increased risk for compromise of penile perfusion by atheromatous disease. Radiation therapy and pelvic trauma are other risk factors for vascular injury.

Venous dysfunction can be equally important and result from age- or lipid-induced loss of venous fibroelastic compressibility. Several authorities argue that venous dysfunction may be more important than previously suspected.

Psychogenic Conditions. Anxiety and depression are potent precipitants of erectile dysfunction. The marked sympathetic outflow that accompanies anxiety increases a-adrenergic tone and impedes trabecular smooth-muscle relaxation. In addition, cortical influences may inhibit sacral cord reflexes that would normally trigger erection by way of parasympathetic stimulation (see Chapter 229).

Zinc Deficiency. Zinc deficiency has been touted in the lay literature as a possible cause of erectile dysfunction, with health food stores promoting zinc preparations. Although zinc replacement has benefited dialysis patients with erectile dysfunction, the frequency of such severe zinc deficiency in most other patients is probably very low. More study of the issue is needed, especially in patients taking diuretics, which may lower zinc concentrations.

DIFFERENTIAL DIAGNOSIS

In a review of 165 men with sexual dysfunction seen at the Cleveland Clinic, 51% were found to have functional disorders, 47% had organic disorders, and 2% had incomplete evaluations. The incidence of sexual dysfunction peaked between the ages of 50 and 59. Among patients with organic sexual dysfunction, diabetes mellitus accounted for 41.5% of cases. In 16.8%, sexual dysfunction was caused by vascular insufficiency. Those with Peyronie's disease (15.5%) could not penetrate because of marked chordee or an inability to achieve sufficient erection. In 12.9%, hypogonadism, resulting from low levels of serum testosterone, was a factor. In 10.3%, erectile dysfunction followed a variety of surgical procedures. Sexual dysfunction secondary to various neurologic diseases occurred in 9%.

The Cleveland Clinic data represent the experience of a referral practice. Reports from primary care practices reveal a higher frequency of medications and alcohol as causes of sexual dysfunction, but not a substantially greater prevalence of psychological disease.

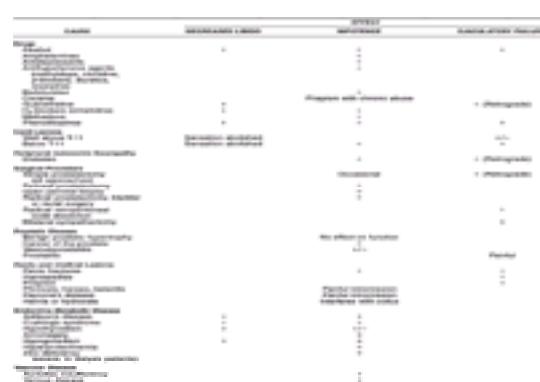
The widespread use of drugs affecting the autonomic nervous system makes pharmacologic agents an epidemiologically important source of erectile dysfunction and ejaculatory disturbances. Table 132-1 provides a listing of some of the more important causes of secondary erectile dysfunction and ejaculatory disturbances.


Table 132-1. Important Organic Causes of Secondary Sexual Dysfunction Effect

In many patients, especially the elderly, sexual dysfunction is multifactorial in origin. Both psychological and organic factors are often present, and in many instances, more than one medical condition is involved.

WORKUP

Advances in the pathophysiologic understanding of erectile dysfunction have yielded an array of new diagnostic methods, many of which require referral to a specialized laboratory to be performed properly. Nonetheless, history and physical examination remain an integral part of proper diagnosis. Obtaining a description of what the patient means by "impotence" is the first task and is best carried out by taking a detailed sexual history. It is essential to establish that erectile function is significantly compromised before an extensive workup is undertaken. Once the presence of erectile dysfunction has been confirmed, the evaluation shifts to differentiating psychogenic from organic disease. If psychogenic disease is deemed likely, the evaluation concentrates on underlying causes (see Chapter 229).

If organic disease is more probable, then the search begins for historical and physical findings suggestive of an underlying precipitant.

History

Differentiating Organic from Psychogenic Disease. The onset of the condition, its clinical course, and its effect on morning erections help differentiate psychogenic from organic mechanisms. A sudden onset and the preservation of erections on awakening or masturbation are characteristic features of psychogenic disease. A gradual onset and the progressive loss in duration and strength of morning erections and erections associated with masturbation and coitus suggest organic disease. These distinctions are not absolute. For example, depression may be associated with a temporary loss of morning erections, mimicking organic disease. Inquiry into libido is also important. A decrease in the context of erectile dysfunction raises the possibility of endocrinopathy in addition to psychogenic disease.

Because an intact nervous system, blood supply, and sexual apparatus are necessary to achieve an erection, any occurrence of erection and ejaculation, even if rare, suggests that the problem may be emotional rather than organic. However, it is important to recognize that in the early phases of organically determined erectile dysfunction, many patients retain some erectile function and are more likely to report a decrease in number of erections, rapid detumescence after penetration, or inability to obtain a sufficiently hard erection for intercourse. Further confusing the issue, early organic disease almost always triggers performance anxiety. Finally, the absence of an erection does not rule out a psychogenic cause, but usually one is able to elicit from patients with a psychogenic etiology a story of an occasional erection (particularly on awakening from sleep).

Inquiry into Medical Etiologies. Of primary importance is checking for symptoms of diabetes (see Chapter 102), alcohol abuse (see Chapter 228), and aortoiliac disease (see Chapter 23). As noted above, unexplained, progressive slowing of erection followed by decreased rigidity may be the presenting manifestation of aortoiliac insufficiency. Atherosclerotic risk factors (hypertension, smoking, diabetes, hyperlipidemia) should be noted. All medications are reviewed, especially antihypertensives, major tranquilizers, antidepressants, other drugs with anticholinergic activity, and histamine $_2$ blockers with antiandrogenic effects (e.g., cimetidine). Careful inquiry into substance abuse is also indicated (see Chapter 235). If libido is reduced, it is worth checking for symptoms of thyroid disease (see Chapter 103 and Chapter 104), hyperprolactinemia (see Chapter 100), hypogonadism (see Chapter 120), and adrenal disease. Past medical history is reviewed for radical prostate or pelvic surgery, pelvic irradiation, spinal cord injury, multiple sclerosis, cancer, and pelvic fracture.

Physical Examination

The vital signs are checked for postural fall in blood pressure (indicative of autonomic or adrenal insufficiency), the general appearance for loss of secondary sexual characteristics, and the skin for spider angiomata, palmar erythema, excessive dryness, hyperpigmentation, and other dermatologic signs of endocrinopathy. The neck is noted for goiter.

The flaccid penis ought to be inspected for tumor, inflammation, discharge, phimosis of the foreskin, and the hard plaques of Peyronie's disease along the dorsolateral aspect of the shaft. If possible, assessment of the erect penis should be attempted, especially if disease of the shaft is suspected, so that precise information on the degree of chordee or erectile weakness can be obtained. Testicles and prostate are checked for size, masses, nodules, and tenderness. Small, soft testes suggest hypogonadism. Intrascrotal pathology such as varicocele, hydrocele, or inguinal hernia may mechanically interfere with performance and can be readily detected by a careful examination (see Chapter 131).

The aorta and femoral arteries need to be palpated and auscultated for bruits and other signs of occlusive disease, especially if the patient has a history of claudication (see Chapter 23). Any femoral bruits are noted. The spine is checked for focal tenderness and evidence of cord compression (see Chapter 147). Neurologic assessment includes testing for pain sensation in the genital and perianal areas and checking the bulbocavernosus reflex to determine the integrity of second, third, and fourth sacral segments of the spinal cord. This reflex is achieved when the anal sphincter contracts around the examining finger as the glans is squeezed. A positive response indicates that S-2, S-3, and S-4 are intact. Other aspects of neurologic function also deserve thorough testing. Evidence of a cortical, brainstem, spinal cord, or peripheral deficit may be an important clue to etiology.

Laboratory Studies

Ordering a routine battery of "impotence" tests is rarely cost-effective. Moreover, no single test or set of tests "rules out" organic disease. The best approach is to tailor the laboratory workup to match the patient's clinical presentation.

Chemistries. A 2-hour postprandial serum *glucose* determination is indicated when diabetes is suspected (see Chapter 93). Hypothyroidism is best confirmed by an elevated *thyroid-stimulating hormone* level. Measurement of serum total *testosterone* and *luteinizing hormone* is indicated when reduced libido accompanies erectile dysfunction. Pooled samples of each (obtained 30 to 60 minutes apart) are necessary to avoid a sampling error from the large oscillations in serum concentration that can occur every few hours. A consistently low testosterone level confirms hypogonadism. Luteinizing hormone and *prolactin* levels help differentiate pituitary etiologies from primary gonadal failure (see Chapter 120). Abnormally high concentrations of total testosterone are seen with hyperthyroidism and represent an indication for testing of thyroid-stimulating hormone. If evidence of peripheral vascular disease is present, a *cholesterol* profile can help guide therapy (see Chapter 27). The usefulness of a serum *zinc* determination is still unproven, except perhaps in dialysis patients. The literature should be followed to see if more widespread measurement has physiologic meaning and therapeutic implications.

Study of Nocturnal Penile Tumescence. Tumescence study serves to confirm loss of erectile function in the patient who reports a total absence of erections, including those normally experienced on awakening from sleep. The physiologic basis for testing at night is the observation that 80% to 95% of young men experience erections during rapid eye movement (REM) sleep. Although the percentage falls with age, nocturnal monitoring represents the most sensitive available means of testing for intactness of the erectile apparatus. The absence of nocturnal tumescence indicates advanced organic disease and remains the "gold standard" for detecting organic erectile dysfunction. However, in early organic disease, some erectile function and morning episodes may persist. Thus, demonstration of tumescence does not negate the need for further medical evaluation.

Formal tumescence study is very expensive and is performed overnight in a special sleep laboratory that monitors the electroencephalogram and eye movements in addition to measures of penile tumescence. The *"postage stamp test"* is a much simpler, inexpensive method of screening for nocturnal tumescence. The patient is instructed to wrap a ring of postage stamps snugly around the flaccid penis at night before going to bed, and to moisten the overlapping stamps to seal the ring. A positive test result is breakage along the perforations on awakening in the morning. Because sleep is not monitored, a single negative test result does not rule out the capacity for nocturnal tumescence. Continued failure on repeated testing is more suggestive. Other devices for home monitoring have been developed, including plastic wires that break at different tensile strengths and a tumescence scanning device (Rigiscan) that entails wearing two rings for three nights.

Other Studies. Most other studies are the province of the specialist in male erectile dysfunction and should be ordered only on the basis of a consultation. A few are worth mentioning because of their popularity. The vascular apparatus can be assessed by *Doppler ultrasonography*, both in the flaccid state and, more meaningfully, after an *intracavernosal injection* of a vascular smooth-muscle relaxant. Color flow technology provides excellent images. Papaverine alone or in combination with the a-blocker phentolamine can be used for the intracavernosal injection. Inability to achieve a full erection within 5 to 10 minutes of injection or an erection that is only partial or lasts less than 1 hour strongly suggests vascular disease. However, the very anxious patient with a normal vasculature may have a false-positive result. One study suggests an increased specificity with a second injection because the patient is less anxious about the diagnostic procedure itself.

Patients in whom sacral neurologic injury is suspected clinically can be objectively tested by measuring the *sacral nerve reflex latency time*. One applies an electrical stimulus to the penile shaft and measures the time it takes for the bulbocavernosal muscles to contract. A time in excess of 35 ms is strongly suggestive of pathology in the nerves comprising the sacral reflex arc.

SYMPTOMATIC MANAGEMENT AND PATIENT EDUCATION

Psychological Support. The deeply upsetting nature of erectile dysfunction necessitates an empathic, understanding, and thorough approach to the problem. Education is essential to help the patient comprehend and cope with the condition. Reviewing the mechanism of erection and how it is impaired can be very useful in providing a rational basis for diagnosis, prognosis, and treatment. These informational and supportive needs are no less intense for the elderly, many of whom derive considerable self-esteem from maintaining their ability to engage in intercourse. The loss can be very demoralizing.

Most patients with organic etiologies acquire performance anxieties when their ability to engage in sexual intercourse becomes impaired. The onset of anxiety can result in full loss of function in a patient who is only partially compromised physiologically. In such instances, patient and partner should come in for supportive counseling, both to remove blame and inappropriately exclusive psychological attributions and to educate about prognosis and available therapy. Fortunately, many options for treatment are available.

Adjustment of Medication Program. Patients taking an antihypertensive medication implicated in erectile dysfunction might benefit from a trial of dose reduction, or from switching to an angiotensin-converting enzyme inhibitor (e.g., captopril), a calcium channel blocker (e.g., nifedipine), or a relatively selective b-blocking agent (e.g., atenolol) (see Chapter 26). The patient experiencing erectile dysfunction and loss of libido with use of cimetidine can be switched to ranitidine, which is similar in efficacy but has no antiandrogen effect. The depressed patient whose erectile dysfunction is clearly related to drug therapy can be tried on a tricyclic antidepressant with less anticholinergic activity (e.g., nortriptyline, desipramine), but switching to a serotonin reuptake inhibitor (e.g., sertraline, fluoxetine) may not help because they too can impair sexual functioning. The psychotic patient with sexual dysfunction believed linked to the medication program should be referred to the psychiatrist for adjustment of the drug regimen.

Sildenafil (Viagra). Effective oral therapy for erectile dysfunction of most causes is now available with the advent of sildenafil (Viagra). The drug selectively inhibits the enzyme that metabolizes cyclic GMP, a mediator of smooth-muscle relaxation in the corpus cavernosum. So long as some sexual arousal occurs that results in nitric oxide-induced production of cyclic GMP, erectile function will improve with sildenafil use. In the absence of arousal, sildenafil will not induce or sustain an erection, nor is it effective when marked vascular insufficiency limits the inflow of blood or when cavernosal fibrosis is present. Preliminary data also indicate that sildenafil is not effective among men who have undergone radical prostatectomy for prostate cancer unless bilateral sparing of the neurovascular bundles has been possible. However, for almost all other forms of erectile dysfunction, including those of psychogenic and mixed causes, it can be helpful. At maximum doses, a 100% improvement in erectile function is noted among responders in comparison with baseline, with successful sexual intercourse achieved in more than two thirds of attempts. Although the drug has no effect on sexual desire, some improvement in orgasmic function occurs. Sildenafil is taken 1 hour before planned intercourse, the time to maximum serum levels. The minimum dose is 25 mg, and the maximum is 100 mg. No more than one dose per day is recommended.

The cost is very high, averaging well over $10 per dose.

It is important to inform patients that the drug has no effect on sexual desire and that it works only in the context of sexual arousal. Although sildenafil works for a wide range of etiologies, a thorough work-up for the cause of erectile dysfunction should always be conducted to identify serious underlying organic and/or psychogenic illness that requires attention in its own right.

Adverse effects are transient and include *flushing, headache, visual disturbances* (alterations in hue or brightness), *and dyspepsia*. Priapism has not been reported. The drug does cause some vasodilation, and several reported deaths of men taking sildenafil have been associated with significant *hypotension*, which occurs when the drug is given concomitantly with agents that lower blood pressure, especially nitrates used in the treatment of ischemic heart disease. Sildenafil should not be prescribed for patients taking nitrates because of the risk for nitrate potentiation resulting in severe hypotension.

Use in Men with Coronary Heart Disease. Stress-test studies suggest that men with erectile dysfunction and ischemic heart disease can use sildenafil without experiencing adverse cardiovascular effects, provided they are not using nitrates concurrently (no nitrates for 72 hrs before sildenafil). However, the ability to engage in sexual intercourse safely and a lack of angina or hypotension during exercise and drug use should be established before the drug is prescribed. The lowest dose (25 mg) should always be prescribed initially and the dose limited to a maximum of 50 mg. Persons taking long-acting nitrates or requiring regular nitroglycerin use should not be considered for sildenafil therapy.

Updated: 3/4/02

Intracavernosal Injection Therapy. Local intracavernosal injection of smooth-muscle relaxants and a-adrenergic blockers has been effective in a wide variety of patients. Diabetics, patients with neurologic injury, those with psychogenic erectile dysfunction, and even some with vascular insufficiency have regained their ability to engage in successful sexual intercourse with intracavernosal injection therapy, a substantial advance for many patients. Follow-up of men introduced to penile injection therapy indicate that more than 70% are sufficiently satisfied to continue treatment. Of those who stop, most do so because of cost; fewer than one in seven who stop do so because of ineffectiveness.

Among the agents used for intracavernosal therapy are *papaverine*, which directly relaxes trabecular smooth muscle; *phentolamine*, a short-acting, a-adrenergic blocker that increases arterial inflow; and most recently, *alprostadil* (an aqueous preparation of prostaglandin E$_1$) that both relaxes smooth muscle and causes vasodilation. Within 10 to 15 minutes of injection in responding patients, an erection develops and lasts for up to 1 hour. Patients with neurologic disease and

psychogenic erectile dysfunction respond most readily and require the smallest doses of medication. Underlying vascular disease is less responsive and necessitates larger doses.

Alprostadil, the only agent approved by the Food and Drug Administration for the intracavernosal treatment of erectile dysfunction, is highly effective. Ninety-four percent of men in mixed populations achieved erections in 87% of attempts, with a good average duration of erection (64 minutes). Furthermore, the risk for priapism (0.4% to 1.0%) or fibrosis (2% to 3%) is smaller than with papaverine (see below). Long-term safety remains to be determined, but the risk for fibrosis is small with continuous use of up to 6 months. The most common side effect of alprostadil is pain at the injection site in 20% to 50%, but this is problematic only in about 11% and depends on the preparation used. Combining a modest dose of alprostadil with papaverine provides better results and less pain than papaverine plus phentolamine or larger doses of alprostadil alone. The recommended frequency of use is no more than three times per week and no more than once in 24 hours. Dosage determination requires titration in the office, started at 1.25 to 2.50 mg and increased by 2.5- to 5.0-mg increments. Patients with psychogenic or neurogenic forms of erectile dysfunction may require as little as 2 mg to achieve an adequate erection. The goal is to identify the least amount of alprostadil necessary to sustain an effective erection for 1 hour. After undergoing titration of dose, patients are set up for self-administration of the therapy at home. Cost is moderate.

Papaverine, used either alone or with phentolamine, achieves response rates of about 50% in mixed populations of impotent men. Duration of erection averages 50 minutes. Adverse effects include pain at the site of injection and a risk for hepatocellular enzyme elevation, priapism, and painless fibrotic nodules. Ischemic injury and scarring of the corporeal tissue may result when erections last longer than 4 hours. Such injury can lead to permanent damage of corporeal tissue and must be treated promptly by intracavernosal injection of an a-agonist (epinephrine, phenylephrine). Penile fibrosis occurs in up to 60% of patients after 1 year of treatment, with some men experiencing sufficient corporeal fibrosis to distort the penile shaft. Alprostadil has replaced papaverine as the drug of first choice for intracavernosal injection, but papaverine appears to be useful as an adjunct in some instances (see above).

Insulin syringes with a very fine (27- to 30-gauge) needle are used for the intracavernosal injection, which is usually placed into the proximal third of the penis in the dorsolateral area of the corpus cavernosum. Unilateral injection suffices because the vessels from each side interconnect. Sides are alternated. Erection usually ensues within 10 minutes of injection and lasts 30 to 60 minutes. Side effects are most common during the titration period, when excessive duration of erection and hypotension occur from doses that are too large. Patients with cardiovascular compromise may be suboptimal candidates for this therapy.

The optimal candidate for intracavernosal injection is one with an intact vascular apparatus and the intelligence and dexterity to self-inject properly. However, even those with concurrent vascular disease may benefit, although higher doses may be required, which increases the risk for side effects and complications. Diabetics have especially benefited because the treatment directly addresses their underlying pathophysiology.

Penile Implants and Other Mechanical Devices. More than 30,000 prostheses are implanted annually in the United States. A prosthesis is a consideration for the patient with refractory erectile dysfunction who expresses a serious need to regain his capacity to engage in coitus. Of the three types of prostheses available, the simpler ones (the semirigid and adjustable malleable types) have proved the most satisfactory. They are least likely to fail and have the fewest complications associated with their implantation and use. Although they might seem the most "natural," the inflatable prostheses have much higher breakdown and complication rates, so that surgical revision is often necessary. Reoperation rates range as high as 44%. The reservoir tends to leak, and infection is a risk on the order of 1% to 10%.

Overall, patient and partner satisfaction with prostheses is in the range of 80% to 90%, with little difference reported among users of the various types. Careful counseling is required before implant surgery is elected. If the cause of erectile dysfunction is a poor interpersonal relationship, then a prosthesis is going to have little effect.

A *vacuum suction device* has been advocated, especially in the elderly. A plastic cylinder is placed over the flaccid penis and connected to a hand-operated vacuum pump. The negative pressure in the cylinder facilitates passive blood flow into the penis. A band is placed at the base of the penis to retard venous outflow, and the cylinder is removed. The device works best in patients who respond to penile injection therapy and is an alternative to such therapy. Pain, ecchymoses, and difficulty ejaculating are experienced by about 10%. Coitus is successfully achieved in about 80% after 3 months of use.

Vascular Surgery. Patients with vascular insufficiency have yet to achieve consistently successful results after reconstructive surgery. Correction of aortoiliac disease often meets with disappointing results because of the high frequency of coexisting disease in distal vessels. Microsurgical techniques have been employed to correct vascular disease within the penis. Success rates range from 20% to 80%. The best results are obtained in young men with traumatic vascular injury; the worst results are in older men with diffuse atherosclerotic involvement of the cavernosal artery.

Hormone Therapy. Testosterone therapy should be reserved for patients with hypogonadism, manifested by a low serum testosterone level, and testosterone should not be used as an all-purpose sexual stimulant. It has little effect in impotent patients with normal testosterone concentrations (although it may add to frustration by increasing their libido). In such patients, particularly the elderly, the use of testosterone is associated with a high incidence of adverse effects, including sodium retention, prostatic enlargement, gynecomastia (from peripheral conversion to estrogens), and polycythemia. Patients with concurrent adenocarcinoma of the prostate may experience a serious flare of their testosterone-responsive disease.

Treatment is given every 3 to 4 weeks by IM injection of a long-acting preparation. A period of trial and error to find the optimal dose requires patience on the part of both physician and patient. Oral preparations are rapidly inactivated. A transdermal delivery system is under development.

Patients with hyperprolactinemia-induced hypogonadism may not respond to testosterone replacement therapy because of the androgen-antagonizing effect of prolactin. Consequently, treatment of the underlying hyperprolactinemia is necessary to restore potency.

Yohimbine. Yohimbine is an a-blocker touted as a medical treatment for erectile dysfunction. In a double-blind, randomized study of the drug in patients with organic erectile dysfunction, it was found ineffective. However, it did prove helpful in a similarly designed study of patients with psychological erectile dysfunction, probably because of their high level of anxiety and sympathetic tone.

Treatment of Underlying Urologic Disease. At least temporary relief from the acute discomfort of prostatosis ensues from repeated prostatic massage (see Chapter 138). Selected patients with Peyronie's disease are candidates for plaque resection and replacement with a dermal skin graft. The ability to perform sexually may return after removal of a large hydrocele or repair of an inguinal hernia. Patients recovering from routine simple prostatectomy (either transurethral or suprapubic) can be reassured that potency and ability to engage in coitus are likely to return within 4 to 8 weeks after surgery.

INDICATIONS FOR REFERRAL

Patients with urologic disease should have a urologic consultation to see if they are candidates for surgical correction. Diabetics and impotent patients with otherwise refractory disease who have a relatively well-preserved penile vascular apparatus are reasonable candidates for referral to consider intracavernous injection therapy if they have failed sildenafil. Even those with a degree of vascular insufficiency may be candidates. The risks and benefits of prosthetic surgery can also be reviewed at the same time. Referral is best made to a urologist experienced in the treatment of erectile dysfunction. Patients found to have symptomatic aortoiliac disease require evaluation by a vascular surgeon (see Chapter 34). Endocrinologic advice is indicated for patients with elevated prolactin levels, primary hypogonadism (low levels of testosterone, high levels of luteinizing hormone), or evidence of pituitary–hypothalamic disease (low concentrations of luteinizing hormone). Patients suspected of harboring a cord lesion need urgent neurologic consultation.

Psychiatric referral is essential when depression, anxiety disorder, or interpersonal conflict appears to be an etiologic factor in a case of erectile dysfunction. However, premature referral to a psychiatrist before an appropriate medical evaluation has been completed should be avoided because of the risk for inappropriately labeling the condition as purely psychological and alienating the patient. Referral may also be useful when the patient with organic disease fails to respond to supportive psychotherapy offered by the primary physician (see Chapter 229).

CHAPTER 133 APPROACH TO DYSURIA AND URINARY TRACT INFECTIONS IN WOMEN

LESLIE S.-T. FANG

Among adult women, urinary tract infection (UTI) is the most common of all bacterial infections. Between 20% and 30% of women have a UTI in their lifetime, and 40% of women with one infection have a recurrence. Thus, UTIs represent a significant source of morbidity among women. Evaluation by the primary physician should be directed at the detection of any anatomic abnormalities that may predispose the patient to recurrent infections. Therapy should be aimed at the eradication of infection to minimize morbidity.

PATHOPHYSIOLOGY AND CLINICAL PRESENTATION

Current evidence suggests that most episodes of UTI in adult women are secondary to *ascending infection*. Bacteria reach the bladder through the urethra and may then ascend to the kidneys through the ureters. Hematogenous spread has rarely been implicated in the pathogenesis of UTIs.

Bacteria that commonly cause UTI are found in the periurethral area in up to 20% of adult women. This *colonization* of the *vaginal introitus* has been shown to be the essential first step in the production of bacteriuria and plays an important role in recurrent UTIs. Colonization with *Enterobacteriaceae* occurs in postmenopausal women and is believed to account for much of the increase in susceptibility to UTI seen in this age group. Entry of bacteria into the bladder through the relatively short female urethra can occur spontaneously. In addition, *sexual intercourse* and use of a *diaphragm* correlate with risk for infection. The use of spermicide with a diaphragm or on a condom predisposes specifically to infection with *Staphylococcus saprophyticus*. Significant increases in bacteriuria follow 30% of intercourse episodes. The use of tampons and wiping from back to front are not risk factors for UTI.

The establishment of a bladder infection also depends on the virulence of the bacteria introduced, the number of organisms introduced, and, most importantly, a lapse in normal *host defense mechanisms*. A number of host defense mechanisms normally act together to decrease the likelihood of infection. Normal voiding eliminates some organisms. Certain chemical properties of the urine are antibacterial; urine with a high concentration of urea, low pH, and high osmolarity supports bacterial growth poorly. The most important host defense mechanism is phagocytosis of bacteria that come into contact with the bladder mucosal surface. Vaginal epithelial cell characteristics also contribute. Susceptibility to UTI correlates with increases in cellular bacterial adhesiveness. Abnormalities in these host defense mechanisms result in recurrent and complicated UTIs. Inability to express blood group antigens is a risk factor.

In approximately 30% of cases of sustained bladder infection, the infection extends further through the ureters into the kidneys. The presence of *reflux* increases the chance that infection will ascend. Once infected urine gains access to the renal pelvis, it can enter the renal parenchyma through the ducts of Bellini at the papillary tips and then spread outward along the collecting ducts to cause parenchymal infection.

Clinical Syndromes

Urinary tract infections are associated with a number of clinical syndromes, ranging from acute urethral syndrome to pyelonephritis. Most are accompanied by dysuria, frequency, urgency, and suprapubic or flank discomfort. Other features are unique to each syndrome.

Acute Urethral Syndrome (Symptomatic Abacteriuria) occurs in about 10% to 15% of women who present with symptoms suggestive of UTI. Patients in this category have fewer than 105 organisms per milliliter on urine culture. In addition, urinalysis findings are usually unimpressive—few white blood cells (WBCs) and no bacteria. These patients can be subdivided into two groups. Approximately 70% have some degree of pyuria (>2 to 5 WBCs per high-power field in a centrifuged sample) and true infection, either with bacterial counts of fewer than 105 organisms or with *Chlamydia trachomatis*. Those with bacterial counts in the range of 10^2 to 10^4 may have early UTI with infection not yet established in the bladder. The remaining 30% have no pyuria and no infection. The cause of their dysuria is unknown. Only those without pyuria have proved to be truly abacteriuric. A subset of truly abacteriuric women with urinary frequency report chronic pelvic pain relieved by voiding, suprapubic tenderness, and dyspareunia. They have normal findings on urinalysis. Cystoscopic dilation reveals submucosal hemorrhages. The term *interstitial cystitis* has been used to designate their condition. The cause is unknown, and the course is chronic. Tricyclic antidepressants are sometimes helpful.

Asymptomatic Bacteriuria. (See Chapter 127 for a discussion of this entity.)

Symptomatic Bacteriuria, in the form of cystitis or pyelonephritis, is the most common of the clinical syndromes. *Cystitis* has traditionally been thought to present primarily as frequency, urgency, dysuria, and bacteriuria. *Pyelonephritis*, on the other hand, is generally believed to be associated with fever, flank pain, and systemic symptoms such as nausea and vomiting. Unfortunately, numerous investigations have shown that the ability to differentiate between bladder and kidney infection on clinical grounds alone is limited. Studies using bilateral ureteral catheterization to localize directly the site of infection have demonstrated that many patients with upper tract infection present with symptoms supposedly characteristic of lower tract infection. Moreover, patients whose infection is limited to the bladder may occasionally have fever, flank pain, and systemic symptoms usually associated with pyelonephritis. Thus, the traditional clinical clues are at best imprecise for identifying the site of infection.

Recurrent Infections are characteristic of some patients. Two basic patterns of recurrence are recognized: (a) *relapse*, in which the original organism is suppressed by antimicrobial therapy and then reappears when the antibiotic is stopped, and (b) *reinfection*, in which the original organism is eradicated by antimicrobial therapy and the recurrent infection is caused by a new bacterial strain. Approximately 80% of recurrences represent reinfection. Ureteral catheterization studies have demonstrated that most reinfections occur in patients in whom infection is restricted to the bladder, whereas most relapses occur in patients with renal parenchymal infection.

Groups frequently bothered by recurrent infections include (a) sexually active women, who report a temporal relationship of urinary symptoms to intercourse; (b) patients with host defenses compromised by underlying systemic illness or residual urine in the bladder; (c) patients with upper tract infections; and (d) pregnant women.

The consequences of recurrent uncomplicated infections are, for the most part, minimal and rarely result in progressive renal impairment. However, patients with infections in the setting of vesicoureteral reflux, pregnancy, or diabetes are at greater risk. *Vesicoureteral reflux* is associated with residual urine in the bladder, ascending infection, chronic pyelonephritis, and a high risk for renal scarring, which leads to focal glomerulosclerosis, proteinuria, and progressive renal failure. Patients most likely to have vesicoureteral reflux are those who report a long history of UTIs beginning in childhood. UTI during pregnancy has been linked to increased rates of fetal complications and prematurity, especially when the infection occurs within 2 weeks of delivery. The mother has an enhanced risk for pyelonephritis. Patients with diabetes show an increased susceptibility to upper tract infection.

DIFFERENTIAL DIAGNOSIS

Dysuria. The differential diagnosis of dysuria includes *UTI, vaginitis*, and *urethritis*. Patients with vaginitis may occasionally be mistakenly thought to have UTI. Vaginal discharge, "external" discomfort (from urinary irritation of inflamed labial tissue), absence of frequency or urgency, and urine cultures negative for bacteria distinguish vaginitis from UTI. *Trichomonas vaginalis* and *Candida albicans* are the most commonly responsible organisms. Women with dysuria and an absence of bacterial growth on routine urine culture may have *urethritis* caused by *Neisseria gonorrhoeae* or *herpes simplex virus*, although, as previously noted, most cases will be caused by *Chlamydia trachomatis* (see Chapter 125). The onset is usually gradual, dysuria is mild, and vaginal discharge may be present. Pelvic pain and vaginal

or cervical discharge suggest spread of infection into the cervix and fallopian tubes, a serious development (see Chapter 116 and Chapter 117).

Pyuria typically accompanies gonococcal and trichomonal infection as well as chlamydial infection. Patients with acute urethral syndrome and no pyuria may have dysuria on the basis *of local trauma* or *irritation*, rather than infection, problems that occur in postmenopausal women secondary to desiccation of vaginal and urethral tissue.

Flank Pain. Patients with *renal calculi* or *embolic infarction* may present with flank pain and hematuria, mimicking *pyelonephritis*. However, urine cultures are sterile and no bacteria are seen on Gram's stain, as they are in UTI.

WORKUP

The pace, extensiveness, and order of the evaluation are largely dictated by the patient's clinical presentation. Candidates for outpatient evaluation include dysuric patients with no evidence of systemic toxicity or obstruction.

Acutely Ill Patients

Those presenting with fever, flank pain, and systemic symptoms require prompt evaluation for the possibility of urinary tract *obstruction* and superimposed infection. Such patients should be questioned about a history of diabetes, sickle cell anemia, and excessive analgesic use; patients with these problems are at higher risk for renal papillary necrosis and subsequent obstruction by sloughed papillae. Likewise, a history of renal calculi is cause for concern in this setting. The patient with any of these risk factors who appears toxic (high temperature, prostration) and restless on examination and who has marked tenderness in the costovertebral angle requires immediate urologic evaluation to rule out obstruction. Infection behind an obstruction constitutes a medical and urologic emergency necessitating urgent therapeutic intervention.

Dysuric Patients

History. The acutely dysuric woman ought to be questioned about vaginal discharge, external irritation on urination, and pain on intercourse to differentiate vaginal causes of dysuria from those referable to the urinary tract. Also helpful is a sexual history to identify risk factors for chlamydial urethritis, including new sexual partners, a partner with a penile discharge or recent urethritis, mucoid vaginal discharge, or gradual onset of symptoms. A recent history of gonorrhea or exposure to gonorrhea should be elicited.

Physical Examination. One begins with a temperature determination, followed by percussion of the costovertebral angle to test for tenderness and palpation of the suprapubic region to detect discomfort and distention. The pelvic examination is essential; any urethral discharge, vaginal erythema, discharge, or atrophy, and cervical discharge, erosion, vesicles, or tenderness on motion must be noted.

Laboratory Studies.

Urinalysis and Gram's Stain of the unspun urine are often diagnostic. Proper collection of the urine specimen is essential. The *clean-voided technique* has withstood the test of time and minimizes contamination from vaginal and labial sources. The female patient is told to straddle or squat over the toilet and to spread the labia with the nondominant hand. This position is maintained throughout collection. With the other hand, the vulva is swabbed front to back with three sterile gauze pads soaked in sterile water or with a sponge soaked in a mild nonhexachlorophene soap. A small amount of urine is then passed. This is a urethral specimen and can be saved if bacterial or protozoan urethritis is suspected. More urine is voided and collected in a sterile cup. Alternatively, the patient can be told to slide the cup into a freely flowing stream to collect a true midstream specimen. The adequacy of collection can be confirmed by examining for epithelial cells; their presence indicates vulvar or urethral contamination.

With an elderly patient, the assistance of a family member or a nurse may be needed. When repeated contamination is suspected, *straight catheterization* of the bladder can be performed with relatively little risk.

Examining the urine promptly minimizes artifactual findings. The finding of *pyuria* (>25 WBCs per high-power field on examination of a spun sediment) is indicative of UTI and predictive of a response to antibiotic therapy. The absence of pyuria suggests a vaginal cause for the dysuria or a noninfectious variant of the acute urethral syndrome. The presence of one organism on high-power field examination of a Gram's-stained unspun urine sample represents clinically significant bacteriuria (>10^5 organisms per milliliter).

Culture. The traditional criterion for infection has been a colony count of more than 10^5 organisms per milliliter; it provides high specificity but poor sensitivity. Studies using suprapubic aspirates find that half of dysuric women with "negative" urine cultures by the traditional criterion are truly infected, although the colony counts were in the range of 10^2 to 10^5. Colony counts of more than 10^2 obtained on clean-voided specimens from acutely dysuric women are diagnostic of true coliform infection. Many such women who previously were labeled as having symptomatic abacteriuria fall into this category. As noted earlier, the presence of pyuria identifies those who are infected and will respond to antibiotics.

The need to obtain a urine culture for every acutely dysuric woman with mild to moderate symptoms has been challenged. The vast majority of organisms that cause infection in this group are sensitive to the antibiotic regimens commonly prescribed (see below). Even when disk-sensitivity testing designates an organism as "resistant" to an antibiotic, the resistance is only relative and the organism is usually susceptible to the much higher antibiotic concentrations found in the urine. Many authorities now recommend basing the decision to treat with antibiotics and the selection of an agent on the results of urine sediment examination and Gram's stain, with urine culture reserved for patients with a recurrence or a report of several UTIs within the past year. Empiric therapy has also been advised. A compromise is patient-initiated antibiotic therapy after a dip-slide urine culture has been performed.

At the other extreme are patients who present acutely with severe symptoms and risk for urosepsis. They require not only urine sediment examination, Gram's stain, and culture, but also at least two sets of *blood cultures* before antibiotics are initiated.

When the urine culture is obtained, familiarity with important urinary pathogens facilitates interpretation of culture results. The most common urinary pathogen in community-acquired UTI is *Escherichia coli*. Occasionally, the other gram-negative rods are responsible. Of the gram-positive organisms involved in UTI, enterococci, *Staphylococcus aureus*, and group B streptococci are common isolates. Less appreciated as a urinary pathogen is *S. saprophyticus*, a coagulase-negative organism frequently found to cause UTIs in female outpatients. Diphtheroids, lactobacilli, and a-hemolytic streptococci represent contaminants.

Intravenous Pyelography and Other Urinary Tract Investigations. Recurrent infection raises the specter of a structural lesion. However, as already noted, the vast majority of recurrences represent reinfection in the absence of upper tract disease or other pathology. IV pyelography, excretory urography, and cystoscopy in women with recurrent infection are of very low yield and are not recommended. Such radiographic and urologic evaluations should be reserved for those in whom anatomic abnormalities are suspected (e.g., onset of UTIs in childhood) or in whom obstruction is likely or renal insufficiency is developing. If evidence of reflux is suggested by IV pyelography, a voiding cystourethrogram should be performed to document the degree of reflux. Urologic evaluation is indicated when urethral meatal stenosis is strongly suspected (see Chapter 134).

PRINCIPLES OF THERAPY

The intensity and duration of therapy should match the patient's clinical presentation and risk for complications. In general, patients who are sick require consideration for hospitalization and parenteral antibiotics, especially if they are metabolically or immunologically compromised or have an anatomic or functional defect of the urinary tract.

Acutely Ill Patients: Pyelonephritis, Urosepsis. Those presenting with high fever, chills, flank pain, costovertebral angle tenderness, nausea, and vomiting may have upper tract or even bloodstream infection and should be hospitalized, especially if elderly. They require fluids, thorough evaluation for treatable precipitants (see above), and prompt initiation of parenteral antibiotics. The choice of initial antibiotic program should be consistent with the findings on urine Gram's stain, although

Enterobacteriaceae account for more than 90% of cases.

Often, broad-spectrum coverage is selected in this setting because of concern for *Pseudomonas* species and other multiply resistant gram-negative rods. In addition, coverage for enterococci is usually included, although the pathogen is more common in men. *Ampicillin* plus *gentamicin* is the time-honored choice for serious UTI, providing effective coverage at low cost. Expensive alternatives for initial treatment include imipenem/cilastatin, ciprofloxacin, and ceftriaxone. When culture and sensitivity results become available, the regimen can be revised to provide more focused coverage. Urosepsis requires 2 to 3 weeks of IV antibiotics. Pyelonephritis without bloodstream invasion can be treated parenterally until fever resolves, then with oral antibiotics to complete a 14-day course.

Outpatient Treatment of Pyelonephritis. Otherwise healthy patients with less severe but still acutely incapacitating symptoms often have *uncomplicated* pyelonephritis; this can be treated entirely on an outpatient basis with 10 to 14 days of oral antibiotics provided that the patient is reliable, can take fluids, is not seriously immunocompromised, and has no obstruction. The choice of initial therapy is based on Gram's stain find-ings. For infection with gram-negative rods, *trimethoprim/sulfamethoxazole* (TMS) or a fluoroquinolone (e.g., *ciprofloxacin, norfloxacin*) is a reasonable choice. Up to 30% of community-acquired *E. coli* infections are now ampicillin-resistant, so that this antibiotic less effective for initial outpatient treatment of pyelonephritis, although the combination preparation of *amoxicillin/clavulanic acid* (Augmentin) produces cure in more than 90% of cases. TMS resistance is also becoming more common, approaching 15% in some areas. With increasing TMS and ampicillin resistance among community-acquired *Enterobacteriaceae*, fluoroquinolone therapy may emerge as the preferred selection for outpatient treatment of pyelonephritis, with amoxicillin/clavulanic acid also assuming an increasingly important role. Gram-positive cocci seen on urine Gram's stain suggest enterococci and *S. saprophyticus*, both of which are best treated with *amoxicillin*.

Repeated culturing 2 to 4 days after completion of therapy is essential. Failure to respond to an appropriate antibiotic program suggests an anatomic or functional abnormality and the need for radiologic evaluation and urologic consultation (see above).

Mild to Moderate Symptoms: Uncomplicated Urinary Tract Infection. Most patients with mild to moderate symptoms have cystitis and respond well to a short course of oral antibiotics. The choice of agent is again based on urine Gram's stain. With *gram-negative rods, TMS* or *amoxicillin* should suffice for most cases of lower UTI, even those caused by "resistant" strains, because of the very high bladder antibiotic concentrations achieved. For patients allergic to both sulfa drugs and penicillin, a fluoroquinolone (e.g., *ciprofloxacin*) is an effective alternative. For *gram-positive cocci, amoxicillin* is the drug of choice.

The optimal duration of therapy for uncomplicated UTI has been a subject of much interest ever since it was found that *single-dose regimens* could provide nearly the same results as conventional 7- to 10-day programs while significantly reducing cost and risk for vaginal candidiasis, rash, diarrhea, poor compliance, and emergence of resistant organisms. Single-dose amoxicillin (3 g orally) and TMS (two double-strength tablets) have been used successfully, with better results reported for TMS. Ciprofloxacin (1 g) is also effective. The oral cephalosporins—cephaloridine, cefadroxil, and cefaclor—have been disappointing. A *3-day course* of antibiotics achieves a slightly higher rate of cure than does a 1-day program yet retains most of the advantages of single-dose therapy. Suboptimal candidates for short-course therapy include patients with diabetes, a history of relapses, more than three UTIs in the past year, and immunocompromise. Such patients are best treated with a more conventional course of antibiotics (up to 2 weeks).

Failure to Respond. Failure to respond to short-course therapy has proved to be a reliable clinical criterion for upper tract disease, correlating well with results of formal localization tests. Patients may report no relief of symptoms or a relapse within days of treatment. Such patients are likely to have subclinical uncomplicated pyelonephritis and should be treated accordingly (see above).

Acute Urethral Syndrome. Patients with *pyuria*, no bacteria on Gram's stain, and no clinical evidence for chlamydial, gonococcal, or other venereal forms of urethritis can be treated with *single-dose antibiotic therapy* in the same manner as any patient with lower tract infection. Alternatively, they can be treated with *TMS* (one single-strength tablet twice daily for 10 days) or *doxycycline* (100 mg twice daily for 10 days). Doxycycline is effective against *Chlamydia* and gonococci and also most common urinary pathogens (see [Chapter 125](#) and [Chapter 137](#)). Recurrences are common in patients with acute urethral syndrome.

Patients *without pyuria* do not respond to antibiotics. Symptomatic therapy with fluids and urinary analgesics such as phenazopyridine (Pyridium) are usually prescribed.

Recurrent Infection. Patients bothered by frequent symptomatic recurrences are potential candidates for prophylactic measures. Recurrent infection should be confirmed at least once by repeated culture. The clinical setting helps determine the appropriate approach to therapy. As noted earlier, recurrences in *sexually active women* are most often reinfections. Prophylaxis at the time of intercourse with *single-tablet* therapy has proved effective in minimizing their frequency and severity. In reliable patients with fewer than three UTIs per year, a patient-initiated *1- or 3-day course* of standard antibiotic therapy for uncomplicated UTI at the first sign of symptomatic infection has proved effective. In *postmenopausal* women, a course of topical *vaginal estrogens* can prevent recurrent infection, presumably by returning the vaginal flora to its premenopausal composition with few *Enterobacteriaceae*. For *very elderly patients* with bladder distention, postvoid residual urine, and recurrent reinfection, *continuous prophylaxis* with nightly TMS (one half of a single-strength tablet daily at bedtime) usually suffices and works better than regimens of sulfisoxazole or methenamine mandelate (Mandelamine) and ascorbic acid. Once prophylaxis is stopped, there is no residual benefit. In patients with defined anatomic abnormalities, such as significant reflux or nephrolithiasis, surgical correction to decrease the severity and frequency of recurrences should be considered.

Treatment of the Pregnant Patient. Treatment of symptomatic UTI in pregnancy is recommended because of an increased risk for upper tract infection in the mother and potential injury to the fetus (low birth weight, prematurity). Antibiotics proved safe for use in pregnancy include ampicillin, amoxicillin, and oral cephalosporins. The combination preparation of amoxicillin/clavulanic acid (Augmentin) is recommended for use against organisms demonstrating resistance to multiple drugs. Nitrofurantoin has also been used without evidence of fetal toxicity; however, its associated risk of inducing peripheral neuropathy, pulmonary fibrosis, and hepatic injury in adults makes it a less preferable choice. The fluoroquinolones should be avoided in pregnant patients.

Treatment of Asymptomatic Bacteriuria in the Elderly. Because the risk for urosepsis, renal failure, or mortality is not increased, the need for antibiotics is not urgent. The risk for asymptomatic infection is increased, but the benefit of treatment is unclear. Antibiotics are indicated if obstruction is present or the patient is to undergo a genitourinary procedure.

THERAPEUTIC RECOMMENDATIONS

[Table 133.1](#) summarizes the therapeutic recommendations for UTIs.

CLINICAL SITUATION	REGIMEN
Acutely ill and toxic patient	Hospitalization, parenteral antibiotics, ampicillin plus gentamicin if urosepsis suspected; otherwise, ciprofloxacin if Gram's stain shows GNR, ampicillin if it shows GPC
Uncomplicated pyelonephritis	Oral TMS (1 double-strength tablet) bid for 2 wks or ciprofloxacin 500 mg bid for 2 wks
Uncomplicated lower UTI	Single dose: TMS (2 double-strength tablets), ciprofloxacin (1 g) or amoxicillin (3 g) if Gram's stain shows GNR; amoxicillin if it shows GPC. 3-day course if more symptomatic with TMS (1 double-strength tablet) bid, ciprofloxacin 500 mg bid, amoxicillin 500 mg tid. 7- to 10-day course if diabetes, recurrent UTI, age >65
Relapse	Same drug as for uncomplicated UTI, but continued for at least 2 weeks
Acute urethral syndrome with pyuria	TMS as for uncomplicated UTI, or doxycycline 100 mg bid for 10 days if *Chlamydia* infection suspected
Acute urethral syndrome without pyuria	No antibiotics
Recurrent infection	
Sexually active	Prophylaxis with nocturnal single-tablet dose of ampicillin, TMS, or ciprofloxacin
Elderly patient with large postvoid residual	Prophylaxis with nightly dose of TMS (half of a single-strength tablet) or ciprofloxacin (250 mg)
Pregnancy	Ampicillin, amoxicillin, and oral cephalosporins have proved safe; nitrofurantoin safe for the fetus, but potentially toxic for the mother; fluoroquinolones should be avoided

TMS, trimethoprim/sulfamethoxazole; GNR, gram-negative rod; GPC, gram-positive cocci; UTI, urinary tract infection.

Table 133.1. Antibiotic Regimens for Urinary Tract Infections in Women

INDICATIONS FOR REFERRAL OR ADMISSION

Hospitalization is indicated in patients with severe symptoms such as rigors, high fever, flank pain, nausea, and vomiting. Patients with suspected obstruction and those unable to maintain oral intake also require hospitalization. Referral to a urologist is indicated if a surgically correctable anatomic abnormality is detected or

suspected.

PATIENT EDUCATION

Certain general measures are important in minimizing the possibility of recurrent infection. The patient should be instructed about increasing fluid intake during symptomatic periods and maintaining urine flow around the clock. Patients with UTIs temporally related to sexual intercourse would probably benefit from voiding after intercourse. The importance of compliance with antibiotic regimens and follow-up for repeated urinalysis and culture must be impressed on patients with serious infections and relapses.

CHAPTER 134 APPROACH TO INCONTINENCE AND OTHER FORMS OF LOWER URINARY TRACT DYSFUNCTION

JOHN D. GOODSON

Patients with lower urinary tract dysfunction may present with incontinence, hesitancy, dribbling, loss of stream volume or force, frequency, or urgency. Such complaints are particularly prevalent among the elderly and a common problem in primary care practice. An efficient and parsimonious evaluation strategy is essential, given the large number of possible causes and available studies.

Incontinence can have a major impact on one's life and family. At the least, it is an embarrassment and an inconvenience. Constant incontinence can predispose to local skin breakdown, serious infection, and social isolation. In many instances, it is the culminating event that leads to nursing home placement. The primary physician must be attuned to the nature of the problem and the needs of the patient and family to design and implement an effective treatment program. Substantial progress has been made in the management of incontinence, and one should be familiar with available treatment strategies and their indications.

PATHOPHYSIOLOGY AND CLINICAL PRESENTATION

Normal Bladder Function and Continence. The *detrusor muscle* of the bladder is normally under simultaneous *sympathetic* and *parasympathetic* control. During the filling phase, sympathetic tone predominates, whereas parasympathetic tone is inhibited. The internal bladder sphincter tightens under a- *adrenergic* influence, and the detrusor relaxes under b -*adrenergic* influence. During voluntary emptying, parasympathetic stimulation produces detrusor contraction; at the same time, sympathetic tone decreases, the external sphincter of the pelvic floor relaxes, and abdominal muscles tighten. Normally, the urethra is oriented to the bladder so as to facilitate continence. With the initiation of voluntary voiding, the *urethrovesicular angle* changes so as to permit full drainage. Complete bladder emptying depends on unimpeded flow.

The process of voiding usually begins with a sensation of bladder fullness mediated by proprioceptive fibers in the detrusor. A reflex arc between the detrusor and the brainstem initiates and amplifies bladder contraction by parasympathetic stimulation. This arc is under cortical inhibition. Voiding occurs with the release of inhibition and voluntary relaxation of the pelvic external sphincter.

Incontinence. The pathophysiology and clinical presentations of incontinence can be divided on clinical and mechanistic grounds into categories of detrusor instability (urge incontinence), sphincter or pelvic incompetence (stress incontinence), reflex incontinence, overflow incontinence, and functional incontinence. Clinically, two or more processes frequently coexist to varying degrees in the same patient.

Detrusor Instability (Urge Incontinence) is characterized by reduced bladder capacity resulting from excessive and inappropriate detrusor contraction. For many, the condition appears to arise as a concomitant of *aging*, although the mechanism is unclear. In some, it seems to be the result of *decreased cortical inhibition* of detrusor contraction. Loss of cortical input can ensue from such conditions as cerebral infarction, Alzheimer's disease, brain tumor, and Parkinson's disease. For others, the detrusor overactivity is linked to *bladder irritation* from such causes as trigonitis (a common accompaniment of cystitis), chronic interstitial cystitis, postradiation fibrosis, and detrusor hypertrophy from outflow tract obstruction. Patients note a few moments of warning, frequent episodes of urgency, moderate to large volumes, and nocturnal wetting. In roughly half of patients, detrusor instability is associated with poor detrusor function. For these patients, voiding is frequent and incomplete.

Sphincter or Pelvic Incompetence (Stress Incontinence) is Usually a Consequence of Pelvic Floor Laxity and is the most common form of urinary incontinence in women. Less frequently, it develops from *partial denervation* that reduces sphincter tone. Pelvic laxity is seen as a concomitant of normal aging and of difficult or multiple vaginal deliveries or direct perineal injury. In some cases, a cystocele forms and further impedes control. Estrogen deficiency in women reduces the competency of the internal sphincter and can also cause urethral symptoms (dysuria and frequency). In men, pelvic incompetence may result from prostatic surgery, although in most cases the abnormality resolves within 6 months if innervation remains largely intact. Patients complain of incontinence, which occurs predominantly at times of straining (coughing, laughing, sneezing, lifting). There is loss of small to moderate volumes of urine, very infrequent nighttime leakage, and little postvoid residual.

Reflex Incontinence derives mostly from *spinal cord damage* above the sacral level. Interference with sensation and coordination of detrusor and sphincter activity secondary to inhibited or absent central control leads to *detrusor spasticity* and *functional outlet obstruction*. The patient is unable to sense the need to void. Spinal cord injury is the most common cause. Diabetes, multiple sclerosis, tabes dorsalis, and intrinsic or extrinsic cord compression from tumor or disk herniation are also important causes. Reflex incontinence takes place day and night with equal frequency and without warning or precipitating stress. Volumes are moderate, and voiding is frequent. Voluntary sphincter control and perineal sensation are reduced; sacral reflexes remain intact.

Detrusor Hypotonia (Overflow Incontinence) results from either long-standing *outlet obstruction, detrusor insufficiency*, or *impaired sensation*. The bladder becomes hypotonic, flaccid, and distended. Voiding consists primarily of overflow spillage. In outflow tract obstruction (most often from long-standing prostatic hypertrophy), the detrusor is constantly overstretched and gradually becomes incapable of generating sufficient pressure to ensure bladder emptying. Retrograde flow of urine and increased ureteral pressures can compromise renal function if the condition is left uncorrected. Often, detrusor insufficiency is a consequence of lower motor neuron damage, as occurs with injury to the sacral cord or the development of peripheral neuropathy. Importantly, numerous medications (e.g., anticholinergics, tricyclic antidepressants) can reduce detrusor tone. Distinguishing clinical characteristics include a palpably *distended bladder* and a *large postvoid residual*. Patients void frequently, especially after fluid loads and diuretics. A history of incomplete emptying, slow or interrupted flow, hesitancy, and the need to strain are reported. Injury either to peripheral nerves (as in diabetes or vitamin B $_{12}$ deficiency) or to the spinal cord may be accompanied by losses of perineal sensation and sacral reflexes.

Functional Incontinence refers to situations in which physical or mental disability makes it impossible to void independently, even though the urinary tract may be intact. Patients with disabling illness or simply an acute change to a bedridden state may be unable to maintain sufficient control over lower urinary function to avoid incontinence. Sedating drugs in such situations may only exacerbate the problem. Patients who are aware of their condition will describe their unsuccessful attempts to maintain continence. Patients with frontal lobe dysfunction secondary to cortical degenerative disease or normopressure hydrocephalus may be unaware of their own voiding and, therefore, functionally incontinent. Rarely, a severely disturbed patient is deliberately incontinent.

Urinary Frequency in Conjunction with Dysuria. Frequency accompanied by dysuria is a common presentation of lower *urinary tract infection*. Inflammation of the bladder trigone and urethra are responsible for most acute symptoms. *Chronic interstitial cystitis, acute urethral syndrome*, and *prostatosis* have been implicated as causes in cases without identifiable infection, although some of these may have inapparent infection with *Chlamydia* (see Chapter 125, Chapter 133, Chapter 136, and Chapter 139). *Carcinoma* of the bladder trigone or urethra is a rare but important cause of dysuria, frequency, and symptoms of outflow tract obstruction.

Urinary Frequency in Conjunction with Difficulty Voiding. When associated with slow stream, hesitancy, and a sense of incomplete emptying, frequency is likely to be a manifestation of *outflow tract obstruction* (extrinsic or intrinsic). At first, the patient may notice only minor slowness of stream. If the obstruction persists, bladder instability may ensue and cause frequent voiding of small volumes, followed later by chronic distention and overflow incontinence (see above). Strictures, tumor (especially prostatic enlargement), and occasionally stones are responsible for most cases of obstruction. In the setting of severe constipation, the rectal vault can become sufficiently impacted that it actually blocks the urethra and prevents bladder emptying. a -*Adrenergic* agents and b-*blockers* can increase sphincter tone and impair voiding acutely, especially in patients with preexisting lower urinary tract dysfunction. *Anticholinergic drugs* may interfere with bladder contraction.

Urinary Frequency and Polydipsia. When frequency presents in association with increased thirst, it suggests a diabetic condition leading to increased urine volume

and the resultant polyuria. *Diabetes mellitus* is distinguished by significant glycosuria (see Chapter 102). *Neurogenic (idiopathic central) diabetes insipidus* is manifested by sudden onset, craving for huge volumes of cold water, and prodigious urine outputs (5 to 10 L/d). Inability to concentrate the urine after overnight fluid deprivation and response to parenteral antidiuretic hormone (ADH), with formation of a concentrated urine, characterize the condition. Patients with *nephrogenic diabetes insipidus* differ from those with the neurogenic variety in that their kidneys do not respond to intrinsic or parenteral ADH. Hypercalcemia, lithium therapy, and pregnancy are precipitants of the acquired variety. Patients with *psychogenic polydipsia* may be hard to distinguish from those with nephrogenic diabetes insipidus because they have washed out their renal concentrating system and also do not adequately respond to parenteral ADH. They do respond normally to fluid deprivation, a diagnostically useful finding, although some patients with neurogenic disease respond in a similar fashion (see Chapter 101).

Isolated Urinary Frequency. Isolated frequency may be a manifestation of reduced bladder capacity, or a presentation of mild diabetes mellitus, mild diabetes insipidus, minor urinary tract infection, or bladder irritation. A large *extrinsic* or *intrinsic mass* impinging on the bladder can reduce its capacity and produce frequent urination, usually of small volumes, which distinguish it from other forms of polyuria. Pelvic surgery, chronic interstitial cystitis, or irradiation can have a similar effect by reducing bladder capacity. Patients who surreptitiously abuse *diuretics* rarely complain of frequency, but those who take them for therapeutic purposes are often bothered by the side effect. Nocturnal urinary frequency and occasional incontinence can represent the *mobilization of fluid* in patients with dependent edema associated with congestive heart failure or intake of certain medications, such as some of the calcium channel blockers.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of incontinence can be classified according to clinical presentation and mechanism (Table 134.1). The differential diagnosis of dysuria and frequency is that of urinary tract infection and its related syndromes (see Chapter 133 and Chapter 140). Most of those with difficulty voiding are men with prostatic enlargement (see Chapter 138). Among other causes of difficult voiding are drugs (anticholinergics, b-blockers, sedatives), urethral stricture, congenital valves, stone, tumor, pelvic abscess, and fecal impaction. Causes of urinary frequency in the absence of other urinary tract symptoms include diabetes mellitus, diabetes insipidus, psychogenic polydipsia, diuretics, and bladder compression.

Table 134.1. Important Causes of Incontinence

WORKUP

The evaluation of incontinence and other lower urinary tract symptoms requires assessment of the major neuromuscular and anatomic elements involved in maintaining urinary continence and flow. Much can be gleaned from the history and physical examination, which provide important clues to the underlying pathophysiology and precipitants.

History. For the assessment of incontinence, one cannot overemphasize the importance of a detailed history, with emphasis on the circumstances, precipitants, timing, frequency, and volume of urine loss, the presence of warning symptoms, and the intactness of perineal and bladder sensation. When the history is sketchy, asking the patient or family to keep a *diary* of events and contributing factors can be of considerable help. This diary should include the following: time of urination; an estimate of the volume; the symptoms associated with each void, such as leakage; and any precipitating events, such as laughing or coughing.

Several clinical pictures are indicative of mechanism. Incontinence triggered only by *straining* indicates stress incontinence, although an occasional patient with overflow incontinence will report leakage under similar circumstances. Patients with overflow differ in that they also experience frequent loss of *small volumes* without warning or straining and are bothered by nocturnal episodes. A history of long-standing obstructive symptoms, such as difficulty with stream initiation or weakened urine flow, suggests an etiology for the overflow physiology.

In contrast to those with overflow disease, patients who have frequent episodes of *urgency*, lose small amounts of urine, yet retain perineal sensation are likely to have detrusor instability. Although there may be a few moments of warning, they too report nocturnal incontinence. When this is accompanied by dysuria, a search for urinary tract infection is indicated (see Chapter 133 and Chapter 140). Frequent voiding of small volumes and urgency are also consistent with a small bladder resulting from extrinsic compression.

Reflex incontinence is suggested by a history of spinal cord injury, diabetes, multiple sclerosis, or dementia with neurologic deficits. Severe loss of cortical function is also a precipitant of detrusor instability. Furthermore, recent physical disability and confinement to bed may produce functional incontinence.

Regardless of the history and type of underlying pathology, the patient and family should be carefully questioned about *medications*, especially those with anticholinergic, a-adrenergic, b-adrenergic blocking, tranquilizing, or diuretic effects (e.g., tricyclic antidepressants, major and minor tranquilizers, decongestants, and antihypertensives). Any excessive use of coffee, tea, or alcohol should be noted.

Patients with isolated urinary frequency need to be asked about *increased thirst*, a feature consistent with diabetes mellitus and diabetes insipidus. Compulsive water drinkers with psychogenic polydipsia may deny their intake of water but do not report nocturia, a feature of both diabetes mellitus and diabetes insipidus. The sudden onset of intense thirst for ice-cold water is very suggestive of diabetes insipidus.

Those with symptoms of slow stream and hesitancy are likely to have outflow obstruction and should be checked for prostatism, stricture, stone, tumor, and fecal impaction.

Physical Examination. For the patient with incontinence, the examination begins by noting general appearance and any lack of attention to personal hygiene. A careful urogenital examination is essential and includes suprapubic palpation and percussion of the bladder after voiding to detect distention and masses. When appropriate, the *rectum* should be checked for impaction or *prostatic enlargement*. Absence of palpable pros-tatic enlargement does not rule out obstruction, especially in a patient with obstructive symptoms; median lobe encroachment on the urethra is often not palpable. Likewise, a large prostate does not predict severe obstruction.

Woman with stress incontinence should be examined in the lithotomy position. *Pelvic motion* and continence should be noted during cough or Valsalva's maneuver. Testing for stress incontinence is best done with the bladder full, unless the problem is severe and requires little provocation. Check the *vaginal mucosa* for atrophic changes (red, thin mucosa with a watery discharge) indicative of inadequate estrogen. A *bimanual examination* completes the evaluation, with note taken of any uterine or adnexal masses.

Neurologic control of voiding needs to be assessed to determine the presence of any deficits above, within, or distal to the autonomic reflex arc. Checking the *bulbocavernosus reflex* tests the integrity of the arc. Normally, squeezing the clitoris or glans penis will cause anal sphincter contraction. Lack of response suggests interruption. Another means of testing the arc is to note *anal sphincter tone*. Because control of the anal sphincter is similar to that of the bladder, the examiner can indirectly estimate its competence by checking the anal tone on rectal examination and by noting the patient's ability to contract the sphincter voluntarily. Loss of

sphincter tone in a patient who retains sensation suggests a motor neuron lesion within the arc.

Perineal sensation is also tested; if it is lacking, yet sacral reflexes are preserved, reflex incontinence from a lesion above the arc is suggested, such as one caused by diabetes, multiple sclerosis, or spinal cord injury. Patients with loss of both sensation and reflexes are likely to have overflow incontinence because of neurologic injury to the reflex arc. Incontinent patients who retain their reflexes and sensation have detrusor instability, stress incontinence, overflow incontinence, or a functional problem.

A mental status examination is usually not necessary to detect underlying dementia in the patient with incontinence; in most cases, the condition is apparent by the time incontinence occurs.

Laboratory Studies. Often, a careful history and examination are sufficient to arrive at a working diagnosis for the patient with lower urinary tract symptomatology. A *urinalysis* and a few simple chemistry studies (*blood urea nitrogen, creatinine*, and *glucose*) are appropriate for most patients. Consider a *serologic test for syphilis* in patients with overflow incontinence. All patients should have a *urinalysis* and possible *culture* to exclude concurrent infection. *Pelvic ultrasonography* offers a noninvasive method of assessing postvoid residual and is especially useful when outflow obstruction or detrusor failure is suspected. *Straight catheterization* after voiding is a simple office technique for determining residual volume, a useful measure when overflow incontinence is in question. A volume over 50 mL is abnormal.

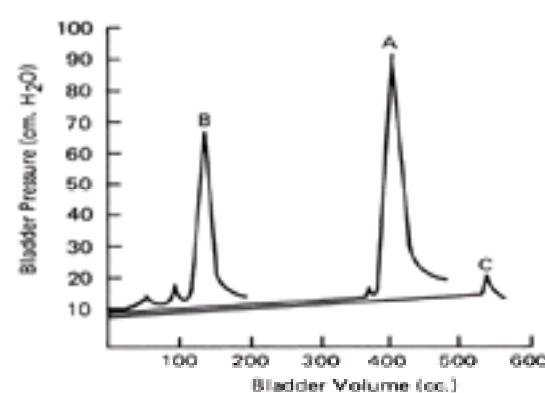
The *cystometrogram* is rarely needed but can help to sort out complicated mixed conditions. Normal persons sense bladder filling between 100 and 200 mL, have a nonurgent desire to void at 250 to 350 mL, and experience detrusor contraction at 400 to 550 mL (Fig. 134.1A). A spastic bladder will demonstrate a small capacity and recurrent uninhibited contraction (Fig. 134.1B). An atonic bladder will show a large volume and little contractile force (Fig. 134.1C).


FIG. 134.1. Cystometrogram findings. **A:** Normal pressure–volume relationship. **B:** Uninhibited neurogenic bladder. **C:** Atonic bladder.

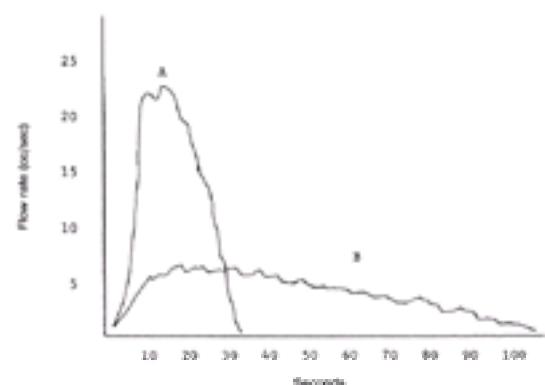
Measurement of *urine flow* rates provides information on outflow obstruction and aids in monitoring the progression of obstruction. Normal flow rates are 10 mL/sec with more than 200 mL in the bladder. The normal curve (Fig. 134.2A) shows an early peak flow rate, whereas the curve of the obstructed bladder manifests a delayed and reduced flow rate (Fig. 134.2B).


FIG. 134.2. Urinary flow studies. **A:** Normal voiding. **B:** Obstructed voiding. The area under each curve represents the volume voided.

Patients with polyuria should be checked for glycosuria, hypercalcemia, and hypokalemia. Those with normal levels should have their urine-concentrating ability tested; this is accomplished by measuring *urine osmolality* after 8 hours of *fluid restriction* (usually overnight). Normal persons and those with psychogenic polydipsia should be able to concentrate their urine to more than 700 mOsm/L after 8 hours of fluid restriction. Inability to concentrate requires further testing, including measurement of serum osmolality before and after water restriction and parenteral administration of ADH. Direct measurement of ADH may be helpful (see Chapter 101).

MANAGEMENT OF INCONTINENCE

General Measures. Management is best guided by the mechanism(s) responsible for the incontinence, the patient's overall medical and mental status, and the capabilities of the family or caretakers (Table 134.2). However, some general measures apply to all incontinent patients:

Table 134.2. Drugs Used to Treat Incontinence

- Restrict fluid loads, coffee, tea, and alcohol.
- Limit the use of diuretics, and, if necessary, give them in the morning.
- Anticholinergic drugs for nonurologic purposes should be given with care and in the lowest possible dosages.
- Avoid use of indwelling catheters because of the risk for infection, exacerbation of detrusor instability, and leakage.
- Avoid use of condom catheters, except for short, well-supervised periods.

- Advise use of an adsorbent pad for patients with refractory symptoms and recommend that it be changed frequently to prevent skin breakdown.
- If long-term indwelling catheterization is unavoidable, the catheter should be inserted only by trained personnel under aseptic conditions, drained with the bag always below the patient's bladder, manipulated as little as possible, irrigated only if flow is reduced, changed if blocked, and removed if upper tract infection is suspected. Antibiotic prophylaxis is not recommended.

Detrusor Instability (Urge Incontinence). Before symptomatic therapy is initiated, one should attend to treatable etiologic factors, such as outflow obstruction or chronic bladder irritation. In most instances, the cause cannot be identified or is not amenable to definitive treatment, so that symptomatic relief becomes the major objective. Much can be done.

- Teach the patient to void at regular, frequent intervals. Patients can learn to suppress the urge to void by contracting pelvic muscles and then relaxing them slowly or by engaging in distracting activities (such as mathematical calculations or conversations). Over time, the intervals can be increased. Sometimes, merely keeping a voiding diary improves urinary control.
- Provide a bedside commode or urinal for the patient.
- Initiate a trial of a tricyclic agent, such as imipramine (10 to 100 mg/d in divided doses).
- Initiate a trial of an agent with both smooth-muscle relaxant and anticholinergic properties, such as oxybutynin (2.5 to 5 mg three times daily). Lower doses can be effective in the elderly, and untoward central nervous system side effects and intolerable dry mouth are thereby avoided. The selective bladder smooth-muscle relaxant tolterodine (1 to 2 mg twice daily) has fewer side effects than oxybutynin and may be better tolerated.

Detrusor Atony (Overflow Incontinence). The first priority is definitive treatment of any mechanical obstruction or reversible neurologic deficit (e.g., herniated disk, vitamin B_{12} deficiency), followed by efforts to reduce the postvoid residual and prevent infection. If a fixed obstruction is present, relief may be sufficient to allow detrusor function to return.

- For both acute and chronic obstruction, place an indwelling catheter or repeatedly catheterize the patient to decompress the bladder.
- If this does not restore bladder function, then teach the patient to void while performing a Credé's maneuver (suprapubic external compression) or Valsalva's maneuver.
- Add an a-blocker such as prazosin (2 to 20 mg/d in divided doses), doxazosin (2 to 8 mg/d), terazosin (1 to 10 mg/d), or tamsulosin (0.4 to 0.8 mg/d) to reduce sphincter resistance.
- Add bethanechol (25 to 125 mg/d in divided doses) to augment bladder contraction.
- Monitor the effects of these agents by checking postvoid residuals; patients with a residual in excess of 300 mL require repeated sterile catheterization on an intermittent basis (three to four times per day).

Sphincter Incompetence (Stress Incontinence). The condition responds well to simple measures, beginning with exercises to strengthen the perineal muscles that terminate the urinary stream. For postmenopausal women, estrogen cream can also help. Surgical approaches are reserved for patients with persistently incapacitating difficulty.

- Instruct the male patient to exercise by voluntarily contracting the anal sphincter slowly 15 times once or twice a day.
- Instruct the female patient in the Kegel exercises.
- For a female patient with evidence of atrophic vaginitis, prescribe a topical estrogen cream (Table 134.2). It should be applied daily for the first 3 weeks and then once or twice weekly thereafter to maintain sufficient estrogen to restore internal sphincter and uretheral tone in postmenopausal women. Continuous use may increase the risk for uterine cancer in women with an intact uterus. This risk can be eliminated with the concurrent use of a progestin (see Chapter 118).
- Prescribe the a-adrenergic agonist phenylpropanolamine (50 to 100 mg/d in divided doses) for patients who need more than exercises. This agent is especially useful in the presence of weakened pelvic muscles and after surgical instrumentation of the urethra. It can be found in most over-the-counter cold remedies but should not be given to patients with hypertension.
- Try a course of imipramine (10 to 100 mg/d in divided doses) for those with symptoms of both bladder irritability and stress incontinence.
- Pessaries come in a variety of shapes and can be successfully fitted to improve continence. They must be changed and cleaned regularly.
- A penile clamp may be necessary in men who do not respond to other measures. Careful monitoring and a competent patient are necessary.

Reflex Incontinence. A major problem is a dyssynergy between bladder contraction and sphincter relaxation that results in ureteral reflux and the potential for hydronephrosis. The bladder needs to be decompressed. An a *-adrenergic blocking agent* or mechanical maneuvers may help. For frequent urination, the mechanical measures and behavioral techniques are similar to those for detrusor instability.

- In a patient with bladder–sphincter dyssynergy, try pharmacologically decompressing the bladder by giving prazosin (2 to 20 mg/d in divided doses), doxazosin (2 to 8 mg/d), terazosin (1 to 10 mg/d), or tamsulosin (0.4 to 0.8 mg/d).
- Consider an agent used for detrusor instability (see above). A sphincterotomy may be required to ensure bladder emptying.

Functional Incontinence. The prime effort is to ease the patient's access to a urinal, bed pan, or commode. Bedside placement is the obvious solution. For more disabled patients, regular use of absorbent diapers, frequent straight catheterization, or rarely condom or indwelling catheterization can be considered.

PATIENT EDUCATION

Incontinence is hard for both patient and family. The primary care physician must ensure that all understand the problem and its cause so that no one blames the patient for being incontinent. The need to provide palliative relief early in the course of the evaluation makes it important to teach symptomatic measures even before the workup is completed. The use of adult diapers, pads, and scheduled voiding times, plus elimination of xanthine-containing beverages and alcohol and rescheduling of medication intake, can do much to lessen symptoms and the stress on patient, family, and caretakers.

INDICATIONS FOR REFERRAL

The incontinent patient with a suspected cord lesion or other form of neurologic injury should be promptly referred for neurologic consultation. Urologic referral is needed in cases of outflow tract obstruction, especially those severe enough to cause a hypotonic bladder and a large postvoid residual (>100 mL). The risk for ureteral reflux and the development of hydronephrosis makes definitive therapy essential. Women with refractory stress incontinence are candidates for reconstructive surgical efforts; referral should be made to a surgeon experienced with correcting pelvic incompetence. Those with stubborn detrusor instability or hypotonia are potential candidates for biofeedback therapies. Patients with severe sphincter dyssynergy and reflex incontinence may require a sphincterotomy if all else fails.

CHAPTER 135 APPROACH TO THE PATIENT WITH NEPHROLITHIASIS

LESLIE S.-T. FANG

Nephrolithiasis is a significant medical problem incurring substantial morbidity and cost. One autopsy series estimated the prevalence as 1.12%. In most industrialized countries, 1% to 3% of the population may be expected to have a calculus at some time, and the likelihood that stone disease will develop in a white man by age 70 is about 1 in 8. The annual frequency of hospitalization for nephrolithiasis is estimated at 1 in 1,000 population. The recurrence rate without treatment for calcium oxalate renal stones is about 10% at 1 year, 33% at 5 years, and 50% at 10 years. In the outpatient setting, the primary physician may encounter patients with a history of renal calculi, asymptomatic nephrolithiasis, or acute colic. Others may present with hematuria or urinary tract infection. One needs to identify the nature of the stone and any precipitating factors, prevent further stone formation, and know when referral for surgical intervention or lithotripsy is needed.

PATHOPHYSIOLOGY AND CLINICAL PRESENTATION

Two major groups of factors are important in the pathogenesis of stones: (a) changes that increase the urinary concentration of stone constituents; and (b) physicochemical changes.

Increase in concentration can occur with reductions in urinary volume or increases in the excretion of calcium, oxalate, uric acid, cystine, or xanthine.

Calcium-containing Stones. The majority of calcium-containing stones contain calcium oxalate; hypercalciuric and hyperoxaluric states promote stone formation. In some instances, hyperuricemia also contributes to calcium stone formation.

Hypercalciuric states can be categorized into three groups according to cause: increased gut absorption of dietary calcium, increased resorption of calcium from bone, and the presence of a renal calcium leak. Combinations of these factors can be at play in certain clinical settings. About 50% of patients with calcium stones are found to be hypercalciuric.

Hyperoxaluria is less common than hypercalciuria, but recent studies indicate that up to 30% of patients with calcium oxalate stones are hyperoxaluric. Hyperoxaluria may result from increased absorption of dietary oxalate, as occurs in patients with small-bowel disease; from increased endogenous production of oxalate, as occurs in patients with a genetic deficiency of enzymes in the glyoxalate pathway or of pyridoxine (an important cofactor in glyoxalate metabolism); or, rarely, from markedly increased ingestion of oxalate or one of its precursors.

Some patients with calcium-containing stones may be hyperuricosuric. It is believed that adsorption of glutamic acid onto a uric acid nidus allows for the growth of calcium oxalate crystals.

Magnesium Ammonium Phosphate Stones (Struvite). Struvite formation occurs in an alkaline environment and is almost invariably associated with urinary tract infection produced by a urea-splitting organism.

Uric Acid Stones. Most patients with uric acid stones have persistently acid urine, which decreases the solubility of uric acid. Some patients may be hyperuricosuric. Hyperuricosuric states are seen in patients with a high dietary intake of protein and with primary and secondary gout. In patients who have myeloproliferative disorders or are undergoing chemotherapy, significant hyperuricosuria can occur, and uric acid stones can form if adequate urine flow and alkalinization are not maintained.

Cystine Stones. Cystine stones are found exclusively in patients with cystinuria. These patients have an inherited disorder in which renal and gastrointestinal transport of cystine, ornithine, lysine, and arginine is abnormal.

Xanthine Stones. These occur in the setting of xanthinuria, an extremely rare genetic disorder of purine metabolism associated with a deficiency of xanthine oxidase. Rarely, xanthine stones may be seen in patients taking xanthine oxidase inhibitors for the treatment of uric acid disorders.

Physicochemical factors that have been identified as important in stone formation include changes in urinary pH and urinary concentrations of potential inhibitors of stone formation, such as magnesium, citrate, sulfate, organic matrix, and pyrophosphate. As noted earlier, an alkaline pH facilitates struvite formation, and an acidic pH facilitates the formation of uric acid and xanthine stones.

Magnesium, citrate, pyrophosphate, and certain anions in high urinary concentrations are potent inhibitors of stone formation. Deficiencies in one or more of the inhibitors have been identified in some patients with recurrent stones.

Three major theories have been advanced to explain stone formation and growth. The *matrix nucleation* theory suggests that some matrix substances (e.g., uric acid) form an initial nucleus for subsequent stone growth by precipitation. The *precipitation–crystallization* theory suggests that when the urinary crystalloids are present in a supersaturated state, precipitation and subsequent growth occur. The *inhibitor absence* theory postulates that the deficiency of one or more of numerous agents known to retard stone formation leads to nephrolithiasis. Evidence for and against each of these theories has been advanced; multiple factors may be involved in any patient.

Clinical presentation is one of pain, bleeding, or silent obstruction. *Renal "colic"* is typically a constant unilateral pain, abrupt in onset, localized to the flank when a stone sits in the upper tract and radiating into the groin when a stone lodges in the lower portion of the ureter. The presentation may be mistaken for pyelonephritis and occasionally for abdominal and pelvic processes, but the initial workup should rapidly lead to the correct diagnosis.

Any *obstruction* that occurs is usually transient and of no lasting significance; however, in some instances, it persists and may be silent and progressive. Occasionally, asymptomatic calcareous calculi are detected on abdominal x-rays films taken for other reasons. Calculi extending from one renal calix to another ("staghorn" calculi) can result in significant renal parenchymal damage, particularly in association with infection.

Natural history of stone formation is still a matter of some controversy. The likelihood of *recurrence* of calcium stones with time was examined prospectively in one study of patients in whom single stones formed. An exceedingly high incidence of recurrence was found, with a mean time to recurrence of 6.78 years. With time, the incidence of cumulative recurrence approached 100%. Recurrence appeared early in half of the patients but took up to 20 years in others.

Other studies have found a more benign course. In one, a group of 101 patients was followed for an extended period (mean, 7 years); additional stone formation was observed in only a third of the patients. These differences in recurrence rates undoubtedly reflect heterogeneity among patients in the respective referral groups. In any case, the incidence of recurrence is high enough to justify evaluation and consideration of preventive treatment.

Most kidney stones pass spontaneously; however, 10% to 30% do not and may cause continuing pain, infection, or obstruction.

DIFFERENTIAL DIAGNOSIS

In the United States, about two thirds of all renal calculi are composed of either calcium oxalate or calcium oxalate mixed with calcium phosphate (Table 135.1).

Stones of pure uric acid account for about 10%. Struvite or magnesium ammonium phosphate stones occur almost exclusively in patients with urinary tract infections caused by urea-splitting organisms, and they constitute about 9% of all stones analyzed. Other stones occur infrequently and are composed of cystine, xanthine, and silicates.

Calcium oxalate	58.8%
Calcium phosphate	8.9%
Mixed calcium oxalate and phosphate	11.4%
Uric acid	10.1%
Struvite (magnesium ammonium phosphate)	9.3%
Cystine	0.7%
Miscellaneous	0.8%

Table 135.1. Types of Renal Calculi

The disease states associated with nephrolithiasis are best categorized according to the type of stones formed. In many instances, stone formation is a manifestation of systemic disease (Table 135.2).

Calcium Stones
Increased gastrointestinal calcium absorption
  Primary hyperparathyroidism
  Sarcoidosis
  Vitamin D excess
  Milk-alkali syndrome
  Idiopathic nephrolithiasis
Increased bone calcium resorption
  Primary hyperparathyroidism
  Neoplastic disorders
  Immobilization
  Distal renal tubular acidosis
Renal calcium leak
  Idiopathic hypercalciuria
Hyperoxaluria
  Small-bowel disease
  Enzymatic deficiency
  Pyridoxine deficiency
  Increased ingestion
Magnesium Ammonium Phosphate Stones
Alkaline environment
  Urinary tract infection caused by urea-splitting organism
Uric Acid Stones
Increased uric acid production
  Primary gout
  Secondary gout (myeloproliferative disorder, chemotherapy)
Cystine Stones
Inherited disorder for amino acid transport
Xanthine Stones
Xanthine oxidase deficiency
Use of xanthine oxidase inhibitor

Table 135.2. Important Conditions Associated with Nephrolithiasis

WORKUP

In the evaluation of the patient with recurrent nephrolithiasis, knowledge of the stone composition is essential to rational management. Obtaining the stone for analysis is the single most important study; therefore, urine should be strained for stones when renal colic is present. Ideally, studies of the stone should include quantitative chemical analysis in addition to crystallographic examination.

History. When no stone is available for analysis, certain aspects of the clinical history can be helpful in the evaluation. The *age* of the patient at the onset of nephrolithiasis should be obtained because metabolic disorders such as hyperoxaluria, cystinuria, xanthinuria, and renal tubular acidosis are often associated with stones at an early age; idiopathic calcareous nephrolithiasis and primary hyperparathyroidism commonly develop after age 30. The *sex* of the patient can also be helpful; idiopathic nephrolithiasis is common in males, whereas primary hyperparathyroidism is more common in females. A *past history* of stones is invaluable if their composition has been previously determined. Any prior history of systemic illness (e.g., sarcoidosis or cancer) and any prior urinary tract infection should be noted. A *family history* of nephrolithiasis increases the risk for stone disease and may suggest a hereditary metabolic disorder. A careful *dietary history* should also be taken to rule out excessive protein, oxalate, or calcium intake. Consumption of apple juice and grapefruit juice has been associated with an increased risk for stone formation. Consumption of alcoholic beverages is associated with a decreased risk. It is important to check for the use of *drugs* that promote stone formation. Medications that result in an increased risk for stone formation include vitamins A, C, and D, loop diuretics, acetazolamide, ammonium chloride, calcium-containing medications, alkali, and antacids. Medications may increase urinary concentrations of calcium (vitamin D, loop diuretics, calcium-containing medications, ammonium chloride), alter urinary pH (acetazolamide, ammonium chloride, and alkali), or decrease urinary concentrations of inhibitors (ammonium chloride, absorbable antacids, and alkali can decrease urinary citrate concentration).

Physical Examination is not particularly revealing in most cases, but the patient should be checked for evidence of a systemic disease, such as sarcoidosis (lymphadenopathy, organomegaly) or cancer (adenopathy, breast mass, and so forth).

Laboratory Evaluation should include *urinalysis* for determination of pH and an examination of urinary sediment for crystals. An alkaline pH suggests infection with urea-splitting organisms and struvite formation. *Urine culture* is needed. Inability to acidify the urine pH below 5.3 despite systemic acidosis suggests renal tubular acidosis. Serum should be obtained for determination of calcium, uric acid, blood urea nitrogen, and creatinine levels, and a *24-hour urine* should be collected for creatinine, calcium, uric acid, and oxalate.

Repeated determinations of *fasting serum calcium* and *phosphorus* are necessary if primary hyperparathyroidism is suspected. The serum albumin should be determined at the same time because 40% to 45% of the serum calcium is protein-bound. If the serum calcium is elevated and hyperparathyroidism is suspected clinically, the diagnosis can be confirmed by obtaining a simultaneous *parathyroid hormone* determination, which should reveal an inappropriately elevated level (see Chapter 96). If the clinical presentation suggests a rare cause of nephrolithiasis, such as cystinuria or xanthinuria, special 24-hour collections of urine should be sent for study.

Roentgenographic evaluation includes a plain film of the *kidneys, ureter, and bladder* (KUB), and an *IV pyelogram*. The flat-plate radiograph of the abdomen can provide an estimate of renal size and is important in detecting the presence of small, radiopaque stones. Staghorn calculi usually denote magnesium ammonium phosphate or cystine stones. The latter usually have a more laminated appearance. The *IV pyelogram* provides better details of any renal abnormalities that may be present, in addition to the level of the obstruction caused by the renal calculus. *Renal ultrasonography* is useful for detecting hydro-nephrosis but is not a substitute for the IV pyelogram in the initial workup of urolithiasis.

The laboratory evaluation permits the identification of stones and hyperexcretory states and therefore allows rational therapy.

PRINCIPLES OF MANAGEMENT

Because of the high incidence of stone formation and its attendant morbidity, preventive therapy is indicated in all patients with nephrolithiasis.

In general, maintenance of dilute urine by means of *vigorous fluid therapy* around the clock is beneficial in *all forms of nephrolithiasis*. A number of studies have indicated that the relative probability of a kidney stone forming decreases with urinary volume. Enough fluid to maintain an output of 2 to 3 L of urine needs to be taken daily. In general, 250 mL of fluid should be taken every 4 hours, and 250 mL of fluid should be taken with meals. A high fluid intake has been associated with a

40% reduction in recurrence risk. Specific therapy should be tailored to the type of stones involved.

Calcium-containing Stones. During the past decade, a considerable amount of information has become available to suggest that dietary manipulation is helpful in the management of calcium-containing stones. Increasing evidence has accumulated to indicate that *restriction of dietary protein* is helpful in preventing the formation of calcium-containing stones. Population studies indicate a clear correlation between increased dietary protein and an increased incidence of stone formation. Protein loading in patients results in an increase in urinary excretion of both calcium and uric acid. A high dietary intake of protein also decreases urinary concentrations of inhibitors such as citrate. These metabolic abnormalities are corrected with restriction of dietary protein. *Sodium intake should also be restricted.* Restriction of dietary sodium predictably results in a decrease in urinary calcium excretion. Oxalate is a metabolic end product of glycine, and the bulk of the urinary oxalate is derived from metabolic pathways. However, in some patients, dietary excesses of oxalate can result in hyperoxaluria. These patients would benefit from a *restriction of dietary oxalate. Evidence does not support dietary restriction of calcium.* Calcium restriction results in an increased intestinal absorption of oxalate, which leads to hyperoxaluria in addition to mobilization of calcium from the bone because of a negative calcium balance. Cohort studies have demonstrated an inverse relationship between dietary calcium intake and stone formation. In other words, a high dietary intake of calcium decreases the risk for symptomatic stone disease. However, supplemental calcium intake has been associated with a modest increase (relative risk, 1.20) in stone formation.

Dietary manipulations have been shown to prevent further stone formation. In one series, in which patients with first-time stones were placed on a dietary program, only a 27% recurrence of stones was noted during a 5-year follow-up.

For patients with recurrent stone formation despite dietary therapy, every effort should be made to rule out underlying systemic conditions (Table 135.2) before *drug therapy* is initiated. Patients with underlying primary hyperparathyroidism should be treated surgically when feasible. Drugs that can promote calcium stone formation should be stopped. Patients with sarcoidosis may benefit from steroid therapy.

Thiazides decrease urinary calcium excretion, and hydrochlorothiazide (50 mg once a day) has been found to be effective in *reducing recurrent stone formation*. Primary hyperparathyroidism has to be ruled out before thiazides are given to avoid hypercalcemia.

Patients with *hyperoxaluria* should have their dietary intake of oxalates limited. Tea, rhubarb, and many leafy green vegetables should be avoided. Dietary calcium, on the other hand, should not be severely restricted because severe calcium restriction has been shown to cause increases in the urinary excretion of oxalate. In the rare patient with pyridoxine deficiency, replacement would improve the hyperoxaluric state.

Patients with *hyperuricosuria* benefit from protein restriction and *allopurinol*. Reduction of the urinary uric acid concentration minimizes the likelihood of calcium oxalate crystal growth around acid adsorbed to uric acid. Two randomized trials have shown that stone recurrence rates are lower with allopurinol treatment.

Studies in patients with *no identifiable metabolic disorder* have demonstrated a drastic reduction in new stone formation when patients are given a *thiazide* and *allopurinol*. In one study, six stones formed in 30 such patients, compared with a predicted 31.8 stones, during a 1- to 7-year follow-up period.

In addition to the therapeutic interventions outlined, several other, less well-evaluated modes of therapy have been advocated. Administration of *magnesium oxide* may improve the solubility of urinary oxalate. In patients with documented hypocitraturia, *potassium citrate* may be useful in inhibiting new stone formation. These forms of therapy have not been evaluated with rigorous controlled trials.

Magnesium Ammonium Phosphate Stones. These are often very large and may have to be removed surgically. Acidification of the urine with ascorbic acid, along with a prolonged (often at least 2 months) course of appropriate *antibiotic treatment* to eradicate any *Proteus* urinary tract infection, is essential to prevent recurrences of struvite stones.

Uric Acid Stones. *Hydration* to maintain copious urine flow, *allopurinol* therapy, and *alkalinization* of the urine are the mainstays of therapy. The solubility of uric acid is 100 times higher at pH 7 than at pH 4.5, and every attempt should be made to maintain alkaline urine by giving 100 to 150 mEq of *sodium bicarbonate* every 24 hours in divided doses. In patients with myeloproliferative disorders who are undergoing chemotherapy, the prophylactic use of allopurinol, saline diuresis, and alkalinization should eliminate the incidence of uric acid stone formation.

Cystine Stones. A copious urine flow and urinary pH maintained above 7.5 are important in preventing and dissolving cystine stones. D-Penicillamine has also been shown to be effective, but significant side effects may be encountered.

Xanthine Stones. Limitation of dietary purines, maintenance of urine flow, and maintenance of very high urine pH (>7.6) minimize difficulties. Prophylactic alkalinization and forced diuresis should be employed in patients with myeloproliferative disorders who are taking xanthine oxidase inhibitors.

INDICATIONS FOR ADMISSION AND REFERRAL

In a patient with renal colic, the need for hospitalization and other interventions is dictated by the clinical presentation. Patients with mild to moderate pain can be managed as outpatients with oral analgesics and instructed to maintain a high fluid intake and urine output around the clock. These patients should be told to strain the urine to retrieve calculi for stone analysis.

Patients with severe pain, nausea, and vomiting require hospitalization for IV hydration and pain control. In these patients, KUB and IV pyelogram are indicated to localize and determine the extent of the obstruction. In the majority of cases, stones will pass spontaneously. Patients with severe symptoms and persistent obstruction beyond 3 to 4 days should be referred for urologic evaluation.

Patients presenting with fever, chills, and symptoms of renal colic require hospitalization and prompt intervention. If the presence of an infection behind an obstructed ureter is indeed confirmed, antibiotic coverage (see Chapter 133) and surgical decompression are mandatory.

Surgical intervention for nephrolithiasis has changed dramatically with the introduction of a number of new techniques; *lithotripsy* and *ureteroscopic interventions* have largely obviated the need for lithotomy in most patients. In lithotripsy, the stone is shattered by subjecting it to focused ultrasonic shock waves, delivered either percutaneously through a nephrostomy or extracorporeally. *Extracorporeal shock wave lithotripsy* is an excellent choice for fragmentation and removal of simple stones in the kidneys and upper ureters. Its very low complication rate and high degree of efficacy are rapidly eliminating the need for surgical lithotomy in the centers where the lithotriptor is available. Because the equipment needed to perform the procedure is expensive and not widely available, *percutaneous ultrasonic lithotripsy* represents an acceptable alternative and may be the preferred initial therapy for upper tract stones lodged in the ureter for more than 4 to 6 weeks. The procedure is also indicated for larger (>2.5 cm) stones. *Ureteroscopic* approaches have allowed basketing of stones that have lodged in the ureters, obviating the need to resort to open lithotomy.

The expense and operator skill required for these technologies limit their availability to regional centers. Patients with documented stones, especially those that are located in the upper tracts and kidney or that cause continuous pain, infection, or obstruction, should be referred to such centers for intervention.

PATIENT EDUCATION

Meticulous care must be taken in giving dietary instructions. Patients should also be instructed regarding how to divide their fluid intake evenly to maintain a dilute urine at all times. As noted previously, a daily fluid intake of 2 to 3 L is needed to help minimize stone formation. Consumption of apple and grapefruit juice has been associated with increased risk, and alcoholic beverages appear to decrease risk. Because there is some evidence that soft drinks acidified solely with phosphoric acid may contribute to stone recurrence, patients might be advised to avoid them. However, most soft drinks also contain citric acid, and the combination appears to have no effect on stone recurrence. Patients who need to alkalinize their urine should be instructed in how to measure urinary pH with litmus test tapes. Long periods of immobilization should be avoided, and appropriate fluid intake should be prescribed if such situations are anticipated.

CHAPTER 136 APPROACH TO THE MALE PATIENT WITH URETHRITIS

JOHN D. GOODSON

A penile discharge or urethral discomfort may be the presenting manifestation of a sexually transmitted disease (STD) and, as such, requires prompt attention. Nongonococcal urethritis (NGU) has surpassed gonorrhea as the principal cause of urethral symptoms in men and has reached epidemic proportions in sexually active adolescents and college-age persons. It can occur as an isolated infection or in conjunction with gonorrhea or other STDs. Because NGU is fast becoming the most common STD among heterosexuals in the United States and a potential source of female infertility and infant morbidity, the primary physician needs to be especially cognizant of its clinical manifestations, epidemiologic importance, and antibiotic treatment.

PATHOPHYSIOLOGY, CLINICAL PRESENTATION, AND CLINICAL COURSE

Most penile discharges are a consequence of urethral infection or inflammation. Numerous bacterial and nonbacterial organisms can invade its mucosal lining. Organisms causing NGU are characterized by their low levels of tissue invasiveness. In older men, a discharge may result from an inflamed prostate gland or, in rare instances, a tumor.

Gonococcal Urethritis. The typical presentation of symptomatic gonococcal disease is a 2- to 4-day history of dysuria and a thick and purulent penile discharge. The Gram's stain reveals polymorphonuclear leukocytes and gram-negative intracellular diplococci. Systemic gonococcemia develops in approximately 3% of patients, manifested by rash, fever, and polyarthritis (see Chapter 137). *Mixed infections*, involving both gonococci and chlamydiae, occur in up to 20% of patients presenting with gonococcal urethritis. Such patients complain of persistence of symptoms after being effectively treated only for gonorrhea.

Gonococcal urethritis responds well to proper antibiotic therapy, with resolution of symptoms and no sequelae. In men, even untreated disease may resolve spontaneously within a few weeks. An asymptomatic carrier state may ensue, or a chronic low-grade discharge may remain. Stricture is a possible consequence of untreated disease.

Nongonococcal Urethritis. Regardless of etiology, the clinical presentation of NGU is rather stereotypical. Compared with gonococcal urethritis, NGU tends to be an indolent illness of longer duration (e.g., 3 to 4 weeks). Dysuria, if present, is not as severe, and the discharge is less purulent, mucoid, sometimes scanty, or even absent. The urethral Gram's stain shows some neutrophils (by definition >4 cells per high-power field) and, at most, a few mixed extracellular pleomorphic organisms, features that help to distinguish NGU from gonococcal infection. Only 20% of ambiguous Gram's stains (rare extracellular gram-negative diplococci) are shown by subsequent culture to rep-resent gonococcal infection. The absence of neutrophils (<10 cells per high-power field) on analysis of the first 15 to 30 cm ^{3} of urine or a urine dipstick test negative for leukocyte esterase is highly specific for urethritis (i.e., a negative test result makes infection highly unlikely).

Chlamydia trachomatis infection of the urogenital tract has reached epidemic proportions, with 20% to 50% penetration of some populations. Prevalence is greatest among sexually active adolescents and young adults, especially those under the age of 20 with multiple partners. The condition is also concentrated among poor, inner-city African-Americans. In heterosexual men, urethritis with penile discharge, dysuria, or both is the most common symptomatic clinical presentation, but 25% to 50% may manifest neither symptoms nor leukocytes on urethral swab. Proctitis can develop in homosexual men engaging in receptive anal intercourse.

In untreated cases, symptoms may wax and wane during several weeks. Spontaneous resolution can occur. Complications are rare. Prostatitis and epididymitis have been reported in untreated or poorly treated cases. Epididymitis may also be part of the initial clinical presentation. Chlamydial infection accounts for about half of the cases of epididymitis in the United States.

Female counterparts of chlamydial NGU have been identified, including mucopurulent cervicitis and urethritis (see Chapter 117, Chapter 125, and Chapter 133). The prevalence of chlamydial infection among female partners of men with chlamydial NGU is very high (almost 70%; see Chapter 125).

Ureaplasma urealyticum has finally been established as a cause of NGU after decades of debate. It accounts for 10% to 40% of NGU cases and is sexually transmitted.

Mycoplasma genitalium invades epithelial cells and has emerged as a common cause of NGU, especially in male homosexual partners. The urethritis is indistinguishable from NGU of other causes. Persistence of symptomatic urethritis after appropriate antibiotic treatment of NGU has been linked to tetracycline-resistant strains. However, most recurrent NGU represents reinfection by an untreated sexual partner rather than infection with a resistant organism.

Trichomonas vaginalis infection is a common cause of vaginitis in women and also an important source of urethritis in men. A 22% urethral prevalence was found among male partners of women with known trichomonal infection and a 6% prevalence among heterosexuals attending a clinic for STD. About 50% of patients are symptomatic and have a discharge on examination. Others have symptoms but no visible discharge. The odds ratio for trichomonal infection in patients with nongonococcal, nonchlamydial urethritis has been found to be 3.8. The condition should be suspected in patients with symptoms but little or no discharge on physical examination.

Reiter's Syndrome The finding of genetic overlap between the histocompatibility antigen HLA-B27 (found in up to 96% of patients vs. 10% of controls) and certain *Klebsiella* and *C. trachomatis* antigens suggests infection in susceptible persons may play a role in the pathogenesis of Reiter's syndrome. It usually presents as urethritis in conjunction with a host of other mucocutaneous and musculoskeletal symptoms. Various combinations of conjunctivitis, iritis, fever, acute asymmetric polyarthritis (see Chapter 146), nonarticular bony pain (e.g., of the heel), circinate balanitis, keratoderma blennorrhagicum, and mucosal ulcerations may be present at any one time. The most characteristic presentation is onset of mild dysuria and a mucopurulent urethral discharge about 2 to 4 weeks after a diarrheal illness or sexual contact. Many patients present first with the urethritis, although involvement of other organ systems is frequently present in subclinical form or develops within a few weeks. Most patients with Reiter's syndrome experience a self-limited illness of 6 to 12 months' duration, although a minority progress to chronic or recurrent symptoms in conjunction with bouts of arthritis.

In older men, prostatic hyperplasia predisposes to obstruction and infection. *Prostatitis* may also represent infectious spread to the prostate. Minor penile discharge may be noted, exacerbated by prostatic massage. Symptoms of urinary outflow obstruction and perineal discomfort may dominate the clinical picture (see Chapter 138 and Chapter 139).

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of a penile discharge is traditionally divided into gonococcal and nongonococcal etiologies, with NGU accounting for the majority of cases. Among the causes of NGU are chlamydial, *Ureaplasma*, and trichomonal infections of the urethra, Reiter's syndrome, prostatitis, and urethral malignancy. Chlamydial disease is responsible for about half of cases of NGU. In up to a third of NGU cases, no pathogen is identified. Occasionally, urethral infection with herpes simplex virus or human papillomavirus may be responsible for the problem.

WORKUP

History and Physical Examination

History. The duration and character of the discharge can be informative. Acute onset of a profuse purulent discharge usually suggests gonococcal infection. Several

weeks of a more indolent, less profuse, mucoid discharge point toward a nongonococcal etiology. However, presentations overlap to some degree, and the history is not sufficient for diagnosis. A blood-tinged discharge raises the question of prostatitis or urethral tumor. Inquiry should be made concerning the number of sexual partners during the past few months and the use or nonuse of barrier contraception (important considerations in assessing risk for chlamydial infection and other STDs). The history is also checked for symptoms of prostatitis (slow stream, perineal discomfort), localized or systemic gonorrheal infection (pharyngitis, proctitis, arthritis, punctate skin lesions, sepsis), and Reiter's syndrome (polyarthritis, dermatitis, conjunctivitis, bony pain). Any history of penile warts or herpes simplex viral infection should be noted, as should sexual contact with a partner known to have had trichomonal infection.

Physical Examination. The temperature is taken and the integument carefully examined for signs of gonococcemia (fever; punctate, centrally hemorrhagic, necrotic skin lesions; tenosynovitis; polyarthritis). Similarly, manifestations of Reiter's syndrome are sought, including conjunctivitis, iritis, oral or meatal mucosal ulcerations, circinate balanitis (ulceration and erythema on the penile glans), keratoderma blennorrhagicum (pustular or hyperkeratotic lesions on the soles of the feet), inflamed joints (knees, ankles, sacroiliac joints), and nonarticular bone pain (especially of the heel). The urethral meatus is examined for herpetic lesions and warts, the epididymis is palpated for tenderness and swelling, and the prostate for enlargement, bogginess, and tenderness. An acutely inflamed prostate should be examined very gingerly because abscess is a possible concomitant.

Laboratory Studies

Gram's Stain of the urethral discharge should be the first study performed because it helps to distinguish gonococcal from nongonococcal disease. Even if no visible discharge is present, a swab is gently inserted into the urethral meatus and a sample obtained. A first morning sample before urination or one several hours after urination offers the best yield. Some of the sample is plated onto Thayer-Martin medium for culture of *Neisseria gonorrhoeae* (see Chapter 137), and the remainder is placed on a glass slide and Gram's-stained. The finding of polymorphonuclear leukocytes with gram-negative intracellular diplococci is highly predictive of gonococcal urethritis. The sensitivity and specificity of the Gram's stain exceed 95%. Four or more polymorphonuclear leukocytes per high-power field and mixed gram-negative and gram-positive pleomorphic extracellular organisms or leukocytes with no visible organisms are indicative of NGU. If no definite gram-negative intracellular diplococci are seen on Gram's stain, then a tentative diagnosis of NGU is appropriate. The diagnosis is confirmed by a negative gonococcal culture. Alternative testing for *N. gonorrhoeae* urethral infection is available with DNA probes or DNA amplification techniques (see Chapter 137); the latter has been approved for urine testing. Both techniques are useful for diagnosing pharyngeal or rectal infection.

Chlamydial Testing. It is not practical to culture for *Chlamydia* or *Ureaplasma* because of the expense, technical difficulty, and 2 to 3 days required to obtain results. However, antigen detection methods provide more rapid, less expensive detection of chlamydial infection. At the time an intraurethral swab is obtained for Gram's stain, a second swabbing should also be performed and the specimen saved for chlamydial testing. Such testing can be valuable, even if the patient is going to be treated presumptively for chlamydial infection, because the information thus obtained often helps to improve compliance, facilitate counseling, and guide care if symptoms persist. Patients with a presumptive diagnosis of gonorrhea may also benefit from chlamydial testing because both infections can exist concurrently.

Direct fluorescent antibody staining of urethral smears and *enzyme immunoassay* of secretions are the antigen detection methods most widely available. The former is more sensitive and specific; the latter is cheaper and better suited for laboratories that process large numbers of specimens. They are the preferred chlamydial testing methods for men with symptomatic urethritis. Sensitivity exceeds 70% and specificity approaches 99% in symptomatic men. Sensitivity is enhanced by obtaining a specimen several hours after the last urination. Enzyme immunoassay may give a false-positive result if lower urinary tract infection is present, which makes the test less useful in older men with prostatic disease. Test results are available within 36 to 72 hours. If posttreatment testing is desired, it should not be performed until 3 weeks after completion of treatment—sufficient time for clearing of antigen. *Rapid chlamydial testing* kits are packaged for office use and provide results within 30 minutes. They too make use of antigen detection methods and are subject to the same false-positive results. In addition, quality control problems arise because of the relatively unskilled persons performing the test.

DNA amplification tests based on ligase or polymerase chain reactions have proved reliable and predictive. These tests are 15% to 35% more sensitive then other nonculture urethral testing techniques and have better than 99% specificity.

Other Studies. When routine cultures and Gram's stains are not diagnostic and an empiric trial of treatment for NGU is unsuccessful (see below), then reevaluation and consideration of culturing for *Ureaplasma* or *trichomonads* may be appropriate. When Reiter's syndrome is suspected clinically, the patient can be checked for the presence of the *HLA-B27* histocompatibility antigen. However, its presence is not diagnostic of Reiter's syndrome, nor does its absence rule out the condition. Bloody discharge warrants referral to the urologist for consideration of *cystoscopy.*

MANAGEMENT OF NONGONOCOCCAL URETHRITIS

Because chlamydial infection accounts for 50% of NGU cases, ranks as the most common STD among heterosexuals in the United States, and represents a potential source of morbidity to female partners and their infants, all patients with NGU should be treated, regardless of whether definite identification of *Chlamydia* has been achieved. Female partners of NGU patients should be tested; if testing is not available, they too should be treated for presumptive chlamydial infection. Male homosexual partners should be tested. Empiric treatment of asymptomatic male homosexual partners is not recommended because of the reduced incidence of *Chlamydia* infection in this population.

Initial Treatment. The Centers for Disease Control and Prevention recommendation for the treatment of NGU is *doxycycline* (100 mg twice daily for 7 days) or *azithromycin* (1 g orally in a single dose). Although expensive, azithromycin provides greatly enhanced ease of use and compliance. Pregnant patients and others who should not take doxycycline or azithromycin can be treated with *erythromycin base* (500 mg four times daily for 7 days; erythromycin estolate is contraindicated in pregnancy). These antibiotic regimens are usually also effective against *Ureaplasma. Ofloxacin* (300 mg twice daily for 7 days) is also effective for the treatment of NGU, with excellent activity against both *Chlamydia* and *Ureaplasma*. It is superior to other fluoroquinolone antibiotics for the treatment of NGU and has also proved effective against *N. gonorrhoeae* (see Chapter 137). Cost is high. *Minocycline*, a once-a-day tetracycline, appears as effective as doxycycline. At a dose of 100 mg/d, vestibular toxicity is uncommon.

Management of Recurrent Nongonococcal Urethritis. Although most patients with NGU experience resolution of symptoms with onset of therapy, up to 30% relapse. Some relapses have been attributed to tetracycline-resistant strains of *Ureaplasma* and others to poor compliance with medication, reinfection, or the presence of prostatitis. Because *erythromycin* is effective against tetracycline-resistant strains of *Ureaplasma* and penetrates the prostate well, it has been used as a 3-week treatment program (500 mg four times daily) for recurrent disease. Such a regimen is particularly useful for patients with NGU caused by prostatitis. However, one should confirm the presence of prostatitis (see Chapter 139) and also evaluate for reinfection before resorting to empiric antibiotics. *Chlamydia* and *Trichomonas* are often found in patients with recurrent disease. If the latter is found, treatment with *metronidazole* (2.0 g as a single dose or 250 mg three times daily for 1 week) may prove useful. Endoscopic urethral examination in search of intrinsic urethral pathology is of low yield and not recommended in patients with recurrent NGU.

Treatment of Reiter's Syndrome. Treatment for *Chlamydia* may shorten the duration of illness and prevent recurrences in patients who appear to have the illness on the basis of sexually transmitted chlamydial infection.

Treatment of Gonococcal Urethritis. See Chapter 137.

PATIENT EDUCATION

The most important message to patients is the importance of prevention through the use of condoms. In addition, successful treatment of the disease requires contacting and treating recent sexual partners. The asymptomatic sexual partner is an important reservoir for reinfection. Treated male patients should be told to return for follow-up evaluation if symptoms return. Female partners should undergo retesting after 3 weeks to ensure eradication of chlamydial infection. No firm data are available concerning abstinence from unprotected intercourse during the treatment period, but it seems reasonable to suggest at least 7 days of treatment before sexual activity is resumed.

RECOMMENDATIONS

- Inquire into the number of sexual partners during the past few months and use or nonuse of barrier contraception.
- Check for symptoms of prostatitis, gonorrheal infection, and Reiter's syndrome and for reports of penile warts, herpes simplex viral infection, and sexual contact with a partner known to have had trichomonal infection.

- Measure the temperature and examine for signs of gonococcemia and Reiter's syndrome. Also check the urethral meatus for herpetic lesions and warts and the testes and prostate for signs of epididymitis and prostatitis, respectively.
- Obtain a urethral swab for Gram's stain and for plating onto Thayer-Martin medium for culture of *Neisseria gonorrhoeae*.
- Obtain a second swabbing for chlamydial antigen detection, either by *direct fluorescent antibody* staining or *enzyme immunoassay*.
- Alternatively, send the second swab for *DNA amplification testing*, which is more sensitive and specific.
- Test female partners of NGU patients; if testing is not available, treat them empirically for presumptive chlamydial infection. Male homosexual partners should also be tested but not treated empirically.
- When routine cultures and Gram's stains are not diagnostic and an empiric trial of treatment for NGU is unsuccessful (see below), then reevaluate and consider culturing for *Ureaplasma* or *trichomonads*.
- Treat all patients with NGU for chlamydial infection, regardless of whether definite identification of *Chlamydia* has been achieved. Test nonetheless because the information often helps to improve compliance, facilitate counseling, and guide care if symptoms persist.
- Treat NGU initially with *doxycycline* (100 mg twice daily for 7 days) or *azithromycin* (1 g orally in a single dose).
- Treat documented NGU recurrences with *erythromycin* (500 mg four times daily for 3 weeks).

CHAPTER 137 APPROACH TO THE PATIENT WITH GONORRHEA

BENJAMIN DAVIS AND HARVEY B. SIMON

Like other sexually transmitted diseases, gonorrhea remains a major public health problem in the United States. Although penicillinase-producing strains have become increasingly prevalent, antibiotic resistance cannot be blamed for the failure to control gonorrhea. In fact, excellent alternative drugs are available. Rather, the continued spread of gonorrhea represents the failure of "safe sex" programs to influence human behavior. Theoretically, primary prevention could control this age-old infection, but 1 million cases of gonorrhea are reported each year in the United States. Because of underreporting, it can be safely estimated that at least 3 million cases occur annually. Gonorrhea is most prevalent among teenagers and young adults, especially those belonging to minority groups and dwelling in the inner city; however, the infection crosses all age and socioeconomic barriers.

The great majority of patients with venereal disease present to an ambulatory care facility and should be diagnosed and treated in this setting. At the same time, the physician must be alert to serious systemic complications requiring hospitalization. In addition, patient education is critical to prevent inadequate treatment and recurrent infections. Finally, the responsibility of the physician must extend beyond the diagnosis and treatment of an individual patient to the identification and treatment of sexual contacts who may otherwise harbor and further disseminate these infections.

PATHOPHYSIOLOGY AND CLINICAL PRESENTATION

Gonococcal infection invariably begins with the direct infection of a mucosal surface during sexual activity. Organisms may then gain access to the bloodstream to produce bacteremia and systemic spread of infection. This is most common in women, especially at the time of menstruation, but it occurs in men also. The clinical features of gonorrhea differ greatly between the sexes. Moreover, symptoms of the primary gonococcal infection may be absent or mistaken for those of another condition, making the diagnosis more difficult.

In men, clinical symptoms usually follow within 2 to 10 days of sexual exposure. The risk that a man will acquire gonorrhea after a single exposure to an infected partner is approximately 35%. Absence of symptoms does not indicate absence of infection. Indeed, up to 10% of infected men are asymptomatic carriers of the gonococcus and are fully capable of transmitting the disease. In men, gonorrhea is principally an infection of the anterior urethra, and hence the major symptom is purulent *urethral discharge*, often accompanied by urinary frequency and dysuria. Although spread of infection to the *prostate* or *epididymis* is uncommon in the antibiotic era, gonococci occasionally gain entry into the *bloodstream* to produce disseminated infection.

In women, the *cervix* is the favored site of gonococcal infection. However, up to 25% of women with gonococcal infection are asymptomatic and must be identified through epidemiologic case finding. When symptoms do occur, cervical discharge is most common. Although the vagina is usually spared, the gonococcal infection may spread downward from the cervix to produce *urethritis*, which presents as dysuria and frequency. Infection of *Bartholin's glands* presents as labial swelling and pain, and rectal infection presents as anorectal discomfort. If, on the other hand, gonococcal infection spreads upward from the cervix, more serious processes may develop. Such upward spread is particularly likely at the time of menstruation and can produce a variety of syndromes. Gonococcal *endometritis* can cause pelvic pain and abnormal vaginal bleeding, whereas *salpingitis* characteristically leads to fever, chills, leukocytosis, and a tender adnexal mass. Both systemic and pelvic signs and symptoms are even more pronounced in frank *pelvic peritonitis*, and further intraperitoneal spread may produce gonococcal *perihepatitis* with right upper quadrant pain and tenderness.

Primary extragenital infections are being encountered more frequently as a result of changing sexual practices. Gonococcal infection of the pharynx is usually asymptomatic but can present as an acute *exudative pharyngitis*, with fever and cervical lymphadenopathy. Gonococcal *proctitis* is also most often asymptomatic but can present as proctitis with anorectal discomfort, tenesmus, or rectal bleeding and discharge.

Gonococcal bacteremia is manifested by the *"dermatitis–arthritis'* syndrome. Patients have fever, chills, and other constitutional symptoms. Skin lesions are an important clue to diagnosis; these are typically pustular, hemorrhagic, or papular, are few in number, and tend to be most common on the distal extremities. *Tenosynovitis*, especially involving the extensor surfaces of the hands and feet, and *migratory polyarthritis* are typically seen. During the early stage of systemic infection, blood cultures are often positive, but joint cultures are characteristically negative. Later in the course of untreated disease, however, gonococci can produce frank *septic arthritis*. Such patients have less fever, no skin lesions, and negative blood cultures but more impressive joint swelling and pain, often with purulent synovial fluid in which gonococci can be demonstrated by Gram's stain or culture. In rare instances, gonococci can produce *osteomyelitis* or even life-threatening bacterial *meningitis* or *endocarditis*.

DIFFERENTIAL DIAGNOSIS

The organisms besides *Neisseria gonorrhoeae* capable of producing female genital infections include *Chlamydia, Gardnerella, Trichomonas*, and *Candida* (see Chapter 117). The differential diagnosis of gonococcal salpingitis and peritonitis mainly encompasses the causes of nongonococcal pelvic inflammatory disease (see Chapter 116), but other conditions, such as appendicitis, ectopic pregnancy, hemorrhagic ovarian cysts, and endometriosis, can produce similar clinical findings and often require urgent therapy very different from that of pelvic inflammatory disease. In the male patient, the causes of nongonococcal urethritis enter the differential diagnosis (see Chapter 136). Gonococcal infection also needs to be considered among the causes of pharyngitis (see Chapter 220) and proctitis (see Chapter 66).

WORKUP

History and Physical Examination. The diagnosis of gonorrhea requires a high index of suspicion and a careful *sexual history*. Physical examination findings in men with urethritis are usually normal except for purulent *urethral discharge*. In asymptomatic women, the physical examination findings are normal, but *cervicitis* may produce cervical inflammation, discharge, and marked cervical tenderness. *Adnexal tenderness* and fullness are signs of salpingitis and may be unilateral or bilateral in women with gonorrhea. Tubal abscesses may be suspected because of a palpable mass, and rebound tenderness is a sign of pelvic peritonitis.

Pelvic inflammatory disease caused by organisms other than the gonococcus may present similarly. Clinical features favoring the gonococcus include purulent cervical discharge, onset early in the menstrual cycle, no previous history of pelvic inflammatory disease, and exposure to a male partner with urethritis.

Laboratory Studies. A properly performed *Gram's stain* of the urethral discharge can be a highly reliable diagnostic tool. A Gram's stain is considered "positive" when biscuit-shaped gram-negative diplococci are seen within polymorphonuclear leukocytes, "equivocal" if diplococci are only extracellular or if intracellular organisms are morphologically atypical, and "negative" if no diplococci are found. Sensitivity of the Gram's stain is more than 95% in symptomatic men but declines to 50% to 60% in those with asymptomatic urethral infection. Gram's stains are much less reliable in cervical, rectal, and pharyngeal infections.

Cultures confirming the diagnosis of gonorrhea are mandatory in both sexes. *N. gonorrhoeae* is a fragile and fastidious organism that requires special handling in the laboratory. The gonococcus is readily killed by drying, so all cultures must be plated promptly. Ideally, this should be done by the physician at the time of examination by streaking the swab across the surface of the culture medium in a Z-shaped pattern. Special culture media must be used. Although chocolate agar has been the traditional medium used, a modified *Thayer-Martin medium* is preferred for specimens obtained from genital, anal, or pharyngeal sites because the addition of antibiotics to this medium suppresses the growth of nonpathogenic *Neisseria* species and other bacteria. The culture medium should be at room temperature at the time of inoculation. Because the gonococcus requires a high carbon dioxide concentration to grow, cultures should be promptly incubated in a candle jar or carbon dioxide incubator. When this is not possible, the cultures should be planted on modified Thayer-Martin medium in bottles with a 10% carbon dioxide atmosphere. These bottles should be kept capped until the moment of inoculation and should be held in an upright position when open to prevent the loss of carbon dioxide, which

is heavier than air.

In the male patient, cultures of the anterior *urethra suffice* unless homosexual contacts are suspected, in which case cultures of the anal canal and pharynx are also indicated. In the female patient, the *endocervix* should be cultured by inserting a swab into the cervical os through a speculum that has been lubricated only with water. In all women, *rectal* cultures are indicated because rectal infection can result simply through direct spread from the genital tract. When pharyngitis is suspected, throat culture is mandatory. When acute arthritis is present, *joint fluid* should be obtained by arthrocentesis and should be evaluated with cell counts, Gram's stain, and culture. *Blood* cultures are indicated in patients with fever, skin lesions, and tenosynovitis or arthritis.

PRINCIPLES OF MANAGEMENT AND THERAPEUTIC RECOMMENDATIONS

Overcoming Penicillin Resistance. The therapy of gonorrhea has undergone dramatic changes during the past 40 years. Penicillin has been used for decades, but during this time penicillin resistance has increased steadily. The recommended dosages of penicillin are 30 times greater than those initially used with success in 1943. Until recently, penicillin resistance was just a matter of degree because it was based on chromosomal mutations that decreased the permeability of the cell wall to penicillin and other antibiotics. Simply increasing the dosage of penicillin sufficed.

Another form of penicillin resistance was recognized in 1975, when gonococcal strains were isolated that resisted the effects of even massive doses of penicillin by producing penicillinase. These strains were found to contain plasmids that produce b-lactamase. In the United States, infections with plasmid-containing strains were initially sporadic, but the number of such infections has increased dramatically and is no longer limited to a few groups of patients. More recently, very high-level, chromosomally mediated penicillin resistance has emerged. In all, about 5% of gonococcal strains are penicillin-resistant. A significant number of clinical isolates are also tetracycline-resistant, and heavy use of spectinomycin has led to emergence of strains resistant to that agent.

Unless the isolate is proven to be penicillin-sensitive, a regimen effective for resistant strains should be used. When possible, drugs that are also effective against syphilis are preferred. Because of problems with patient compliance, single-dose regimens are recommended. The parenterally administered *ceftriaxone* and the orally administered *cefixime* presently meet these requirements.

Concurrent Infection. In addition to the problem of antibiotic resistance, the management of gonorrhea is complicated by the need to treat coexisting sexually transmitted infections. Chlamydial disease is of greatest concern, coexisting with gonococcal infection in up to 20% of men and 50% of women with sexually transmitted disease. As a result, all patients with gonorrhea should also be treated for chlamydial infection. Although much less common than chlamydial infection, incubating syphilis can be a more serious problem, and patients should be screened for syphilis (see Chapter 124 and Chapter 117). Confidential testing for HIV infection may be of benefit not only for case identification, but also for promotion of safer sexual practices (see below).

THERAPEUTIC RECOMMENDATIONS

Uncomplicated Gonorrhea (Including Urethral, Cervical, and Rectal Infection)

- Prescribe ceftriaxone (125 mg IM once), cefixime (400 mg PO once), ciprofloxacin (500 mg PO once), or ofloxacin (400 mg PO once) *plus* azithromycin (1 g PO once) or doxycycline (100 mg twice daily for 7 days).
- Prescribe spectinomycin (2 g IM once) for patients who are allergic to b-lactam antibiotics (i.e., cephalosporins and penicillins) or who cannot take fluoroquinolones (e.g., pregnant women).
- Prescribe erythromycin base (500 mg four times daily for 7 days) for patients who cannot take doxycycline (e.g., pregnant women and those allergic to the drug).

Disseminated Gonococcal Infection

- Hospitalize initially and begin *ceftriaxone* (1 g IV or IM every 24 hours for 7 days).
- Treat with higher doses for a more prolonged period if meningitis, endocarditis, or osteomyelitis is present.
- Treat with *spectinomycin* (2 g IM every 12 hours for 7 days) those persons who are allergic to b-lactam antibiotics.
- Discharge those who respond well to the initial 1 to 2 days of parenteral therapy, provided they return daily for IM ceftriaxone or complete a week of oral therapy with *ciprofloxacin* (500 mg twice daily).
- Treat also for chlamydial infection, as in uncomplicated disease.

Monitoring

Because treatment failures with ceftriaxone–doxycycline are rare, immediate *follow-up cultures* are not mandatory. It may be more cost-effective to delay repeated evaluation with cultures until 1 to 2 months have passed. This allows detection of reinfection and treatment failures and reinforcement of patient education. Patients treated with regimens other than ceftriaxone–doxycycline do require follow-up cultures 4 to 7 days after therapy has been completed.

All patients with gonorrhea should undergo *serologic testing for syphilis*. Seronegative patients treated with ceftriaxone do not require follow-up serologies because this regimen is effective for incubating syphilis. However, patients receiving other antibiotic regimens do require repeated serologic testing in 3 months. All patients with gonorrhea should be offered confidential *testing for HIV* infection. All gonorrhea cases should be reported to the appropriate local health department. Because many patients are asymptomatic, vigorous case finding represents the only present means of controlling this epidemic.

PATIENT EDUCATION AND PREVENTION

Health education about the prevention of sexually transmitted disease is extremely important. Properly used barrier methods of contraception are effective means of preventing gonorrhea. *Condoms* do not permit transmission of the gonococcus or *Chlamydia*. The diaphragm or contraceptive sponge may also offer some protection against gonorrhea and chlamydial infection, especially when used with a *vaginal spermicide* containing nonoxynol 9, the active ingredient in many preparations. However, diaphragms and sponges *do not reduce the risk for HIV transmission*.

Preventive measures also include attention to *partner notification*. Patients should be encouraged to notify their sexual partners of their exposure and encourage them to seek medical care. This is *patient referral*. If patients are unwilling or unable to notify their partners, then the assistance of state and local departments of public health can be enlisted. This is *provider referral*.

INDICATIONS FOR ADMISSION

Patients with disseminated disease who are febrile, who are unreliable, or who have evidence of osteomyelitis, endocarditis, or meningitis must be hospitalized. The same is true of the woman with pelvic inflammatory disease who appears toxic, pregnant, or unlikely to comply, or who has pelvic pain of unclear etiology in association with peritoneal signs.

CHAPTER 138 APPROACH TO BENIGN PROSTATIC HYPERPLASIA

MICHAEL J. BARRY AND JOHN D. GOODSON

Benign prostatic hyperplasia (BPH) is a common condition among older men, causing morbidity primarily through lower urinary tract symptoms. The primary physician should attempt to distinguish BPH from the other causes of such symptoms, objectively determine symptom severity, and, when the symptoms are bothersome enough, design a therapeutic approach that offers symptomatic improvement. For patients who elect a course of "watchful waiting" or medical therapy, a strategy of regular follow-up visits should be instituted to monitor for symptom changes or BPH complications. The treatment of BPH has changed substantially in recent years, with increasing emphasis on nonsurgical approaches. The result is an expanded role for primary care providers in BPH management.

PATHOPHYSIOLOGY AND CLINICAL PRESENTATION

Pathophysiology. BPH arises from *nodular hyperplasia* of prostatic stromal and glandular elements. Growth begins in the *periurethral* glandular tissue. As these nodules expand and coalesce over years, the true prostatic tissue is compressed outward and forms a "surgical capsule" around the adenomatous hyperplasia. The etiology of age-related prostatic hyperplasia is still unknown, although it is reasonably well established that androgenic stimulation at the cellular level has a major influence. A better understanding of these influences on prostatic hyperplasia is beginning to help define hormonal manipulations that may affect the natural history of the disease.

As the gland enlarges, urethral resistance to urine flow increases and *bladder muscle hypertrophy* ensues. *Bladder instability* may develop, and emptying may become incomplete. The resulting *residual urine* predisposes to infection, which in turn may produce further bladder irritation. *Bladder herniations* can form between the thickened, overlapping muscular bands that comprise the detrusor. These diverticula are incompletely emptied with voiding, which further predisposes to infection.

A large fluid load, impairment of the contractile function of the bladder by anticholinergics, or increased outflow resistance resulting from sympathomimetic drugs may lead to *acute urinary retention*. Some proportion of acute retention may be precipitated by painless infarction in the enlarged gland. The hyperplastic prostate is highly vascular and predisposed to *bleeding*; painless hematuria can occur.

The late-stage complications of chronic retention caused by BPH include *hydroureter, hydronephrosis*, and *renal failure*. Fortunately, these complications are rare.

Clinical Presentation and Course. BPH manifests clinically through lower urinary tract symptoms. Although BPH is the most common cause of such symptoms among older men, other diseases can cause them also. The old term "prostatism" implies a diagnostic specificity to these symptoms that does not in fact exist; as a result, this term should be avoided. Simplistically, "voiding" (or "obstructive") symptoms (such as a weak stream, straining, hesitancy, and intermittency) have been attributed to mechanical bladder outlet obstruction, whereas "filling" (or "irritative") symptoms (such as frequency, nocturia, and urgency) have been attributed to secondary detrusor instability. In reality, the situation is much more complex; the way that the histologic process of BPH eventually leads to symptoms is in fact poorly understood. The severity of lower urinary tract symptoms correlates poorly with prostate size and urodynamic measurements of the severity of bladder outlet obstruction, and some treatments (such as microwave thermotherapy) can reduce symptoms considerably without having much effect on these parameters.

It is quite common for patients to have a waxing and waning symptomatic course, with very gradual deterioration through many years. Sometimes, urinary tract infection is the first indication of bladder outlet obstruction secondary to BPH. Hematuria may be an early symptom of BPH, but neoplasm must be considered as an alternative diagnosis.

In the elderly, BPH can have protean manifestations. It may occasionally cause a lower abdominal mass because of bladder enlargement with a paucity of symptoms. Confusion, anorexia, a palpable kidney, anemia, and a bleeding diathesis secondary to hydronephrosis and uremia constitute a rare presentation of advanced disease. Other symptoms include sleep disturbance and incontinence related to detrusor instability or overflow.

DIAGNOSIS

The digital rectal examination of the prostate provides a rough estimate of overall gland volume but is of little help in assessing the degree of mechanical obstruction. Severity can be assessed by symptoms and a few basic laboratory studies (see below). Clinicians tend to underestimate prostate size, but the inability to palpate the distal margins of the gland generally indicates massive enlargement (more than three times normal size).

Assessing Severity of Symptoms. In older men presenting with lower urinary tract symptoms thought likely to be caused by BPH, the clinician should first objectively document symptom severity. The seven-item *American Urological Association (AUA) Symptom Index* is a quick, self-administered questionnaire that is widely used for this purpose (Fig. 138.1). Scores on individual questions can be summed to yield an *AUA symptom score* ranging from 0 to 35. Scores of 0 to 7 represent mild symptoms, 8 to 19 moderate symptoms, and 20 to 35 severe symptoms. Importantly, clinicians should determine the extent to which the patient is bothered by his symptoms.

FIG. 138.1. American Urological Association symptom index for benign prostatic hypertrophy.

A *creatinine* determination and a *urinalysis* should be obtained for all patients to assess renal function and check for infection or hematuria. Measurements of *postvoid residual urine* can be made by catheterization (>50 to 100 mL of residual urine is abnormal) or, less invasively, by transabdominal ultrasonography. However, these measurements are poorly reproducible in individual patients and probably helpful only if persistently and grossly increased (>350 mL).

Urinary flow studies have become widely available. These tests do not require catheterization and are particularly useful in assessing patients whose presentations are atypical (e.g., younger patients or men with dominantly filling symptoms). A normal peak flow rate (>15 mL/s) in the setting of lower urinary tract symptoms should prompt further evaluation for alternative explanations. However, men with true bladder outlet obstruction may sometimes maintain normal flow rates by generating high bladder pressures. Similarly, men with hypotonic bladders may have low flow rates without physiologic obstruction. A low voided volume <150 mL may produce a

falsely low peak flow rate.

Imaging studies are not routinely necessary in typical cases of BPH. Radiographic assessment of the bladder and upper urinary tract is not recommended unless an elevated creatinine level, hematuria, or another specific indication is present. If necessary, transabdominal *ultrasonography* can be used to exclude hydronephrosis and assess the postvoid residual volume without an *IV pyelogram*, which entails the risk for a contrast reaction. Similarly, cystourethroscopy should be performed only when specifically indicated (e.g., prior genitourinary instrumentation, hematuria). More sophisticated *urodynamic studies* (cystometrics and pressure–flow studies) are best reserved for patients with conflicting results on simple tests (e.g., severe symptoms but a normal flow rate), neurologic disease, or prior unsuccessful prostatectomy.

Assessing Significance of Symptoms. For some, frequency and nocturia significantly interfere with a restful night of sleep, whereas for others, they are a minor inconvenience. It is generally best to monitor the patient for 3 to 6 months, often while he attempts some life-style changes (discussed below), to determine the stability or progression of symptoms before making any major therapeutic decisions. It is essential that the physician understand the *importance of symptoms* to the patient and their impact on his quality of life because the individual patient may be willing to accept a given level of symptomatology and a small risk for future BPH complications to avoid surgery.

Checking for Prostate Cancer. When the digital rectal examination findings are not suggestive of prostate cancer, a test for serum *prostate-specific antigen* (PSA) is optional for men with symptomatic BPH. The sensitivity of PSA in this setting is 60% to 70%, and specificity is only 50% to 70%. Moreover, the "prior probability" of subclinical cancer does not seem to be appreciably elevated in the presence of lower urinary tract symptoms. No trials have documented that early detection of prostate cancer improves patient outcomes (although, in fairness, trials have not ruled out such a benefit either). Even advocates of PSA screening do not advise the test for men with less than a 10-year life expectancy (ages 75 and older for men with average comorbidity), given its dubious impact on mortality among these men. Nevertheless, men of any age with BPH should understand that they run a 10% to 15% risk for harboring coincidental prostate cancer and that further tests are availableif the patient and his physician wish to screen for prostate cancer (see Chapter 126).

PRINCIPLES OF MANAGEMENT

General Measures. Most patients with urinary symptoms arising from BPH that are not particularly bothersome should simply be followed (" *watchful waiting*"). The decision to proceed to prostatectomy should rarely be made quickly. Complicating and exacerbating factors, such as infections, should be treated, and medications that impair lower urinary tract function should be eliminated if possible. In particular, *diuretics* should be stopped if possible or taken early in the day to avoid nocturnal bladder distention. Drugs that can exacerbate the symptoms of bladder outflow obstruction (e.g., *anticholinergics, tricyclic antidepressants, disopyramide*) should be used only with great care. Patients should be warned about over-the-counter *decongestants* and cough-and-cold preparations. The patient should be told to *void frequently*, take extra time to void completely, and to avoid *beverages* that are likely to produce a diuresis (coffee, tea, alcohol), particularly before bed.

a-Blockers. The efficacy of these agents in reducing symptoms in men with BPH has been documented in clinical trials of up to a year's duration. They probably work mainly by relaxing the bladder neck and prostatic smooth-muscle tone, thereby relieving some of the "dynamic" component of obstruction. Selective a $_1$-blockers (*prazosin, doxazosin, terazosin*) have fewer side effects than nonselective a-Blockers (phenoxybenzamine), and doxazosin and terazosin can be given just once a day. These drugs can induce orthostatic hypotension, particularly in the frail elderly, and can cause fatigue and dizziness unrelated to blood pressure changes. Doses need to be escalated carefully, with monitoring of supine and standing blood pressure. *Tamsulosin* is a new a-blocker developed to reduce prostatic rather than vascular smooth-muscle tone; this agent does not appear to affect blood pressure. Whether tamsulosin has fewer side effects than doxazosin or terazosin (most of which are not blood pressure-related) has not been tested in head-to-head clinical trials.

Many physicians give a-Blockers at night to reduce side effects (particularly the first dose at a particular strength), but whether the strategy accomplishes this aim is poorly documented. Doses should be increased (unless side effects ensue) until the patient is satisfied with the result; underdosing is a common reason for treatment failure. Typical dose escalations are from 1 to 2 mg up to 4 to 8 mg daily for doxazosin, or 1 to 2 mg up to 5 to 10 mg for terazosin. Tamsulosin is started at 0.4 mg daily and can be increased to 0.8 mg. About 70% of patients report symptomatic improvement on a-Blockers. Whether a-Blockers reduce the rates of BPH complications (such as acute urinary retention or progression to surgery) is not well documented.

Inhibition of 5-a-Reductase. *Finasteride* blocks the conversion of testosterone to its metabolite dihydrotestosterone, a potent intraprostatic androgen. The drug reduces prostate size by about 20% during a year of treatment. Mild improvements in symptoms and urinary flow rates relative to placebo have been demonstrated in some trials but not others. The efficacy of the drug appears restricted to men who have large prostates. A Veterans Administration randomized trial comparing finasteride alone, terazosin alone, finasteride and terazosin, and placebo demonstrated efficacy for terazosin but not finasteride; the addition of finasteride to terazosin produced no additional benefit in terms of symptom relief. On the other hand, long-term trials have demonstrated that finasteride use significantly reduces the risk for acute urinary retention or progression to prostatectomy. Because the absolute risks of these events are low, about 16 men would have to take the drug for 4 years to prevent one event (acute retention or surgery). However, this "number needed to treat" is more favorable among men with higher prostate volumes, or higher baseline levels of PSA (>3.2 ng/mL), the latter probably serving as a practical proxy for prostate volume.

Sexual dysfunction in the form of decreased libido, impotence, or ejaculatory difficulties occurs in about 5% of men taking finasteride. Finasteride is given at a dose of 5 mg daily and does not require dose titration. It can take 6 to 12 months of continuous use before benefit is noted. The drug reduces serum PSA levels by an average of 50%, which means PSA results need to be interpreted differently among men on this drug. One common strategy is simply to double the PSA value in a man on finasteride and then interpret the results in the same way as for a man not on the drug.

Phytotherapy, or treatment with plant extracts, is widely prescribed for men with BPH by clinicians in Europe and is being used more commonly by men in the United States. The best studied of these medications are extracts of the *saw palmetto plant (Seranoa repens)*. In a recent meta-analysis of trials of saw palmetto extracts, this therapy was found to reduce symptoms somewhat more than placebo, and was roughly equivalent to finasteride. Side effects were few. Given the marginal efficacy of finasteride in reducing symptoms, however, this impact is not impressive. Whether saw palmetto extracts share the ability of finasteride to prevent future BPH complications is unknown. A problem with this treatment is that many products are available, without standardization of dose.

Surgical Approaches. Prostatectomy is indicated in patients who have acute retention without a predisposing cause, hydronephrosis, repeated urinary tract infections, recurrent or refractory gross hematuria, or an elevated creatinine level that responds to a period of bladder decompression with catheter drainage. More commonly, refractory, bothersome symptoms are an indication to consider surgery. The primary care physician must integrate the patient's report of his symptoms with an assessment of how bothered the patient is by these complaints. Surgery does provide excellent symptomatic relief in most cases, but any procedure entails risks and costs that some patients may not be willing to undertake. Furthermore, there are patients for whom surgery might not provide much benefit, particularly if concurrent detrusor abnormalities are present.

Transurethral prostatectomy (TURP) is the most common surgical procedure for BPH, with a dominant track record of effectiveness at reducing both symptoms and the risk for BPH complications. The degree of symptom reduction is, on average, much greater than that achieved with any of the medical therapies. A *retropubic or a suprapubic ("open") prostatectomy* may be required if the gland is substantially enlarged. The mortality rate for all these operations is low (<1% for TURP). TURP has classically been said to be associated with potential complications such as incontinence and erectile dysfunction, but a Veterans Administration trial that randomized men to immediate TURP versus a strategy of watchful waiting found that the risk for these problems was no higher after TURP. On theother hand, retrograde ejaculation and resulting infertility are common complications of prostatectomy and should be discussed with the patient before operation. A *transurethral incision* of the prostate (TUIP) may be a good choice for younger men with small prostate glands. TUIP has been shown to be nearly as effective as TURP in providing symptom relief and carries a lower risk for retrograde ejaculation and other complications. More recently, urologists have been using *laser* energy or *electrical vaporization* to destroy prostate tissue, still via a transurethral approach. These procedures seem to cause less bleeding than TURP does and can often be performed as "day surgery," but results of comparative trials with long-term follow-up are not available.

Operations for BPH leave a substantial amount of prostatic tissue in place. The postoperative risk for future malignancy is the same. Because residual prostatic tissue may continue to grow, symptoms may recur after surgery. Patients undergo reoperation at a rate of about 1% per year.

Device Therapies. *Balloon dilation* has lost favor because of frequent relapse of symptoms. Two newer therapies for BPH are *transurethral microwave thermotherapy* (TUMT) and *transurethral needle ablation* (TUNA). In both, a device generates heat to coagulate prostate tissue. In the former, a microwave antenna is placed in the urethra surrounded by a cooling jacket (to protect the urethra), and in the latter, radiofrequency energy is delivered directly to the prostate via intraprostatic needles. Both procedures can be performed in a single outpatient session and may be complicated by urinary retention requiring catheter drainage. In general, studies have

suggested short-term symptom relief somewhat less than that obtained with TURP but greater than obtained with medical therapy. The mechanism of symptom relief with these treatments is unclear, as the coagulated intraprostatic tissue is not removed. Long-term trials comparing the results of TUMT and TUNA with TURP or medical therapy are not yet available.

INDICATIONS FOR REFERRAL

A urologist should be consulted when a patient presents with absolute indications for surgery, as discussed previously. In addition, consultation can be helpful when the diagnosis is unclear, particularly when evidence of an alternative cause of a patient's lower urinary tract symptoms is present. Most commonly, a consultation will be called for when a patient still has bothersome symptoms despite maximal medical therapy and would like to consider a surgical intervention.

PATIENT EDUCATION

One cannot overestimate the value of patient education in the effective management of BPH. When patients are provided with information about the waxing and waning natural history of symptoms and the advantages and risks of the full range of treatment options, they are likely to choose differently than when exposed only to a surgical opinion. Reviewing such information enables the primary physician and the patient to make a joint management decision. A joint management strategy ensures a therapeutic approach best suited to the patient's preferences. Watchful waiting is a reasonable choice for patients without absolute indications for surgery, provided both patient and physician share a commitment to periodic review and reassessment.

TREATMENT RECOMMENDATIONS

- The primary care physician should objectively assess the severity of lower urinary tract symptoms and determine their effect on the patient's quality of life.
- All patients with symptoms likely caused by BPH should have a baseline creatinine determination and urinalysis.
- Routine urinary tract imaging is not necessary. Upper tract imaging, preferably by ultrasonography, is indicated if hydronephrosis is a concern (a large postvoid residual urine volume or an elevated creatinine level).
- A urine flow rate measurement may be useful when symp-tomatology is confusing or ambiguous; it helps to identify patients who have symptoms but little evidence of obstruction (peak flow rates <15 mL/s).
- Patients should be made aware of the possible coexistence of prostate cancer and BPH and the availability of further evaluation, including PSA screening. However, the impact of early detection of prostate cancer on prostate cancer mortality is doubtful in men with a life expectancy of less than 10 years.
- Most patients can be followed expectantly unless evidence of hydronephrosis, recurrent or persistent infection, or deterioration in renal function is present. Such complications warrant prompt surgical attention. Nighttime fluids and drugs that affect lower urinary tract function should be avoided.
- Selective a_1-blocker therapy (*doxazosin, prazosin, terazosin, tamsulosir*) can provide symptomatic relief for some patients.
- The 5-a-reductase inhibitor finasteride may be worth considering in persons with larger prostate glands (reflected by baseline PSA levels <3.2 ng/mL), primarily to reduce the future risk for acute retention or surgery. It is less effective than a-blocker therapy in reducing lower urinary tract symptoms in the short run.
- Elective urologic consultation is indicated when the diagnosis is confusing or when, despite medical therapy, the quality of life is sufficiently compromised to warrant consideration of an operation to achieve symptomatic relief.
- Less invasive treatments for BPH will provide an increased array of treatment options in the coming years, but *prosta-tectomy* remains the standard for long-term symptom relief.

CHAPTER 139 MANAGEMENT OF ACUTE AND CHRONIC PROSTATITIS

JOHN D. GOODSON

Prostatitis is the most important cause of urinary tract infection in men. Chronic prostatitis is a common infection that can cause persistent and annoying symptoms, whereas acute prostatitis is less common but potentially much more serious. Both conditions require accurate recognition and treatment by the primary physician. Prompt initiation of therapy is especially important for acute prostatitis. Pain in the male perineum can arise from both infectious and noninfectious inflammation and can represent pain referred from retroperitoneal structures and low sacral nerve roots. Further complicating management is the ongoing controversy about the role of low-level commensal microorganisms that can be cultured from symptomatic patients. Experts continue to disagree about the value of extended antibiotic treatment and empiric therapy. A consensus panel has addressed some of this confusion by proposing a scheme for classifying prostatitis syndromes (Table 139.1).

Category I	Acute bacterial prostatitis	Acute infection
Category II	Chronic bacterial prostatitis	Persistent infection
Category III	Chronic abacterial prostatitis	No infection
IIIA	Inflammatory	WBCs in EPS or VB$_3$ (postmassage urine)
IIIB	Non-inflammatory	WBCs in EPS or VB$_3$ (postmassage urine)
Category IV	Asymptomatic inflammatory prostatitis	WBCs in EPS or VB$_3$ (postmassage urine) or on biopsy specimen, but no symptoms

WBC, white blood cell; EPS, expressed prostatic secretion; VB, voided bladder. After Nickel JC. Prostatitis: myths and realities. Urology 1998;51:563, with permission

Table 139.1. Classification and Definition of Prostatitis

CLINICAL PRESENTATION, PATHOPHYSIOLOGY, AND COURSE

Bacterial prostatitis may ensue from ascending urethral infection, reflux of infected urine, extension of rectal infection, or hematogenous spread. Gram-negative bacilli (predominantly *Escherichia coli, Proteus, Klebsiella*, and *Pseudomonas*) and *enterococci* account for most of the single isolates obtained from culture. Occasionally, *Chlamydia, Ureaplasma*, a virus, or *Trichomonas* may be the etiologic agent. In the immune-compromised patient, infection with fungi, such as *Aspergillus*, should be considered.

Small numbers of bacterial isolates from prostatic fluids are very difficult to interpret, especially when the organisms identified are not usually thought of as urinary tract pathogens (e.g., gram-positive organisms such as *Staphylococcus epidermidis* or *Corynebacterium* species). When bacterial growth is associated with evidence of prostate inflammation (defined below), then antibiotic treatment is warranted. When no evidence of inflammation is present, then treatment may be warranted, but neither physician nor patient should anticipate success.

Acute Prostatitis. The condition is readily identified by the onset of diminished urine flow, perineal pain, dysuria, and fever. On gentle rectal examination, the gland is enlarged, exquisitely tender, and boggy. Abdominal examination occasionally reveals striking bladder distention. Some patients may appear toxic at the time of presentation.

Chronic Prostatitis. In older men, the symptoms are generally those of bladder outflow obstruction. Patients complain offrequency, dribbling, loss of stream volume and force, double voiding, hesitancy, and urgency. Younger men more often complain of dysuria and dribbling, intermittent discomfort in the perineum, low back, or testicles. Some patients present initially with hematuria, hematospermia, or painful ejaculations. Rectal examination usually reveals an enlarged prostate with a variable amount of asymmetry, bogginess, and tenderness. Untreated or incompletely treated chronic prostatitis is characterized by recurrent symptomatic exacerbations, although these may be separated by long asymptomatic intervals.

Both acute and chronic prostatitis can cause urinary tract and systemic complications. The acutely infected gland may lead to renal parenchymal infection or bacteremia. Rarely, acute infection will progress to a well-defined abscess of the gland. Chronic infection can produce small prostatic stones, which may serve as a nidus for further inflammation and recurrent symptomatic bouts of infection.

Prostatodynia. Patients with prostatodynia complain primarily of persistent *pelvic* and *perineal* pain, but no bacterial pathogen can be identified and no evidence of prostatic inflammation can be documented. Sometimes, the pain may be associated with urinary symptoms such as frequency, urgency, decreased stream flow, and decreased bladder capacity. As noted, some of these patients will be found on extensive culturing to have small numbers of commensal gram-positive organisms in their prostate secretions, and for this reason, low-level infection with bacterial or nonbacterial agents has been argued as the cause of this syndrome. However, a sizable number of patients have negative cultures, and this group remains a management challenge. Some of these patients may have nonperitoneal causes of peritoneal pain, such as pain referred from other pelvic structures or sacral nerve root irritation.

DIFFERENTIAL DIAGNOSIS

Acute prostatitis is readily evident by the clinical presentation and exquisitely tender prostate found on rectal examination. However, chronic prostatitis presents a more difficult diagnostic problem, often resembling, in clinical presentation, other common forms of urinary outflow tract obstruction, such as benign prostatic hypertrophy (see Chapter 138), prostatic carcinoma (see Chapter 143), and urethral stricture (see Chapter 134). The lower urinary tract irritative symptoms associated with chronic prostatitis may be seen with urethritis (see Chapter 136), bladder carcinoma (see Chapter 143), sphincter dyssynergy, and neurogenic bladder (see Chapter 134).

WORKUP

History and Physical Examination. The pertinent history and physical examination depend on the clinical presentation. For suspected *acute prostatitis*, check for acute onset of fever, perineal pain, dysuria, and diminished urine flow. A urethral discharge is sometimes reported. On rectal examination, the prostate is exquisitely tender. Examination should proceed cautiously to avoid precipitating bacteremia. If symptoms of urinary outflow obstruction are present, then the abdomen should be checked for bladder distention. For *chronic prostatitis*, inquire into recurrent perineal, back, or testicular discomfort, dribbling, slow stream, dysuria, and hematospermia. The prostate is enlarged, boggy, and sometimes tender on examination.

Laboratory Studies. Because the documentation of prostate inflammation and the identification of infecting organisms are essential to categorizing prostatitis, and because prostatic infection can be recurrent and elusive, it is well worth the effort to obtain *prostatic fluid* and *urine* for analysis.

Prostatic Fluid. The most rigorous approach is to obtain a series of specimens before and after *prostate massage*. Specimens representing urethral, bladder, and

post-massage urine are collected and labeled VB$_1$, VB$_2$, and VB$_3$ (voided bladder; see appendix), in addition to any expressed prostatic secretions (EPS) that can be obtained as a result of massage. Vigorous massage should be avoided in patients with severe acute prostatitis because of the risk for inducing bacteremia. Gram's stain of the EPS or the spun VB$_3$ will sometimes demonstrate organisms or white blood cells (>10 cells per high-power field is abnormal). Fewer than 10 white blood cells per high-power field on EPS examination excludes prostatic infection with a specificity of 88%. Cultures of the EPS and VB$_3$ should show significant growth (>5,000 colony-forming units per milliliter), whereas the VB$_1$ and VB$_2$ should be sterile or have a colony count that is smaller by one order of magnitude.

Urine. On a more practical level, when urethritis is not suspected clinically and no prostatic secretions can be obtained, then urine specimens can be collected before and after prostate massage (*pre-massage/post-massage test*). If leukocytes are present in the urine after massage when none were present before, then pros-tatic inflammation can be inferred. Occasionally, the *urine culture* after massage will show a single organism or mixed organisms when none were present before massage. Even low levels of bacterial growth (<100,000 colony-forming units per milliliter) should be identified and sensitivities determined. Some laboratories require notification to do this. When no bacterial growth is identified on the EPS, VB$_3$, or post-massage urine despite the presence of leukocytes in any of the three, then bacterial infection has been missed, a nonbacterial infectious agent such as *Chlamydia* is present, or a noninfectious inflammation is present. Unfortunately, these patients cannot reliably be further differentiated. Older men who are without evidence of infection yet are bothered by lower urinary tract irritative symptoms should undergo *urine cytology* to help exclude a bladder malignancy. A bladder carcinoma located in the trigonal region can mimic chronic prostatitis.

Other Studies. *Cystoscopy* may be indicated when the diagnosis is not confirmed by urine culture data. *Blood urea nitrogen* and *creatinine* levels should be determined at the initial visit and periodically thereafter depending on the chronicity and severity of symptoms. An *IV pyelogram* or *spiral computed tomography* is indicated when evidence of renal deterioration or symptoms of persistent outflow obstruction are present. *Abdominal* and *pelvic computed tomography* may be indicated to exclude a retroperitoneal process, and occasionally *lumbosacral magnetic resonance imaging* is indicated to exclude sacral nerve entrapment or impingement.

PRINCIPLES OF MANAGEMENT

Acute Prostatitis. When accompanied by severe pain, high fever, rigors, and marked leukocytosis, acute prostatitis requires *hospitalization* for *IV antibiotic therapy*. Such patients should be examined gently for the presence of a fluctuant prostatic mass suggestive of an abscess, which may necessitate surgical drainage. Less toxic patients can be treated as outpatients with an oral antibiotic program. *Trimethoprim/sulfamethoxazole* (TMS), a fluoroquinolone such as *ciprofloxacin* or *levofloxacin*, and *doxycycline* all work well. Extended therapy, 4 to 6 weeks, is recommended to prevent acute infection from becoming established. Most other antibiotics effective against gram-negative rods (e.g., *amoxicillin*) penetrate the acutely inflamed prostate well and work satisfactorily in the acute phase of illness, but not so well in subacute and chronic states.

Local measures can help reduce discomfort. Sitz baths two to three times a day for 20 minutes can relieve perineal pain. Stool softeners, antipyretics, analgesics, and bed rest are all helpful.

Chronic Prostatitis. This condition is more difficult to eradicate, partly because of poor penetration by oral antibiotics into the prostate. Curative antibiotic therapy requires elimination of bacteria from prostatic fluid. Because the prostatic secretions are normally acidic (pH 6.5 to 7.4), the most efficacious drugs are those that readily penetrate membranes (lipid-soluble) and become ionically trapped (high pH). *TMS*, the *fluoroquinolones*, and *erythromycin* have these characteristics, with good prostatic fluid levels demonstrated. Because *TMS* and *ciprofloxacin* are more effective than *erythromycin* against gram-negative bacteria, they are preferred. However, *TMS* is not effective against enterococci. *Carbenicillin* and *doxycycline* also penetrate the prostate reasonably well. The latter is especially active against *Chlamydia* and some *Ureaplasma* organisms.

With chronic infection, the prostatic fluid becomes increasingly alkaline, which tends to reduce antibiotic penetration. As a result, prolonged treatment may be necessary. Some patients may not achieve cure even after 8 to 12 weeks of antibiotics. Cure rates with TMS range from 30% to 70%; slightly higher rates have been reported with 2 to 4 weeks of ciprofloxacin. To demonstrate cure, the EPS or VB$_3$ (post-massage urine) should be inspected and cultured after the treatment period. Because causative organisms are hard to identify and treatment is frequently empiric, analysis of the prostate fluid after treatment is valuable. If evidence of infection is still present (>10 white cells per high-power field in the EPS or pus in the urine after massage), then a longer course of antibiotics is indicated. After 12 weeks of antibiotic therapy, cure is unlikely; 6 to 12 months of treatment is not unreasonable.

Peripheral a-*adrenergic blockers*, such as doxazosin, tamsulosin, or terazosin, should be used in conjunction with antibiotic therapy for both acute and chronic prostatitis to reduce symptoms. Some data suggest that these drugs also help facilitate cure.

The relatively low cure rate achieved with antibiotics in chronic prostatitis requires that therapeutic goals be adjusted to the patient's age. In most cases, a-adrenergic blockade can be used to control symptoms. If infection relapses, one *TMS* tablet daily appears to be an effective *suppressive regimen. Transurethral prostatic resection* (TURP), *transurethral thermotherapy*, and *total prostatectomy* provide alternatives when repeated courses of antibiotics fail. Such procedures are associated with significant morbidity, including possible impotence or sterility, and should be reserved for carefully selected patients. Recurrent infection associated with prostatic stones is an indication for removal of the gland.

Local measures can help reduce symptoms in patients with chronic prostatitis. The patient with obstructive symptoms can try voiding while in a warm water bath with the pelvic muscles relaxed. The value of prostatic massage is a subject of debate. Many claim that *prostatic massage* relieves gland congestion in chronic cases and should be repeated every 1 to 2 weeks. (Massage of the acutely infected gland is contraindicated.) The patient should avoid alcohol, coffee, tea, or other beverages that might produce rapid bladder expansion. The physician should discontinue or reduce the dosage, if possible, of anticholinergics, sedatives, and antidepressants, all of which can impair bladder function (see Chapter 134). Ejaculation is not contraindicated.

Prostatodynia or Chronic Perineal and Pelvic Pain. Patients with pain and urinary symptoms and no evidence of infection should be watched for the emergence of infection. A limited (4 to 6 weeks) course of antibiotics may be worthwhile; antibiotics can then be continued for an extended course (3 to 4 months) if a clinical response is noted. a-Adrenergic blockade has been used with some success in these patients.

PATIENT EDUCATION

Patients should be advised of the chronic and relapsing nature of the disease and alerted to the early signs of infection in the upper urinary tract. They can also be reassured that isolated prostatitis does not cause infertility or impotence. Local measures that can be suggested for symptomatic relief include sitz baths and voiding into a warm water bath. The importance of compliance with the prolonged antibiotic course and physician monitoring of the response to treatment needs to be stressed.

THERAPEUTIC RECOMMENDATIONS

Acute Prostatitis

- Obtain Gram's stain and culture of the EPS or VB$_3$ (post-massage urine) and treat immediately.
- For the nontoxic patient, oral antibiotic therapy is sufficient. Prescribe either double-strength *TMS* (160 mg trimethoprim, 800 mg sulfamethoxazole twice daily), *ciprofloxacin* (500 mg twice daily), or *levofloxacin* (500 mg daily) for 4 weeks. *Amoxicillin* (500 mg three times daily), *doxycycline* (100 mg twice daily), and *carbenicillin* indanyl sodium (1 g four times daily) are reasonable alternatives, all given for 4 weeks.

Chronic Prostatitis

- Document an infectious organism and the presence of prostatic inflammation, either with sequential urinary culturing and EPS examination or with the pre-massage/post-massage test.
- Treat with a prolonged course of antibiotics, such as double-strength TMS (twice daily for 8 to 12 weeks), or *ciprofloxacin* (500 mg twice daily) or *levofloxacin* (500 mg daily) for 4 weeks. The latter two are considerably more expensive.
- After treatment, follow closely for return of infection. A second course of antibiotics with the same or an alternative drug for up to 12 weeks may be necessary in

partially responsive infections. For patients who fail to respond initially, prescribe a 12-week course of *doxycycline* (100 mg twice daily), *erythromycin* (500 mg four times daily), or *carbenicillin* indanyl sodium (1 g four times daily).

- Schedule a return 1 to 2 weeks after the completion of treatment to assess the effects of therapy by checking the EPS or VB_3 (post-massage urine specimen).
- Prescribe a peripheral a-adrenergic blocker such as *doxazosin* (2 to 8 mg daily), *terazosin* (2 to 10 mg daily), or *tamsulosin* (0.4 to 0.8 mg daily) with the initiation of antibiotic therapy. Continue as long as the patient derives benefit.

Prostatodynia or Chronic Pelvic and Perineal Pain

- Prescribe a trial of a peripheral a-adrenergic blocker, as above.

INDICATIONS FOR ADMISSION AND REFERRAL

Patients with high fever, leukocytosis, and severe perineal pain require IV antibiotics, antipyretics, and analgesics; hospitalization is indicated. In the presence of marked outflow obstruction, suprapubic bladder decompression may be necessary. A fluctuant prostatic mass suggestive of an abscess may require surgical drainage. Until culture and sensitivity data are available, treatment of the toxic patient is directed toward gram-negative bacteria and enterococci, with parenteral administration of ampicillin and gentamicin or levofloxacin.

Patients with outflow tract obstruction or refractory chronic infection should have a urologic consultation. Patients with prostatodynia or an unexplained chronic pelvic and perineal pain syndrome should be referred to a urologist with expertise in this area.

Appendix: Urine and Prostatic Fluid Collections in Men

Standard Clean-voided Specimen. Specimen collection in *male patients* varies with the clinical situation. When cystitis is suspected, the patient is traditionally instructed to retract the foreskin and clean the glans penis with three moist gauze pads or soap sponges. A small amount of urine is voided into the toilet and then a midstream specimen is collected. Cleansing and retraction of foreskin make no difference if a midstream specimen is obtained. However, omitting these steps does lead to contamination of initial specimens. When urethritis or prostatitis is suspected, voided bladder specimens are indicated.

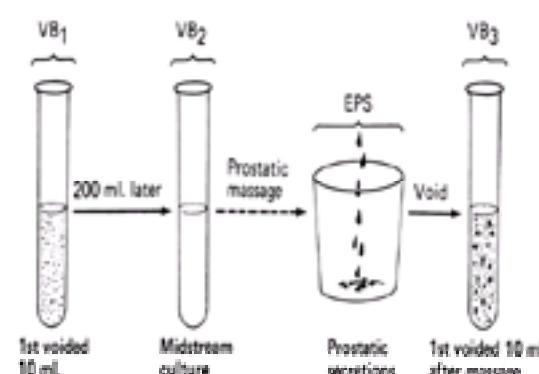
Voided Bladder Specimens. The patient retracts the foreskin and cleans the glans penis. The first 10 mL is collected and labeled VB_1 (Fig. 139.1). This represents a urethral specimen, which is also useful in cases of suspected urethritis (see Chapter 125 and Chapter 136). A midstream specimen is collected in the standard fashion. This is labeled VB_2. The bladder must not be completely emptied. The physician then massages the prostate with continuous strokes. The resulting prostatic fluid, which either comes from the meatus or is milked from the penis by the patient, is collected in a sterile container labeled EPS; this can be used for culture and Gram's stain or acid-fast stain. If no fluid can be collected, the patient is told to void another 10 mL into a sterile container. This specimen, labeled VB_3, represents roughly a 100:1 dilution of prostatic fluid and can be cultured or spun and stained. Vigorous prostatic massage can produce a transient bacteremia and should be avoided if acute prostatitis is suspected. If the patient has chronic prostatitis and known valvular heart disease, endocarditis prophylaxis may be necessary (see Chapter 16).


FIG. 139.1. Segmented culture of the lower urinary tract in male patients. (Adapted from Meares EM, Stamey T. Bacteriologic localization patterns in bacterial prostatitis and urethritis. Invest Urol 1968;5:492, with permission.)

The EPS and VB_3 can be inspected under the microscope for the presence of fat globules, leukocytes, and organisms. If fewer than 10 leukocytes are seen per high-power field, bacterial prostatic infection is unlikely. A Gram's stain may aid in identifying the responsible organism. With bacterial prostatitis, growth will occur in VB_3 and EPS, but not in VB_1 and VB_2. When bacterial growth is noted in both VB_2 and VB_3 samples, a prostatic infection may be masked by a bladder infection. In this situation, antibiotics that sterilize the bladder contents but do not penetrate the prostate [e.g., 500 mg of penicillin G four times a day orally, or 100 mg of nitrofurantoin

(Macrodantin) three times a day orally] may be given for 2 to 3 days before specimen collection. With bacterial prostatic infection, the EPS will still grow organisms.

Urethral catheterization of male patients is rarely required for culture and should be reserved for the symptomatic relief of marked outflow obstruction.

CHAPTER 140 MANAGEMENT OF URINARY TRACT INFECTION IN MEN

Urinary tract infection (UTI) is rare in young men, but the incidence begins to increase with age, particularly after the age of 50. By age 65, it equals that of women. In elderly debilitated patients confined to nursing homes, the prevalence may reach as high as 20% to 50%. The primary physician needs to know the clinical significance of UTI in men, what type of workup is indicated, and what modes of therapy are most cost-effective.

PATHOPHYSIOLOGY, CLINICAL PRESENTATION, AND COURSE

Young Men. UTI in young men usually represents urethritis or introduction of bacteria through *instrumentation* (e.g., bladder catheterization for surgery). At times, a *congenital anomaly* of the urinary tract is responsible, although usually the presentation is at an earlier age. Dysuria, frequency, and urgency accompany most forms, with urethral discharge characteristic of urethritis. Most cases of urethritis are venereal in origin and respond well to treatment (see Chapter 136). The condition of patients with an anatomic defect does not improve unless the structural problem is alleviated. Patients who respond fully to a 7-day course of antibiotics are unlikely to have any serious underlying pathology.

In some young men, uncomplicated *cystitis* may develop because of exposure to uropathogenic strains of *Escherichia coli*. The exposure is seen among homosexual men engaging in anal intercourse and in heterosexual men having vaginal intercourse with a colonized partner. Lack of circumcision is a risk factor, as is HIV infection with a CD4-lymphocyte count below 200/mm^3.

Middle-aged Men. The increase in rate of UTI that occurs in men ages 50 to 65 parallels the increase in prostate size that occurs with hyperplasia of the gland. The enlargement leads to bladder outflow tract obstruction, and a postvoid residual begins to develop in the bladder. The reduced antibacterial activity of prostatic secretions among men in this age group may also contribute to infection risk. Infection of the prostate may serve as a nidus for recurrent UTI.

Elderly Men. With further prostatic enlargement, the *postvoid residual* and consequently the risk for infection continue to rise. Use of condom or urethral *catheters*, urinary incontinence, and history of a previous UTI are other risk factors for UTI in this age group. Asymptomatic bacteriuria may occur, especially among nursing home residents. Additional contributing factors include neurogenic bladder dysfunction (see Chapter 134) and *concomitant illness* (pneumonia is a common precipitant of UTI).

Despite the high prevalence of infection with pathogenic organisms, the vast majority of infected elderly men remain asymptomatic and seem to be at low risk for serious complications. However, the usual manifestations of serious, symptomatic UTI may be absent, replaced by such vague findings as "failure to thrive" or worsening mental status. Gram-negative sepsis from a urinary tract source can be life-threatening. Debate continues as to whether bacteriuria per se increases mortality; studies controlling for comorbid conditions show no increase.

Bacteriology. In patients with infection caused by a single organism, *E. coli* accounts for about 25% of cases, other gram-negative rods (*Proteus, Pseudomonas, Providencia*) for another 50%, and *enterococci* and *coagulase-negative staphylococci* for the remaining 25%. Patients with indwelling catheters and those with recurrent infections and multiple antibiotic exposures are likely to have unusual organisms with resistance to multiple antibiotics. Multiple organisms are found in as many as a third of infected nursing home patients.

WORKUP

History and Physical Examination

In men, complaints of dysuria, frequency, and urgency have a predictive value of about 75% for UTI. Acute onset of hesitancy, nocturia, slow stream, and dribbling have a predictive value for UTI of about 33%. No symptoms differentiate upper from lower tract infection, with the possible exception of fever (which is rare in men with lower tract disease).

The temperature should be taken and a careful genitourinary tract examination performed. The urethral meatus is examined for erythema and discharge, the testes and epididymides for tenderness and swelling, and the prostate for enlargement, nodularity, and pain on palpation. In the patient with suspected acute prostatitis, palpation should be very gentle to avoid causing a bacteremia. The abdomen is checked for suprapubic distention and tenderness in the costovertebral angles.

Laboratory Studies

Urine Culture and Microscopic Examination. Unlike women, men require a urine culture because of the wider range of causative agents and their less predictable drug sensitivities. A diagnosis of UTI is justified on isolation of a pure culture of 10^3 colony-forming units (CFU) per milliliter of urine. A culture that grows fewer than 10^3 CFU/mL or three or more organisms (without one being predominant) is suggestive of contamination. A midstream urine sample or even an initial void sample without prior cleansing of the glans suffices for most clinical situations, even if the patient is uncircumcised. Sensitivity and specificity are in excess of 97%. Initial and midstream urine samples correlate very well with bladder specimens (r = .96).

Both spun and unspun urine specimens should be examined. The spun sediment is examined for the presence of white blood cell casts (indicative of pyelonephritis) and pus, and a Gram's stain is performed to identify a predominant organism, if present. Gram's stain of the unspun urine is also performed. The finding of a single organism or white blood cell per high-power field on Gram's stain of the unspun urine has a sensitivity of 85% for UTI and a specificity of 60%, about the same as those of other rapid diagnostic methods.

Culturing the Incontinent Patient. Specimens from patients with an indwelling catheter can be obtained for culture by first cleansing the side port of the catheter with a povidone–iodine solution and then drawing up urine through a needle attached to a sterile syringe. A culture of urine drawn from an indwelling catheter is positive for organisms when 100 or more CFU/mL are present. Most patients with indwelling catheters have positive cultures.

A specimen from an *incontinent patient* can be obtained for culture without resorting to catheterization by cleansing the glans penis with povidone–iodine solution, applying a fresh *condom catheter* and drainage system, and collecting the first voided specimen in the drainage bag within 2 hours. The criterion for a positive study is the presence of more than 10^5 CFU/mL; lesser growth is considered to represent contamination.

Straight catheterization and direct bladder aspiration are alternative methods of obtaining urine for culture in incontinent patients. The former carries a slight risk of inducing a bacteremia (see Chapter 16); skill is required to perform the latter procedure.

Measurement of Renal Function. Some UTIs or their causes may compromise renal function. Blood urea nitrogen and creatinine are reasonable determinations. A white cell count usually contributes little to the diagnosis but may provide confirmatory evidence in the patient who appears toxic.

Intravenous Pyelography. The dictum that all UTIs in men are complicated (i.e., caused by an anatomic or functional disruption of the urinary tract) has led many to obtain an IV pyelogram routinely when a UTI is detected in a male patient. In the absence of suspected obstruction or refractory infection, there is little evidence to support such a practice in male adults. (In bacteriuric infants and boys, the situation is different.) Although it is true that the prevalence of abnormalities on IV pyelogram is high in men with UTI, the contribution of these findings to management is often minimal. Pending better data regarding who benefits most from IV pyelography, many authorities recommend reserving the test for those with recurrent infection, suspected upper tract obstruction, or pyelonephritis. The IV pyelogram

also provides an estimate of the postvoid residual. Renal ultrasonography offers a dye-free means of checking for obstruction.

Determination of Residual Volume. In the elderly patient with recurrent UTI, assessment is often directed at identifying risk factors for recurrence. Residual volume is among the most prominent. Straight catheterization after voiding is a simple technique to determine residual volume. It entails a very low risk for infection if performed after the urine is sterilized. A volume of more than 50 mL is abnormal. The IV pyelogram also provides an estimate of residual volume. Whether reduction in residual volume by treatment of bladder outlet obstruction reduces the risks and morbidity of UTI remains to be determined.

Testing for Prostate Involvement. In the setting of recurrent or relapsing UTI, there is usually some concern that the prostate may be harboring organisms. A *three-glass test*, which includes culture and Gram's stain of the expressed prostatic secretions (see Chapter 139), may provide objective evidence for prostatic infection. However, the test is expensive (several cultures are required), and its interpretation remains uncertain (no "goldstandard" test is available to provide a basis for comparison). Under most clinical circumstances of recurrent UTI, it is assumed that the prostate is involved to some degree, and treatment is initiated empirically without the need for such testing (see below). However, when the results of testing for prostate infection would alter clinical decision making (e.g., as in planning prostate surgery), then the test may prove worthwhile.

Localization Studies. Differentiating upper from lower tract infection is helpful because of the implications for clinical course and treatment. Clinical findings are usually nonspecific. Instrumentation (ureteral catheterization, bladder washout) is the only proven method for making such a determination. *Antibody coating* is useful as a research technique but not in clinical practice because false-positives occur in patients with prostatic involvement. The best available test has been the response to an initial course of antibiotics.

Testing for Sexually Transmitted Disease in Young Patients. Sexually transmitted diseases may present with urethral symptoms and mimic UTI. Young patients with acute urethral symptoms, even if unaccompanied by discharge, need to be tested for chlamydial infection, which has reached epidemic proportions among adolescents and young adults. Urethral swabbing is carried out (see Chapter 125 and Chapter 136). Methods that can identify chlamydial infection from a urine sample are under development. In addition, any urethral discharge should be Gram's-stained, examined for gonococci and leukocytes, and plated promptly on Thayer-Martin medium (see Chapter 137).

PRINCIPLES OF MANAGEMENT

Symptomatic Infection

Initial Infection. Acute onset of a symptomatic UTI in a male patient should be treated. In the absence of evidence for serious renal parenchymal disease or marked obstruction, one can immediately start a course of oral antibiotics. The initial choice of agent is based on Gram's stain findings, pending culture results. If gram-negative rods are found, then one double-strength tablet of *trimethoprim/sulfamethoxazole* (TMS) twice daily usually suffices. If the organisms are gram-positive cocci, then *amoxicillin* (500 mg three times daily) represents a better choice. The initial program can be revised, if need be, after urine culture results and antibiotic sensitivities become available. As noted above, urine culturing is important in men because of the wide range of organisms and drug sensitivities.

Unlike women, who respond well to single-dose and 3-day treatment regimens, men are customarily treated with a *7- to 10-day* course of antibiotics, based on the view that all male UTIs are at least partially "complicated." Hardly any data are available on abbreviated antibiotic regimens in men. If symptoms clear, no further evaluation or repeated culturing is necessary.

Refractory or Recurrent Infection. Failure to clear symptoms or quick relapse suggests persistence of the original infection. Prostatic involvement (about half of instances), obstruction, anatomic anomaly, or functional disease may be responsible, necessitating repeated urine culture and consideration of IV pyelogram, three-glass testing, and a prolonged course of therapy (6 to 12 weeks) with an antibiotic that both penetrates the prostate and is active against resistant organisms. Many authorities recommend the fluoroquinolone antibiotics in this setting (e.g., 400 mg of *norfloxacin* twice daily). Although a third more effective than *TMS* (which is also prescribed in this setting), the fluoroquinolones are several times more expensive.

Overall, about 65% to 90% of men are cured by a prolonged course of antibiotics. The variability in results depends on the frequency and severity of important underlying pathology. A patient with prostatitis and no postvoid residual has a reasonable chance for cure, but the person with a large postvoid residual is unlikely to derive lasting benefit until the underlying cause has been addressed. Looking for and correcting any treatable precipitants of infection (obstruction, bladder dysfunction, anatomic anomaly) is likely to be more productive than depending solely on repeated or prolonged courses of increasingly potent antibiotics.

Long-term antibiotic prophylaxis against symptomatic recurrences is sometimes prescribed (e.g., double-strength tablet of TMS daily at bedtime). However, concerns about selecting for resistant strains, drug toxicity, and cost have limited this practice to a very small number of patients (those with frequent incapacitating episodes and those at high risk for a serious complication of infection). Because even the frail elderly have low rates of UTI complications, very few patients are treated with long-term antibiotics.

Asymptomatic Infection

Debate continues on the need to treat the debilitated elderly nursing home patient who has asymptomatic bacteriuria. The issue will remain moot so long as it continues to be virtually impossible to eradicate infection in many such patients, especially those who become incontinent and require indwelling or condom catheterization on a long-term basis. In those with an indwelling catheter for more than 30 days, infection becomes a near certainty. Antibiotics may temporarily clear the infection, but relapse within 4 weeks is the rule. Only those who become symptomatic derive benefit from a course of antibiotics. More important are regularly scheduled catheter changes, which reduce the risks of encrustation and obstruction. Although the incidence of bacteriuria is lower with use of a condom catheter, it still approaches 40%. A daily change of the collecting system apparatus helps to cut the rate of infection.

The role of antibiotic therapy is different for men with asymptomatic bacteriuria who are scheduled to undergo surgery and will require short-term urinary tract instrumentation. Preoperative urine testing and treatment are essential to avoid introduction of bacteria into the upper urinary tract and bloodstream. This is especially important for patients scheduled to undergo urologic surgery or surgery in which a foreign body is to be introduced. A fluoroquinolone antibiotic is a reasonable choice for antibiotic therapy under these conditions, but culture and sensitivity results are the best determinants of antibiotic choice.

INDICATIONS FOR REFERRAL AND ADMISSION

Any UTI patient who appears toxic or obstructed requires immediate hospitalization. Urosepsis is a potentially life-threatening complication of UTI that necessitates high-dose parenteral antibiotics and prompt evaluation and treatment of the underlying precipitant. Symptoms of pyelonephritis andurosepsis in elderly patients may be vague (change in mental status, new onset of "failure to thrive"), so a high index of suspicion is warranted. The patient with recurrent symptomatic UTI who promptly relapses after a 6-week course of fluoroquinolone therapy should be considered for urologic evaluation, as should the person with UTI in the context of declining renal function. An infectious disease consultant can also be helpful in these difficult situations.

CHAPTER 141 MANAGEMENT OF SYPHILIS AND OTHER SEXUALLY TRANSMITTED DISEASES

BENJAMIN DAVIS AND HARVEY B. SIMON

SYPHILIS

In 1943, the dramatic efficacy of penicillin treatment was established, and for the next 15 years the incidence of new cases of syphilis declined steadily to a low of about 6,500 in 1956. Although *Treponema pallidum*, the spirochete that causes syphilis, has not developed resistance to penicillin, the incidence of syphilis has increased progressively in the last 25 years, largely because of a change in sexual mores, with many new cases occurring in adolescents, young adults, and homosexuals. An accelerating resurgence had been noted among inner-city residents, IV drug abusers, and HIV-infected persons, which peaked in 1991. Since then, the rates have declined steadily to an all-time low since reporting began.

Pathophysiology, Clinical Presentation, and Course

Humans are the only natural reservoir of *T. pallidum*. Except for cases of transplacental transmission, virtually all cases are acquired by sexual contact with persons having active infectious lesions. *T. pallidum* readily penetrates abraded skin and intact mucous membranes to multiply locally and disseminate through the lymphatics and bloodstream.

The course of syphilis can be divided into primary, secondary, latent, and tertiary phases.

Primary Syphilis. The lesion of primary syphilis is the chancre, which occurs at the site of inoculation about 3 weeks after exposure. The chancre is usually located on the genitalia, but, depending on sexual practices, it can occur in the anal canal, on oral mucosa, on the hands, and in other locations. The lesionbegins as a small papule that enlarges and undergoes superficial necrosis to produce an ulcer with a clean base and sharp margins. The chancre is typically painless, and patients are free of constitutional symptoms, although regional nodes may be enlarged. The chancre is teeming with spirochetes and is highly infectious. Even without therapy, the chancre heals completely in 2 to 6 weeks.

Secondary Syphilis. About 2 months after the primary infection, the features of secondary syphilis may appear. Secondary syphilis is a systemic disease. A flulike syndrome is common, as is generalized lymphadenopathy. The most characteristic feature of secondary syphilis is a generalized skin eruption. Lesions may be macular, papular, or papulosquamous but tend to be symmetric and uniform in size; typically, the palms and soles are involved. Patches and split papules often occur on the mucous membranes. Secondary syphilis can involve many other organs; clinical manifestations may include aseptic meningitis, hepatitis, nephritis, or uveitis. Patients with secondary syphilis are contagious. As in primary syphilis, the manifestations of secondary syphilis resolve spontaneously even without therapy, although up to 25% of patients exhibit a brief relapse of secondary lesions.

Latent and Tertiary Syphilis. Untreated patients without active lesions are considered to have latent syphilis. About two thirds of these people remain entirely asymptomatic, but in the remaining third, the lesions of tertiary syphilis develop, usually 10 to 40 years after primary infection. The major forms of tertiary syphilis include (a) *cardiovascular syphilis*, characterized by aneurysmal dilation of the ascending aorta and aortic insufficiency; (b) *neurosyphilis*, which may be asymptomatic; alternatively, it may present as general paresis with disorders of intellect and personality, or as tabes dorsalis, with ataxic gait, impaired pain and temperature sensation, autonomic dysfunction, and hypoactive reflexes; and (c) *gummas*, which are isolated, slowly progressive, destructive granulomatous lesions of skin, bone, liver, or other organs.

Infection of the Central Nervous System infection may occur at any point in the natural history of untreated syphilis and may be more likely in HIV-positive patients. Even in the absence of neurologic symptoms, about 25% of patients with primary, secondary, or latent infection have cerebrospinal fluid abnormalities (pleocytosis, elevated protein, serologies positive for syphilis). Although it is not clear how many of these patients will ultimately be affected by symptomatic neurosyphilis, concern is warranted. Organisms have been detected from the central nervous system in 30% of patients with untreated primary and secondary disease.

Syphilis and HIV Disease. Patients with syphilis are at increased risk for other sexually transmitted diseases, including HIV infection. Moreover, those with HIV infection are at increased risk for syphilis. Some studies find that HIV-infected patients have unusually high titers in their syphilis serology, whereas others find that seroconversion can be delayed or blunted by concomitant HIV infection, particularly in patients with symptomatic AIDS. In addition to being more common in HIV-infected persons, syphilis in these patients may be clinically atypical, unusually severe, or more difficult to treat successfully. Central nervous system syphilis is also more likely in HIV-positive patients.

Congenital Syphilis occurs as a result of transplacental transmission of spirochetes during the second or third trimester of pregnancy. Fetal loss is about 60%, and up to half of surviving infants have stigmata, which can result in serious permanent handicaps. Congenital syphilis can be prevented by prompt treatment of maternal infection.

Diagnosis

Treponema pallidum cannot be cultured in vitro, but the diagnosis of syphilis can be made by direct visualization of treponemas from the chancre. This is a specialized technique that requires *dark-field* or *fluorescent microscopy* and very experienced observers. As a result, the diagnosis usually depends on clinical features and serologic testing.

The most widely used serologic tests for syphilis employ a nontreponemal antigen (lipoidal extract of mammalian tissues). Examples include the *Venereal Disease Research Laboratory* (VDRL), *Hinton*, and *rapid plasma reagin* (RPR) tests. These are excellent screening tests, but the false-positive rate is as high as 30%, often as the result of unrelated infections or inflammatory diseases that produce hyperglobulinemia. More specific serologic tests employ treponemal antigens and can distinguish true-positive from false-positive results. The most frequently used treponemal test is the *microhemagglutination–T. pallidum* (MHA-TP) test (see Chapter 124).

Some patients with primary syphilis manifest false-negative nontreponemal and treponemal test results. False-negatives are most likely to occur in patients with infections of less than 30 days' duration. For persons with a suspect primary lesion, dark-field examination should be performed and serologic studies repeated in 10 to 14 days. For *HIV-infected* patients with suspect skin lesions and negative serology, skin biopsy may be necessary to rule out syphilis. The Warthin-Starry stain can be used to visualize organisms in biopsy specimens.

Principles of Management and Therapeutic Recommendations

The results of treatment of early syphilis are excellent. *T. pallidum* is very sensitive to *penicillin*. Because the organism multiplies slowly, the goal is to attain long-lasting antibiotic levels. Present recommendations include the following:

- For early syphilis (primary, secondary, early latent stages), treat with 2.4 million units of *benzathine penicillin* IM at a single session. Penicillin-allergic patients should receive 500 mg of oral *tetracycline* four times daily for 14 days or 100 mg of *doxycycline* twice daily for 14 days. Doxycycline and tetracycline are contraindicated in pregnancy.
- For syphilis of more than 1 year's duration (latent, tertiary, or unknown duration), treat with 2.4 million units of *benzathine penicillin* IM weekly for 3 weeks consecutively. Penicillin-allergic patients should receive 500 mg of oral *tetracycline* four times daily for 28 days or 100 mg of *doxycycline* twice daily for 28 days.
- Neurosyphilis should be treated with 18 to 24 million units of *aqueous penicillin G* IV, divided every 4 hours, for 14 days. Some experts recommend a single dose

of 2.4 million units of *benzathine penicillir* IM at the end of IV therapy. Aftertherapy, the cerebrospinal fluid should be reexamined every 6 months until findings are normal.

- HIV infection may increase the risk for neurosyphilis, but cerebrospinal fluid abnormalities are common in HIV-infected patients, and their presence is of uncertain significance. Lumbar puncture should be considered. There are no data to suggest that the treatment regimens prescribed for HIV-negative patients will be less effective in HIV-positive patients. HIV-infected patients should be monitored closely after therapy.
- Syphilis in pregnancy and neurosyphilis should always be treated with penicillin. Patients allergic to penicillin should be desensitized if necessary.
- A febrile reaction (the Jarisch-Herxheimer reaction), often with headache and myalgia, may occur within the first 24 hours after treatment of syphilis, especially early syphilis. Patients should be warned of this possibility, but treatment should not be delayed.

Immunity to syphilis is incomplete and reinfection may occur, especially in patients treated with penicillin within a year of infection. Follow-up of patients is essential. Quantitative nontreponemal serologies at 3, 6, and 12 months after treatment help determine adequacy of therapy. HIV-infected patients should be followed more closely. Failure to sustain a fourfold decline in titers with therapy suggests treatment failure or reinfection, and examination of the cerebrospinal fluid should be considered. If lumbar puncture is not possible, retreatment with a regimen used for syphilis of more than 1 year's duration should be considered.

All cases of syphilis should be reported to the appropriate public health authorities so that appropriate case finding can be performed. Like all patients with sexually transmitted diseases, syphilis patients need to be screened for other venereal infections, including HIV infection, chlamydial infection, and gonorrhea (see Chapter 7, Chapter 125, and Chapter 137), and counseled about HIV infection and safe sex practices.

CHANCROID AND GRANULOMA INGUINALE

Chancroid, which is endemic in some areas of the United States, is caused by the gram-negative bacillus *Haemophilus ducreyi*. It typically produces painful genital ulcers that are often accompanied by regional adenopathy. Azithromycin (1 g PO) or ceftriaxone (250 mg IM), both given as a single dose, are the treatments of choice.

Painless, slowly progressive genital ulcers are characteristic of *granuloma inguinale*, caused by the gram-negative bacterium *Donovania granulomatis*. Double-strength *trimethoprim/sulfamethoxazole* twice daily or 100 mg of *doxycycline* twice daily, both for 21 days, are the treatments of choice. Both chancroid and granuloma inguinale are rare in temperate climates.

LYMPHOGRANULOMA VENEREUM

A microorganism belonging to the *Chlamydia* group of obligate intracellular parasites is the cause of lymphogranuloma venereum. In this disease, the primary genital lesion is a small, painless papule that heals spontaneously and often escapes notice. The major impact of the disease is on the regional lymphatics. Inguinal nodes enlarge and may suppurate to produce chronic draining sinuses. Scarring and lymphatic obstruction may result. Women and homosexual men may have proctocolitis, which can lead to rectal fibrosis, strictures, and fistulas. A 21-day course of doxycycline (100 mg twice daily) is the treatment of choice. An alternative is a 21-day course of erythromycin (500 mg four times daily).

CHAPTER 142 MANAGEMENT OF THE PATIENT WITH CHRONIC RENAL FAILURE

LESLIE S.-T. FANG

INTRODUCTION

Although many diseases can lead to chronic renal failure, the resulting clinical manifestations and functional derangements are remarkably constant. The primary physician is often responsible for initial conservative management, including interventions that have been shown to delay progression of disease. Additional objectives are to prevent or minimize the complications of uremia, monitor disease progression, and judge when referral to the nephrologist is indicated for consideration of dialysis or transplantation.

PATHOPHYSIOLOGY, CLINICAL PRESENTATION, AND COURSE

Pathophysiology

Chronic renal failure can result from glomerular, vascular, or tubular disease. Congenital anomalies, infection, metabolic diseases, obstructive uropathy, and collagen vascular disease can all lead to renal insufficiency. Irrespective of underlying disease, the major clinical manifestations of chronic renal failure result from disturbances in electrolyte and fluid balance, elimination of metabolic wastes and toxins, erythropoietin production, and blood pressure control. The role of urea and other toxins in the production of symptoms remains controversial.

Fluid and Electrolyte Problems. These include hyperkalemia, volume overload, hypocalcemia, hyperphosphatemia, and metabolic acidosis. With moderate renal insufficiency, the *urinary concentrating ability* is impaired, so that to handle the same solute load, patients have to drink and excrete more water than normal. This results in polydipsia, polyuria, and nocturia. The ability to dilute urine is compromised with further renal impairment, producing isosthenuria and obligate fluid intake. As renal function continues to decline, oliguria supervenes. The situation is similar with sodium; moderate renal failure produces mild *salt wasting*. In the later stages, sodium excretion becomes limited, *salt retention* develops, and edema supervenes.

Potassium excretion is usually preserved until late in the course, when *potassium retention* occurs as oliguria develops and the ability of the distal tubules to secrete potassium is compromised.

Decreased renal function produces *phosphate retention, secondary hypocalcemia*, and, consequently, *secondary hyperparathyroidism*. Decreased intestinal calcium absorption secondary to impaired hydroxylation of vitamin D also contributes to hypocalcemia.

Acidosis results from an inability to excrete urinary ammonium and, with further impairment, titratable acid. Loss of bicarbonate exacerbates the problem. *Uric acid* levels increase as urate excretion falls.

Endocrine Problems. Impairment of renal endocrine function contributes to anemia, hypertension, and congestive failure, which may further compromise renal function. *Decreased erythropoietin* production results in a mild to moderate normochromic normocytic anemia. Anemia also develops as a consequence of increased hemolysis and bleeding, aggravated by impaired platelet adhesiveness. *Increased renin* levels sometimes occur, causing modest hypertension and fluid retention. In addition to renal osteodystrophy, *secondary hyperparathyroidism* may lead to alterations in central nervous system calcium, which have been implicated in some of the neurologic manifestations of renal failure.

Hematologic Problems. Anemia in the patient with chronic renal failure develops as renal production of erythropoietin declines. The anemia may be severe enough to cause symptoms, which usually occur when the creatinine level rises above 4 mg/dL and the hematocrit falls to less than 25%.

Clinical Presentation and Course

Early in renal failure, anorexia, lassitude, fatigability, and weakness are prominent symptoms. As renal failure worsens, the patient may complain of pruritus, nausea, vomiting, constipation, or diarrhea. Shortness of breath may occur secondary to cardiomyopathy and fluid overload. Edema, hypertension, and pericarditis are common late in the course. Neurologic manifestations include drowsiness, lethargy, peripheral myopathy, seizures, and, terminally, coma.

The course of renal failure is punctuated by periods of rapid deterioration, often precipitated by dehydration or infection. The rate of progression depends, in part, on the underlying renal disease, being more rapid in patients with diabetic nephropathy or severe hypertension and slower in patients with polycystic kidneys. However, in patients with advanced renal failure (creatinine level .10 mg/dL), mean survival without intervention is 100 to 150 days.

PRINCIPLES OF MANAGEMENT

Conservative management of renal failure can prolong survival and preserve quality of life by compensating for the excretory, regulatory, and endocrine functions of the kidney. The goals of therapy are to reduce symptoms, slow progression, and avoid preventable complications.

Drug Therapy to Slow Progression to End-Stage Renal Failure. Early initiation of therapy with *angiotensin-converting enzyme inhibitors* (ACE inhibitors) reduces the risk for progression to end-stage renal disease. This effect was first established in diabetic renal disease (both normotensive and hypertensive), but it also pertains to cases with nondiabetic causes. The effect is independent of reductions in blood pressure and protein excretion that accompany improved blood pressure control (see below). ACE inhibitors are thought to slow the rate of injury by decreasing glomerular hyperfiltration. Renal function should be monitored carefully during ACE inhibitor therapy because acute deterioration in renal function may be seen in some patients, particularly those with bilateral renal vascular disease. **Updated: 10/02/03**

Protein Intake. The excretory function of the kidneys involves the removal of nitrogenous waste. Reduction of dietary protein intake has long been the cornerstone of therapy for uremia. Early in the course of renal disease, reduction of protein intake helps reduce the rate of progression, but the degree of benefit is actually quite modest. Late in the course of renal disease, reduction of protein intake is useful in preventing azotemia from worsening.

Restricting the daily intake of protein to 0.5 g/kg usually allows sufficient amounts for daily requirements while slowing the progression of renal failure. Foods rich in *essential amino acids* are the most effectively utilized source of nitrogen.

Blood Pressure Control. Hypertension is a common complication of renal disease and also a major determinant of disease progression. Systolic blood pressure appears to be the single most important predictor, especially in persons with significant proteinuria (>1.0 gm/d). (Diastolic pressure does not appear to confer the same predictive power.) Blood pressure control is beneficial regardless of the antihypertensive agent or agents employed. However, the best results are associated with the use of *ACE inhibitors*, particularly if they are administered early. Calcium channel blockers have also been shown to delay the onset of nephropathy in patients with type I diabetes. ACE inhibitors may provide additional reduction in proteinuria. Alternative antihypertensive agents include b-blockers, diuretics, and vasodilators. **Updated: 10/02/03**

Fluids and Electrolytes. Judicious fluid and electrolyte management is exceedingly important because patients with chronic renal failure have difficulty adjusting to variations of either excessive intake or rigid restriction of salt and fluids.

Sodium. In the early and middle stages of renal failure, salt and fluid intake must be adequate to match the excess losses that occur as tubular functions begin to deteriorate. Restriction of intake can actually accelerate renal damage by causing decreased extracellular volume and reduced renal perfusion. The concentrating ability can be measured by determining the specific gravity of a first morning urine specimen, and sodium requirements can be estimated by testing a 24-hour urine collection for sodium excretion. In later stages, as excretion of sodium and water becomes limited, cautious sodium and fluid restriction becomes necessary.

Potassium. Because potassium excretion is preserved until late in the course of renal failure, there is usually no need to restrict its intake until oliguria sets in. However, it is prudent to *avoid* or at least use with caution *drugs* that predispose to potassium retention, such as potassium-sparing diuretics, potassium supplements, b-adrenergic blockers, and NSAIDs. Because acidosis worsens hyperkalemia, it should be corrected promptly. On the other hand, severe protracted hypokalemia can itself cause tubular damage; therefore, serum potassium should be monitored regularly and low levels corrected.

Calcium. Hypocalcemia and secondary hyperparathyroidism are best countered by reducing the elevations in serum phosphate that result from decreased renal excretion of the anion. The principle of therapy is to lower serum phosphate by reducing dietary sources, inhibiting absorption, and maintaining adequate calcium levels with pharmacologic doses of *vitamin D* and exogenous *calcium*. In patients with hypocalcemia and hyperphosphatemia, calcium citrate can be used to help with phosphate binding. It should be administered either shortly before or shortly after a meal to maximize phosphate binding. Aluminum hydroxide antacids are now used infrequently because of concern that excessive ingestion may lead to aluminum-induced osteomalacia and neuropathy.

In advanced disease, renal hydroxylation of 25-hydroxyvitamin D is impaired, so that the use of 1,25-dihydroxyvitamin D_3 becomes necessary. This reduces the prevalence of secondary hyperparathyroidism and the ensuing metabolic bone disease. In patients with severe hyperparathyroidism, partial parathyroidectomy should be considered.

Hyperuricemia. Urate reduction is necessary only if gouty attacks develop (see Chapter 158).

Acidosis. Correction of acidosis becomes desirable when the serum bicarbonate level falls below 15 mEq/L. Any external acid loads, such as aspirin, vitamin C, or excess protein intake, should be removed. *Sodium bicarbonate* is given as long as the sodium load can be tolerated. The goal is to titrate the serum bicarbonate level to 16 to 20 mEq/L.

Hematologic Problems. The advent of *recombinant erythropoietin* has greatly enhanced the management of the anemia of chronic renal failure. After patients become symptomatic (usually when the hematocrit falls below 25%), erythropoietin therapy can be started, administered either SQ or IV three times per week in doses of 1,000 to 6,000 units. Patients require close monitoring of hemoglobin, reticulocyte count, and ferritin. Iron supplementation must be provided to patients who are iron-deficient to maximize the efficacy of erythropoietin therapy. Most patients with symptomatic anemia respond well, with improvement in quality of life in addition to hematologic parameters. Judicious use of erythropoietin can usually raise the hematocrit to the 30% level and avoid the need for repeated transfusions.

Transfusion therapy is sometimes used, but repeated transfusions carry the risk for hepatitis (see Chapter 70) and sensitization to leukocyte HLA antigens, which can complicate finding a compatible cadaver donor for renal transplantation.

Patients with chronic renal failure should be cautioned to avoid antiplatelet drugs. Abnormalities in platelet function can be aggravated by drugs such as aspirin and other NSAIDs (see Chapter 81). The abnormalities can be corrected by dialysis or the administration of cryoprecipitates, DDAVP (deamino-8- D-arginine vasopressin), or estrogens. Uremia-induced megaloblastic changes are unresponsive to folate or vitamin B_{12}.

Cardiovascular Complications. The onset of congestive heart failure poses a very difficult problem, especially late in the course of the disease, when the ability to excrete sodium may be very limited. *Salt restriction* and a trial of a *loop diuretic* (e.g., furosemide) may be tried, but these measures are often insufficient. *Metolazone* can be added to a loop diuretic regimen; it often augments the diuretic effect. Renal function and the electrolyte profile should be carefully monitored. Digitalization must be carried out with care, as the renal excretion of digoxin is compromised (see Chapter 32). *Dialysis* may be the only recourse in patients with refractory fluid overload.

Uremic pericarditis is another late cardiovascular complication. Patients may have symptoms of atypical chest pain and progress to pericardial tamponade. The development of pericarditis is an indication to proceed with dialysis.

Neuromuscular Difficulties. Lethargy, an inability to concentrate, and asterixis improve with *protein* restriction. However, peripheral neuropathies often progress despite comprehensive conservation therapy. Muscle cramping and tetany respond to correction of hypocalcemia.

Itching, Hiccups, and Nausea. These symptoms are not life-threatening but certainly contribute to the patient's misery and require attention. Pruritus can be quite stubborn but responds to topical measures (see Chapter 178). *Prochlorperazine* is effective in lessening hiccups and nausea.

Not all drugs that cause an elevation in serum creatinine are necessarily nephrotoxic. Cimetidine and trimethoprim compete with creatinine for tubular excretion; elevations in serum creatinine may ensue, especially in patients who are azotemic. Methyldopa and cefoxitin interfere with some autoanalyzer measurements of creatinine and can give falsely elevated readings.

Aggravating Conditions. Of chief importance is early detection and correction of any condition that may further compromise renal function. Urinary tract infection, dehydration, gastrointestinal bleeding, and congestive heart failure can cause acute decompensation.

PATIENT EDUCATION AND SUPPORT

Successful therapy and good morale depend strongly on a well-developed doctor–patient relationship. The patient must be educated about chronic renal failure and the rationale behind therapy because compliance is central to successful conservative management, especially if the treatment requires dietary restrictions. Renal failure is a serious chronic disease that often precipitates depression, denial, anger, and noncompliance. The physician's patience, understanding, support, and interest are powerful but sometimes underutilized elements of the treatment program.

Keeping the patient well informed enhances a sense of control and facilitates compliance. Treatment alternatives must be presented honestly and completely. Discussions about diet, medications, prognosis, and therapeutic options should include the family. Psychosocial management should aim at minimizing dependence and social isolation.

INDICATIONS FOR REFERRAL AND ADMISSION

Patients can generally be managed as outpatients, but referral to a nephrologist should be made if clinical deterioration continues despite maximal supportive therapy. As the serum creatinine level approaches 10 mg/dL, mean survival drops to between 100 and 150 days, so that consideration of dialysis or transplantation is warranted. Moreover, vascular access for hemodialysis needs to be constructed with 2 to 3 months of lead time to permit maturation of the fistula and revisions. Decisions regarding dialysis and transplantation require a comprehensive evaluation of the patient's medical, psychological, and social situation, which necessitates a close working relationship between the patient, family, primary physician, and nephrologist.

Continuous ambulatory peritoneal dialysis (CAPD) and *continuous cycling peritoneal dialysis* (CCPD) are outpatient options that provide a high degree of independence for the patient and the physiologic advantage of a slow, continuous dialysis process. Dialysate administrations are conducted through an indwelling abdominal catheter three to five times per day. Results are comparable with those of hemodialysis. The main disadvantage is a substantial risk for peritonitis; fortunately, most cases are mild and can be managed on an outpatient basis by self-administration of antibiotics through the catheter.

Hospitalization may be required for control of fluid overload, hypertension, hyperkalemia, or infection. In general, the multiplicity of possible metabolic disturbances in the patient with chronic renal insufficiency demands careful follow-up and constant adjustments of the treatment program.

MANAGEMENT RECOMMENDATIONS

Angiotensin-Converting Enzyme Inhibitors to Slow Progression to End-Stage Renal Failure

- Consider initiation of ACE inhibitor therapy (e.g., 25 mg of captopril 2 to 3 times daily) early in the course of renal failure, especially in patients with diabetes, but also in persons with nondiabetic renal disease. Hypertension is not a prerequisite for such treatment. Exert caution with ACE inhibitor use in the setting of acute dehydration. Monitor blood pressure, renal function, and serum potassium regularly. Omit in persons with bilateral renal artery stenosis. Aim for a systolic blood pressure between 110 and 129 mm Hg (see below). **Updated: 10/02/03**

Protein and Calories

- Restrict protein intake to 0.5 g of high-quality protein per kilogram daily if the patient is symptomatic or acidotic, and to 0.5 to 0.75 g/kg daily if the blood urea nitrogen level is above 75 mg/dL but the patient is asymptomatic.
- Maintain calorie intake at 40 to 50 cal/kg daily.

Fluids

- With mild to moderate renal insufficiency, fluid restriction is not necessary unless concomitant hypertension or congestive heart failure is present.
- Restrict fluids only in the presence of oliguria. Intake should equal urine output and insensible losses.

Hypertension and Proteinuria

- ACE inhibitors are the treatment of choice, especially in diabetics and those with marked proteinuria, but also in those with nondiabetic renal disease. Calcium channel blockers have also been shown to delay onset of nephropathy in patients with type I diabetes. The choice of agent can be on the basis of cost and convenience (e.g., 25 mg of captopril 3 times daily). Monitor renal function. Alternatives include b-blockers and vasodilators (see Chapter 26). **Updated: 10/02/03**
- Monitor systolic blood pressure closely. Aim for a systolic blood pressure of between 110 and 129 mm Hg, especially in persons with significant proteinuria (> 1.0 gm/d). Aim for the lower end of the range, especially in persons with marked proteinuria (> 2 gm/d). Avoid reduction in systolic pressure to below 110 mm Hg. **Updated: 10/02/03**
- Also monitor urinary protein excretion either by 24-hr collection or by spot urinary collection (measuring urinary albumin-creatinine ratio). Aim for a ratio of < 1.0, which corresponds to a 24-hr urinary protein excretion of approximately < 1.0 gm/d. If this is not achieved, consider adding an ACE inhibitor to the medical regimen. **Updated: 10/02/03**

Sodium

- With mild to moderate renal insufficiency, salt restriction is not necessary.
- In patients with hypertension or congestive heart failure, salt restriction to 2 g of sodium daily may be necessary.
- Restrict sodium in the presence of oliguria or congestive heart failure.

Potassium

- For hypokalemic patients, administer potassium supplements in low doses and check levels frequently. Do not maintain potassium supplementation indefinitely.
- Avoid potassium-sparing diuretics in patients with moderate renal insufficiency.
- Monitor potassium frequently in oliguric patients. Treat levels above 6 mEq/L and admit if electrocardiographic changes accompany levels above 6.5 mEq/L. Mild chronic hyperkalemia is best treated with exchange resins such as sodium polystyrene sulfonate (Kayexalate), given by mouth or instilled as an enema in sorbitol. Kayexalate exchanges sodium ion for potassium ion; therefore, be alert to possible sodium and volume overload.

Calcium and Phosphate

- Correct hyperphosphatemia with calcium citrate (667 mg three times daily before meals).
- Symptomatic or severe hypocalcemia despite normalization of serum phosphate requires calcium supplements (e.g., 600 mg of calcium carbonate twice daily), vitamin D in pharmacologic doses (e.g., calcitriol 0.25 mg daily), or both.

Acidosis and Hyperuricemia

- Treat if serum bicarbonate concentration is less than 15 mEq/L.
- Remove external acid load.
- Treat acidosis with 600 mg of sodium bicarbonate twice daily initially, and titrate bicarbonate to the range of 16 to 20 mEq/L. Follow serum potassium and calcium levels during the treatment of acidosis because both may fall.
- Treat hyperuricemia only if symptomatic gout develops; use allopurinol (see Chapter 158).

Anemia

- Treat with 1,000 to 6,000 units of erythropoietin SQ three times per week; monitor hemoglobin, hematocrit, reticulocyte count, and serum ferritin.
- Avoid antiplatelet drugs.
- Give 325 mg of oral ferrous sulfate per day to patients with iron deficiency.
- Transfuse for high-output failure or angina. Avoid unnecessary blood work and injections.

Congestive Heart Failure

- Treat with restriction of salt.
- Add furosemide if congestive failure persists.

- Add metolazone (2.5 to 5 mg) if refractory fluid overload is present; monitor renal function and electrolytes closely.
- Consider use of an ACE inhibitor (e.g., start with 12.5 to 25 mg of captopril two to three times daily); monitor renal function closely.
- Digoxin can be used, but frequent monitoring of digoxin levels is needed.

Itching, Hiccups, and Nausea

- Minimize symptoms by reducing dietary protein intake.
- Prescribe 5 to 10 mg of prochlorperazine orally four times daily for nausea.
- Treat itching topically with menthol or phenol lotion or a trial of capsaicin cream; cholestyramine and ultraviolet light have also been used successfully (see Chapter 178).

Dialysis and Transplantation

- The conservative management outlined is directed toward prolongation of the symptom-free period. If dietary therapy becomes intolerable or is no longer effective, dialysis or transplantation must be considered. Referral to a nephrologist is necessary at this point. The primary physician should continue to participate in the important decisions about dialysis and transplantation.

CHAPTER 143 MANAGEMENT OF GENITOURINARY CANCERS IN MEN

Cancers of the genitourinary tract in men are often localized, and, if so, they can be managed by surgery or radiation. Unfortunately, advanced disease is common and requires a team approach involving the surgeon, oncologist, radiotherapist, and primary physician. The responsibilities of the primary physician include prevention, screening for early disease (see Chapter 126), counseling, support, and monitoring of patients with advanced disease. A more active role in therapy has been created by the advent of hormonally active therapy for advanced prostate cancer.

CARCINOMA OF THE PROSTATE

Epidemiology and Risk Factors

Carcinoma of the prostate has become the leading cancer in men, with an estimated 200,000 new cases annually. Incidence rose during the years before 1992 but has since leveled off, in part because of advances in the detection of prevalence cases, but perhaps also because of increases in dietary, environmental, and genetic precipitants. Evidence is mounting for possible pathogenetic roles for monounsaturated fats, heavy metals, and certain oncogenes. Some familial clustering has been observed, and risk doubles among first-degree relatives. These factors may account for some of the differences in prevalence encountered across geographic and racial boundaries. Testosterone is likely to play a major role, evoked as the cause of the high prevalence of this disease among African-American men and its absence among those who have been castrated. No association with benign prostatic hypertrophy or sexual activity has been found. However, age is a major determinant, with incidence and mortality rising sharply after age 50. By the ninth decade, more than 70% of men have at least microscopic evidence of prostate carcinoma at autopsy.

Although prostate cancer may be a common affliction of older men, it is far from being harmless. Approximately 30,000 die annually from the disease, making it the second leading cause of cancer death among men in the United States. Lifetime risk for a 50-year-old man developing clinical cancer is estimated to be 10%; lifetime risk of dying from the cancer is 3%.

Pathophysiology, Clinical Presentation, and Course

Most of the prostate cancers found at autopsy are *incidental* and have no clinical import. They are small in volume, well differentiated, diploid, and noninvasive, and they originate from the transition zone; prostate-specific antigen (PSA) levels are often normal. *Clinically important* lesions are larger, less well differentiated, invasive, and nondiploid, and they originate from the peripheral zone; PSA is often elevated. What converts microscopic pathology to clinically evident disease remains unknown. It is also unclear what percentage of all prostate cancers become clinically important.

In 85% of cases, clinically evident tumor arises in the *periphery* of the gland (posterior lobe or lamella), so that detection by digital examination is possible in many instances. However, only 30% of new cases are discovered by this means. Many patients now present with nonpalpable, asymptomatic lesions, detected by PSA screening followed by prostate ultrasonography (see Chapter 126). Others present with nonspecific symptoms of urethral obstruction (see Chapter 134). Renal insufficiency resulting from prolonged urinary tract obstruction ensues in a small but important fraction. About 15% of patients have bone pain or other manifestations of metastatic disease as the presenting complaint. Osteoblastic metastases predominate; they can be painful and are the major cause of morbidity. Metastasis to regional lymph nodes is common and usually asymptomatic. It may occur even when disease appears clinically to be confined to the gland and before spread to bone.

Prognosis is a function of disease stage at the time of diagnosis, histologic grade of the tumor, and level of PSA. Because of the advanced age of this patient population, many men die of other conditions.

Staging

Staging is essential to formulating a prognosis and selecting therapy. However, clinical staging continues to underestimate the extent of disease. Metastases to regional lymph nodes often go undetected. The inadequacy of clinical staging accounts in part for the often-noted poor correlation between clinical stage and response to therapy. It is also the reason for the conflicting reports of treatment results that pervade the prostate cancer literature. Attempts to compensate for the shortcomings of clinical staging and to estimate better the likelihood of metastatic disease include the designation of subcategories within each stage and consideration of the histologic pattern (patients with histology of a higher grade are more likely to harbor lymph node metastases).

Determining Extent of Local Disease. The clinical assessment begins with careful *palpation* of the prostate to establish the extent of local tumor. Emphasis is on establishing tumor size and any spread into the surrounding soft tissue. However, digital examination understages about one third of patients thought to have disease limited to the prostate. The *PSA* concentration correlates with tumor volume. Levels in excess of 15 ng/mL (Hybritech assay) suggest extension through the capsule or into the seminal vesicles. Transrectal *ultrasonography* and *magnetic resonance imaging* (MRI) are often used to stage local disease, but the accuracy of such imaging studies has been disappointing (range, 58% to 69%), so that biopsy confirmation of any positive findings is necessary. MRI adapted for transrectal use is being studied and may prove better. Computed tomography (CT) is not useful.

Determining Metastatic Involvement. Physical examination initiates the search, with careful palpation of all nodes, bones, and the abdomen. PSA determination has become increasingly useful. If the PSA concentration exceeds 20 ng/mL (Hybritech assay), distant metastasis to bone is likely and a *bone scan* should be ordered. If the result of the bone scan is positive, more elaborate imaging studies are unnecessary because the disease is already stage D2 (see below). A PSA level below 20 ng/mL greatly reduces the likelihood of bony involvement (<1%) and obviates the need for bone scan, but regional metastasis still needs to be considered. *CT* of the pelvis and abdomen is often ordered to assess pelvic and retroperitoneal lymph node involvement noninvasively, but results have been disappointing in predicting outcome. Sensitivity is especially poor. Biopsy confirmation of a positive finding is required. *Lymphangiography* has also proved inadequate because of poor visualization of obturator–hypogastric nodes, which are the only site of nodal disease in up to one third of patients. Pelvic lymphadenectomy is the only definitive means of establishing nodal disease, but its morbidity is substantial. It is typically performed when radical prostatectomy is being considered for cure.

Staging Categories and Prognosis. A typical A, B, C, and D staging system is used, based on TMN categories. In *stage A*, palpable evidence of tumor is absent. Disease at this stage consists of malignancy found incidentally during prostatectomy for treatment of benign prostatic hyperplasia. *Stage A1* represents disease with a microscopic focus of well-differentiated malignant cells occupying less than 5% of tissue examined. Risk for progression is low (12% to 18%), with little effect on survival of older men. *Stage A2* denotes multiple foci or more poorly differentiated disease, with a markedly increased risk for mortality if the tumor is left untreated. Pathologically, as many as 25% of these patients already have lymph node metastases.

In *stage B*, a palpable prostatic nodule is noted on rectal examination. If the lesion is less than 1.5 cm in diameter and confined to one lobe, it is designated *stage B1*. Clinical B1 disease usually proves to be confined to the gland and has a very good prognosis with treatment. If the palpable lesion is larger than 1.5 cm or extends beyond one lobe, it is considered *stage B2*. Patients with clinical stage B2 have a 15% to 45% chance of having occult metastases to lymph nodes at the time of presentation. Consequently, their prognosis is less favorable.

In clinical *stage C*, rectal examination reveals local extension beyond the prostate to the pelvic wall, seminal vesicles, or bladder neck. In C1 disease, tumor is not fixed to the pelvic wall; in C2 disease, it is. Bone scan findings are normal, suggesting localized disease, but 40% to 80% of patients at this clinical stage have lymph node metastases. Thus, many people with clinical stage C disease already have metastases and a poor prognosis.

Stage D designates metastatic disease. *D1* denotes spread to pelvic lymph nodes. *D2* indicates distant metastasis, usually to bone. Palliation is the most that can be expected.

Histologic Grading

Histologic grading helps to overcome some of the prognostic shortcomings of clinical staging. Adenocarcinomas are scored according to the *Gleason system* on a *scale of 2 to 10*. The more disrupted and undifferentiated the normal glandular architecture, the higher the grade of tumor and the poorer the prognosis.

Retrospective cohort studies indicate that men who have a Gleason score in the *range of 2 to 4* rarely die of prostate cancer in the ensuing 15 years regardless of age at diagnosis. For men with a Gleason score in the *range of 8 to 10*, the prognosis is much worse, with 15-year case fatality rates of 80% or more except for the oldest men, who face a higher risk for death from other causes because of their age. Cancers with a Gleason score of 5 confer a prognosis similar to that for cancers with a Gleason score of 2 to 4. Gleason 7 scores are similar to Gleason 8 to 10. The prognosis for men with a Gleason 6 score is intermediate.

Principles of Management

For lack of a better method, the selection of a treatment modality is determined largely by clinical stage, with some adjustment according to histologic grade (especially in stage A disease).

Stage A1. Elderly patients with stage A1 disease and low-grade histology *need not be treated* because survival is unaffected by the disease. Such patients do require regular follow-up that includes monitoring the PSA, checking the prostate, and inquiring about symptoms. Patients with 10 or more years of life expectancy have a definite risk for disease progression and should undergo curative therapy (see below).

Stages A2 and B. These patients are candidates for curative therapy, either with radical prostatectomy or radiation. The 10-year disease-specific survival rates for these patients are similar for both treatment modalities and approach 90%. *External beam radiation* is a relatively low-morbidity procedure and the radiation therapy procedure of choice. It rarely causes incontinence, and potency is preserved in well over 50% of patients. Proper technique spares permanent rectal injury, although temporary diarrhea, tenesmus, and rectal bleeding may occur. The problem of *residual tumor* after radiation therapy remains unresolved. PSA often remains detectable, and biopsy sometimes reveals residual tumor. Its importance and the need for further treatment are subjects of ongoing study. The frequency of the problem is estimated to be as high as 35% in patients treated by radiation therapy and is an argument against the use of radiation, especially in younger persons who have many years of life expectancy. The use of ultrasonographically guided interstitial implant therapy, or *brachytherapy*, has received a great deal of attention, but evidence to date is insufficient for valid comparisons to be made with external beam radiation. Although the approach has real appeal for men who want to avoid the complications of other treatment options, all men considering brachytherapy should understand the limited evidence for this approach, especially men at intermediate or high risk.

Radical prostatectomy used to cause permanent impotence in almost all patients and was shunned by many for that reason. Advances in surgical technique have made the preservation of erectile function possible, but so-called *nerve-sparing* procedures are not always possible and not always successful when they are possible. When impotence does occur, the vascular apparatus and capacity for erection via injection therapy or sildenafil may remain intact (see [Chapter 132](#)). Although postoperative incontinence occurs in most patients, it clears by 5 weeks in more than 50%. It remains a long-term problem in approximately 30%. Bilateral pelvic lymphadenectomy is usually performed before removal of the prostate. The frozen-section findings determine whether proceeding with curative surgery is appropriate. Node dissection and prostatectomy increase the risk for thrombophlebitis and lymphocele. Postoperatively, PSA becomes undetectable when all tumor is removed. Factors favorable to radical prostatectomy are a small stage B lesion.

Stage C. Treatment remains unsatisfactory, with the optimal approach yet to be defined. Radiation is useful for local control of tumor but fails to sterilize pelvic nodes, which are highly likely to be involved by tumor. Surgery fails for similar reasons. *Antiandrogen therapy* (see below) may represent the most effective approach. Studies are in progress.

Stage D. The mainstay of treatment for symptomatic metastatic disease is hormonal manipulation. Prostate cancers contain both hormone-dependent and hormone-sensitive cells and hormone-independent cells. Hormone-dependent cells die a programmed death in the absence of testosterone. Hormone-sensitive cells stop dividing, but hormone-independent cells continue to grow. As a result, although prostate cancer can be halted by antiandrogen therapy, such treatment does not effect a permanent cure.

Orchiectomy. Castration is the time-honored hormonal manipulation. Bilateral removal of the testes can be performed at low cost on an outpatient basis. This reduces by 95% the total body production of androgen. A small amount of adrenal androgen synthesis persists. Psychologically, orchiectomy is difficult for many patients, including the elderly. Prostheses can be placed to lessen the psychological impact.

Luteinizing Hormone-releasing Hormone Agonists. Many patients want a biochemical alternative to castration. Synthetic peptides that act as *luteinizing hormone-releasing hormone* (LH-RH) *agonists* have been developed. Leuprolide was the first to be commercially available, packaged as a 7-mg depot preparation given IM once a month. These agents prevent the pulsatile release of luteinizing hormone necessary for testosterone secretion and effect castration levels of testicular androgens after causing an initial stimulative effect. The LH-RH agonists are convenient to use, effective, and well tolerated, but they are very expensive, costing several thousand dollars per year. Hot flashes are the main side effect. Because of the initial stimulative effect, this therapy should be given in conjunction with an antiandrogen at the outset. Some studies suggest that combination use with an antiandrogen improves survival (see below).

Estrogen Therapy. The estrogen *diethylstilbestrol* has been used for decades to achieve a "chemical castration." It inhibits LH secretion and competitively blocks circulating androgens. Doses of 3 mg daily halt testosterone production but are associated with an increased risk for thromboembolic disease. The thromboembolic risk is reduced with lower doses (e.g., 1 mg daily) and aspirin therapy, but lower doses do not suppress testosterone secretion as well. Gynecomastia is another side effect, which can be prevented by prophylactic low-dose irradiation of breast tissue. The effect is comparable to that of orchiectomy in inducing tumor regression. The combination of orchiectomy plus estrogen is no better than each used alone. Moreover, patients failing to respond to orchiectomy are unlikely to benefit from estrogen.

Antiandrogens. These agents block the effects of testosterone at the receptor level, which makes them useful for countering adrenal androgen secretion and the surge that accompanies early LH-RH agonist therapy. They may be steroidal (e.g., megestrol acetate) or nonsteroidal (e.g., *flutamide, bicalutamide*). These drugs cannot be used as monotherapy because they induce an increase in LH release that eventually stimulates sufficient testosterone secretion to overcome their blocking effect. Side effects include gynecomastia and diarrhea; a chemical hepatitis sometimes develops. Although they do not induce a hypercoagulable state or gynecomastia, they do cause impotence.

Combination Therapy. Although monotherapy with a hormonally active agent appears to provide some symptomatic relief (tumor shrinks, bony pain lessens), there is little evidence that it prolongs life in patients with metastatic disease. Consequently, such therapy is reserved for the onset of symptoms. About 10 years ago, evidence of a survival advantage emerged with the use of combination programs that provide *total blockade* of both testicular and adrenal sources of androgen. Total androgen blockade is a conceptually attractive option for the treatment of a testosterone-responsive tumor like prostate cancer. The most widely studied is the combination of *leuprolide plus flutamide*. A significant benefit (2-year increase in survival) was observed in patients with asymptomatic bony metastasis and excellent functional status. Such findings suggest that total androgen blockade be considered early in patients with metastatic disease. The cost could be lowered by substituting orchiectomy for LH-RH agonist therapy. Combination therapy is little better than monotherapy in patients with advanced, symptomatic, metastatic disease. It is best reserved for nonpalliative use.

New evidence emerging from the group that initially showed a survival benefit with long-term combination therapy now challenges that finding, raising doubt about the validity of the initial findings and the need for indefinite antiandrogen therapy in persons subjected to castration. The addition of long-term flutamide in persons treated with castration did not confer an additional survival advantage. However, data are available only for patients undergoing surgical castration; whether the findings also pertain to "biochemical castration" with an LH-RH agonist remains to be determined.

Secondary Hormonal Therapy. When initial hormonal monotherapy fails, flutamide is sometimes considered. Responses average 6 months and occur in only about 20% of patients. Hydrocortisone, aminoglutethimide, and ketoconazole have all been used to suppress adrenal androgen production. Under investigation are the *5-a-reductase inhibitors* (e.g., finasteride), which block the peripheral conversion of testosterone to its more active metabolite dihydroxytestosterone.

Much can be done to make the patient with advanced disease comfortable. In addition to the palliative measures mentioned above, the use of adequate analgesia

Radiation and Chemotherapy. External beam radiation is an effective means of palliation for patients with bone pain. It can prevent fracture and is used in cases of impending spinal cord compression (see Chapter 92). Chemotherapy has been disappointing,with no agent altering survival. Response rates are somewhat less than 20%.

Monitoring Therapy. The serum *PSA* determination is the best means of monitoring response to therapy. The 48-hour half-life of PSA allows it to reflect changes in tumor activity and mass quickly. The serum concentration directly correlates with tumor burden. Although prostatic procedures may transiently elevate the PSA level, it quickly returns to baseline so that interpretation is usually unaffected by recent examinations or procedures.

Although the *bone scan* is sensitive for detection of bony involvement, its findings are not specific. Areas of increased uptake may reflect repair as much as damage. Thus, the test may provide confusing information when used to monitor response to therapy. It is best reserved for the initial evaluation or when bone pain of unclear significance arises.

For the asymptomatic patient not currently receiving therapy, regular inquiry into the development of *symptoms* has proved an economical yet effective means of monitoring. The routine repetition of blood tests and radiographic studies can become expensive and should be considered only when the result will substantively alter clinical decision making.

Patient Education and Indications for Referral and Admission

The primary physician plays a central role in helping the patient choose among a variety of options that he is likely to face. For the patient with curable disease, the choice will be between radiation and radical prostatectomy. Risks of impotence, incontinence, and recurrence need to be reviewed. For the person with early metastatic disease, the issue of initiating total androgen blockade and the decision of whether to undergo orchiectomy or commit to a program of leuprolide therapy will need to be faced. Patients are surprised and comforted to realize that they will not become feminized after removal of the testes.

These difficult decisions require consultative help, but the patient will often return to the primary physician for discussion, which requires one to keep abreast of the options in the treatment of prostate cancer. Because the patient knows the primary physician best, the patient is likely to ask his primary care doctor to select the option that would best meet his needs. Phone calls to one's consultants may be helpful in this situation.

Referral to the urologist is indicated at the time a prostate cancer is first suspected. Careful planning of the evaluation is necessary, and a tissue sample will be needed (see Chapter 126). Although most staging of the tumor can be performed by the primary physician, the limitations of imaging techniques must be kept in mind. When curable disease is suspected, referrals to the urologist and radiation oncologist are indicated to help in choosing the optimal approach. When metastatic disease is encountered, an oncology consultation may facilitate design of antiandrogen therapy. Urgent hospital admission is indicated if spinal cord compression is deemed imminent (see Chapter 92).

TESTICULAR CANCER

Testicular cancer is the most common malignancy in men between the ages of 15 and 35 and is a major cause of death in this age group. Its seriousness and curability, both in early stages and, more recently, in advanced stages, make it an important disease for the primary physician. One needs to encourage self-examination, screen young men during routine checkups (see Chapter 131), and help guide the patient with advanced disease through his illness.

Pathophysiology, Clinical Presentation, and Course

Known predisposing factors are testicular atrophy (secondary to an undescended testicle) and Klinefelter's syndrome. Suspected risk factors include natural exposure to intrapartum estrogens, exposure to insecticides, and prior history of a testicular tumor. Trauma is not a known precipitant.

Almost all testicular cancers are germ cell tumors. *Seminomas* account for 40% to 50%. Most are confined to the testicle at the time of presentation. The remainder are termed *nonseminomatous germ cell tumors* (NSGCTs). These include *teratomas, choriocarcinomas, embryonal cell carcinomas*, and *endodermal sinus tumors*. Many are of mixed cell type. Their metastases may be less differentiated than the primary.

Both groups commonly present as solid, painless, nontransilluminating testicular masses in young men (see Chapter 131). Some patients describe "heaviness" in the scrotum. Pain is less common. These tumors grow rapidly and spread by the lymphatics and blood. Local extension to the epididymis occurs in 10%. Occasionally, the tumor is occult at the primary site, with metastases already established. If chorionic gonadotropin is secreted (as may occur with several of the NSGCTs), gynecomastia may be an initial complaint. Disease already established in the lung may present with cough or hemoptysis.

Diagnosis and Staging

Any solid, nontransilluminating, painless testicular mass in a young man should be presumed to represent a primary testicular cancer until proven otherwise. *Testicular ultrasonography* should be performed to obtain a more definitive determination of the location of the lesion. If testicular, prompt urologic consultation is required for consideration of surgical removal of the involved testicle. Testicles with suspect lesions are subjected to *orchiectomy* through an inguinal canal approach to minimize the risk for seeding the scrotum, as might occur with a transscrotal operative procedure. If the lesion is extratesticular, urologic consultation is less urgent but still advisable. Surgical removal is less likely.

Staging Procedures and Surveillance. Staging begins with *orchiectomy* findings and proceeds to *chest radiography* and *chest CT* for metastatic disease of the chest, and to *abdominal CT* for assessment of retroperitoneal lymph nodes. Circulating *tumor markers* also provide a means to detect occult disease. The b-*subunit of human chorionic gonadotropin* (HCG) is always elevated in choriocarcinoma and in about half of the other NSGCTs (it is rarely elevated in pure seminoma, but a number of seminomatous cases have mixed disease and elevated HCG). a-*Fetoprotein* is produced by about 80% of patients with embryonal cell cancer. Both markers also provide an excellent means of monitoring response to therapy (see below). *Lactic dehydrogenase* is sometimes elevated in germ cell tumors.

False-positive rates are low for abdominal CT, but false-negative rates are as high as 30%, with the poorest results inthin persons. Previously, if no evidence of metastatic disease was found by staging studies, then an ipsilateral complete lymphadenectomy and a contralateral partial *lymphadenectomy* to the level of the aortic bifurcation were considered mandatory, especially for NSGCT, because of the high incidence of microscopic nodal involvement. However, lymphadenectomy is now being used less often because advances in chemotherapy have made it possible to achieve high rates of cure even if the diagnosis of metastasis is delayed. Moreover, lymph node dissection involves extensive surgery, with an attendant risk for ejaculatory failure (a risk that has been reduced by improvements in surgical technique). Finally, retroperitoneal lymph node dissection is unnecessary if the primary cancer is a seminoma and a course of radiation therapy to the nodes (which is highly curative) is being planned. *Lymphangiography* is sometimes useful in patients with seminomatous tumors whose CT results are negative. Abnormal paraaortic nodes are detected in 13% to 22%.

The decision of whether to proceed with nodal dissection or opt for close surveillance with measurement of tumor markers and repeated CT remains a judgment call. Factors associated with an increased risk for relapse and thus favoring node dissection include a high percentage of embryonal cell carcinoma in the primary tumor, a marked degree of local disease, and the presence of vascular or lymphatic invasion. If surveillance is elected after orchiectomy, it must be done rigorously, with monthly monitoring of tumor markers, repeat CT scanning every 2 to 3 months, and periodic physical examination. Noninvasive staging may be followed by chemotherapy, with secondary surgical exploration to evaluate the retroperitoneum after treatment.

Clinical Stages. A host of staging systems are used, with one set for seminomatous disease and another for nonseminomatous disease. Common designations are stage I or stage A for disease confined to the testis, stage II or stage B for spread to regional nodes, and stage III or stage C for spread beyond retroperitoneal nodes. Within each stage are subcategories denoting the degree of tumor burden.

Management

Treatment decisions are based on stage, histology, and levels of tumor markers.

Seminomatous Tumors. *Stage I* disease is treated with inguinal *orchiectomy*, which is followed by adjuvant retroperitoneal node *irradiation* in most centers, although surveillance is now considered an option by some. The cure rate is close to 100%. Patients who relapse are candidates for combination chemotherapy, which is extremely effective (see below). Patients with *stage IIA* disease are also treated with retroperitoneal radiation, but they no longer undergo prophylactic mediastinal irradiation because of its associated morbidity and the success of chemotherapy in treating relapses. Cure rates are still close to 100% at this stage. Patients with stage *IIE* and stage *III* disease are treated with *cisplatin-based chemotherapy*. Cure rates exceed 90%.

Nonseminomatous Tumors. *Stages I and IIA* NSGCT disease is treated with *surgery only*. Surgical cure rates average 95% when lymph node dissection shows no regional disease. Even when retroperitoneal disease is detected, lymphadenectomy is likely to suffice for treatment as long as nodes are less than 3 cm in diameter. Patients with stage IIB disease have a high probability of relapse and thus are candidates for chemotherapy, as are patients with stage III disease.

Cisplatin-based Chemotherapy. Multiple-agent chemotherapy based on cisplatin represented an important breakthrough in treatment of testicular cancer. Even patients with distant metastatic disease now have a high probability of cure. The need for maintenance therapy has been eliminated. Even the severe nausea and vomiting associated with the use of cisplatin have become much less problematic with the advent of *ondansetron*, a serotonin receptor-blocking agent capable of reducing cisplatin-induced emesis. Cisplatin-induced renal toxicity is preventable with good hydration.

Monitoring. Close monitoring of the response to therapy is essential. *HCG* and a-*fetoprotein* levels are used to detect subclinical relapse and failure to respond to treatment. An elevated serum marker level failing to decline with therapy suggests resistance to therapy. Its rise during follow-up indicates relapse. Patients having isolated elevations in tumor markers as the sole manifestation of relapse have nearly a 100% chance of cure when treated promptly with chemotherapy. In patients with advanced disease, a decline in HCG after initial chemotherapy is an excellent predictor of response to treatment. *Periodic physical examination* to check for the development of palpable adenopathy or an abdominal mass and chest and abdominal CT are additional components of the monitoring and surveillance processes (see above).

Patient Education

Although most of the details of care are related by the oncologist, the primary physician is often consulted by the patient and needs to be familiar with some of the basic questions regarding prognosis, treatment options, and side effects. Patients are greatly relieved to know the favorable prognosis for testicular cancer, especially those with metastatic disease. Nonetheless, treatment is not without its adverse effects. Lymph node exploration is an extensive procedure and thus not without considerable morbidity. Retrograde ejaculation and subsequent infertility are still associated risks, although they have been reduced to about 12%. The ability to achieve an erection is only rarely compromised. Radiation therapy is associated with a risk for decreased spermatogenesis in the remaining normal testicle, although shielding methods have reduced the radiation exposure and, consequently, the period of infertility associated with low sperm counts. The fear of chemotherapy can be lessened by reassurance that there are effective means of minimizing its adverse effects. If the risk of infertility is greater than 5%, sperm banking should be considered before treatment. A pretreatment sperm count may be helpful in decision making.

CARCINOMA OF THE BLADDER

Bladder cancer strikes about 45,000 patients annually in the United States, causing about 10,000 deaths per year. Prevalence is greatest among persons ages 60 to 70. Risk factors include smoking, exposure to naphthalene or aromatic amine antioxidants, use of cyclophosphamide, and schistosomiasis.

Clinical Presentation and Course

Tumors of the bladder are usually detected when gross or microscopic hematuria is noted. In most instances, the hematuria is otherwise asymptomatic, but, in elderly men especially, dysuria, urgency, frequency, or voiding of small volumes of uninfected urine may be noted. Such symptoms of vesicle irritation suggest carcinoma in situ. Because urothelial tissue extends up into the ureters and renal pelvis and down into the proximal urethra, cancer of the urothelium can present in any of these areas.

More than 90% of bladder cancers are transitional cell carcinomas; squamous cell tumors account for most of the others. A few are undifferentiated. Multiple tumors may arise simultaneously. About 80% are superficial and remain so; the remainder are invasive from the outset. Depth of invasion is the most important predictor of survival, although histologic grade is also a factor. Five-year survival with appropriate treatment is 95% for patients with carcinoma in situ, 60% for disease that invades the subepithelial connective tissue, 35% for superficial muscle invasion, 15% for deep-muscle invasion, and nil for extension to the pelvis. Spread to the lymph nodes is common in patients with deep-muscle invasion.

Diagnosis and Staging

Cystoscopy and *biopsy* of multiple sites are required for diagnosis. Urine cytology is not sensitive enough to obviate the need for invasive study, although a positive result may provide the only means of detecting an otherwise occult carcinoma in situ. *IV pyelography* is performed to detect evidence of an infiltrated bladder wall, a filling defect, or a bladder diverticulum.

Staging is performed by *cystoscopy with biopsy and bimanual rectal–abdominal examination* under anesthesia to determine the depth of tumor penetration and infiltration into the bladder wall. Although the tumors of almost half of patients with infiltration into deep muscle have spread to the lymph nodes (which carries a poor prognosis), such spread is hard to detect without resorting to pelvic lymphadenectomy. Early spread involves the hypogastric and obturator nodes. *Abdominal CT* is obtained to evaluate them. Chest radiography, determination of the alkaline phosphatase level, and a bone scan are commonly ordered to check for distant metastases.

The *prognosis* has also been linked to the presence of blood group antigens on the surface of bladder cancer cells. Patients with tumors that elaborate A, B, or H antigens have a better prognosis than those with tumors that do not. A separate T antigen correlates with invasiveness.

Treatment

Noninvasive stages of disease are often curable with local measures. *Excision* at the time of cystoscopy in conjunction with fulguration represents a most effective form of therapy for early disease. In the setting of multiple tumors, a cytotoxic agent can be instilled. *Thiotepa* has been widely used. *Bacille Calmette-Guérin* (BCG) has emerged as a superior treatment for carcinoma in situ in patients with superficial transitional cell disease. It decreases the risk for progression to invasive disease and improves survival in comparison with resection alone. Irradiation of the bladder can effect tumor regression, but the recurrence rate is high. Rapid recurrence of multiple lesions is an indication for combined *cystectomy and prostatectomy*. Diffuse carcinoma in situ with persistently positive washings despite treatment has a poor prognosis and may necessitate early cystectomy.

Infiltrative disease carries a poor prognosis because of the substantial likelihood of lymph node metastases (see above). Options include *partial bladder resection, cystectomy* with urinary diversion via an *ileal loop*, radical radiation, and combination therapy. Although partial cystectomy has the attraction of preserving some of the bladder, only a few patients are suitable candidates. *Combination therapy* consisting of *preoperative irradiation plus cystectomy* is often used. Complications include a surgical mortality rate of 5%, postoperative problems necessitating a prolonged hospitalization in about 25%, and the possibility of a need for revision of the ileal loop. Hyperchloremic metabolic acidosis sometimes occurs in these patients.

Those with *deeply invasive disease* are not candidates for surgery. External beam *megavoltage irradiation* provides a reasonable chance (50%) for local control and a small chance (no more than 25%) for cure. The rate of bowel and bladder complications is 10% to 15%. About half of these patients maintain sexual potency. In patients with *distant metastases, cisplatin* in conjunction with *cyclophosphamide* and *doxorubicin* has achieved substantial, but not lasting, regression. Intravesicle cisplatin is associated with anaphylaxis.

Because many patients with bladder cancer present with advanced disease, the focus of treatment is often palliative. If not previously used, radiation can provide

relief from pelvic and bone pain. The onset of ureteral obstruction and subsequent uremia presents a relatively comfortable means of dying to patients with advanced disease; relief of the obstruction is rarely indicated.

Monitoring. Monitoring patients treated for early disease is essential. Surveillance cystoscopy and washings are conducted every 3 months during the first year and then at less frequent intervals. Monoclonal antibody staining of washings has enhanced the detection of tumor cells, as has the use of hematoporphyrin derivatives, which stain malignant urothelium and make them more visible at cystoscopy.

Patient Education

The best treatment for bladder cancer is prevention. Risk factors such as smoking and occupational exposure should be addressed. Patients who are to undergo cystectomy need prior counseling about management of the ileal loop. Most adjust reasonably well to managing the stoma and bag. Stoma groups and instruction by a stoma nurse can be helpful.

RENAL CELL CARCINOMA (HYPERNEPHROMA)

Renal cancer is uncommon, accounting for fewer than 2% of all cancers. However, it is a potentially curable disease if detected before it penetrates through the capsule. There is no systemic treatment.

Clinical Presentation and Course

The disease is notorious for its protean presentations. *Painless hematuria* is the most common, found in 50% to 75% of cases. Aching flank pain and a palpable mass are other classic, although far less frequent, manifestations and represent advanced disease. Unexplained weight loss, nausea and vomiting, fever of unknown origin, and a markedly elevated erythrocyte sedimentation rate (ESR) are sometimes systemic clues of early disease, occurring in up to a third of patients. Paraneoplastic syndromes are associated with this disease, including polycythemia and hypercalcemia secondary to production of a parathyroid hormone–like substance.

The natural history of the tumor is unique, with occasional spontaneous regression and long intervals before the appearance of metastases. Nevertheless, in a major proportion of patients with hypernephroma, metastases are found at presentation or develop later.

Diagnosis

A high index of suspicion is needed to make an early diagnosis of this disease. Hematuria in the setting of a normochromic, normocytic anemia and a markedly elevated ESR are suggestive, as is the triad of fever, elevated ESR, and increased a $_1$-globulin.

If suspicion remains high, radiologic evaluation should begin with *IV pyelography*. If a mass is found on IV pyelography, it must be determined whether it is cystic (and therefore most likely benign) or solid. Renal *ultrasonography* plus *CT* or *MRI* helps to determine the local extent of disease, including perinephric involvement, renal vein obstruction, and spread to the retroperitoneal nodes. MRI has the advantage of detecting vessel invasion and caval thrombosis. Needle aspiration biopsy can be performed under imaging guidance if cytologic confirmation is desired.

Management

Tumor confined to the kidney is curable. When it extends beyond Gerota's capsule, the prognosis is poor. Some authorities suggest that removal of the primary tumor may trigger the regression of metastases, although the only evidence derives from case reports. Large series have failed to demonstrate such an effect or an improvement in survival. Most argue that the primary tumor in patients with metastatic disease should be removed only for control of local pain or bleeding. Metastases to lung, bone, and brain are treated with chemotherapy or irradiation.

Effective chemotherapeutic regimens are lacking for this disease. Hormonal therapies (progesterone and androgens) have produced responses in some patients, but without prolonging survival. A minority of patients have partial or complete responses to interferon, interleukin-2, or both, but the response is rarely durable. Studies are ongoing.

PART 10 MUSCULOSKELETAL PROBLEMS

CHAPTER 144 SCREENING FOR OSTEOPOROSIS

ALLAN H. GOROLL

INTRODUCTION

One of the major concerns of postmenopausal women is the development of osteoporosis. Osteoporotic fractures in aging women represent a major health problem in industrialized nations. In the United States, approximately 150,000 hip fractures occur annually in women over the age of 65, with 15% to 25% of these women experiencing excess mortality or needing long-term nursing home care. Current expenditures for osteoporotic fractures and their consequences are well in excess of $15 billion annually and rising with the aging of the population. The pathophysiologic mechanisms for postmenopausal osteoporosis are imperfectly understood, but the means to ensure maximal skeletal growth and strength, prevent loss of bone mass, and noninvasively evaluate bone mass are now available (see Chapter 164).

The frequency and clinical significance of osteoporosis, combined with the capabilities to detect and treat it effectively so as to prevent fractures, argue strongly for screening. Many now recommend that osteoporosis screening become an essential part of the health maintenance program for women; however, data from prospective, long-term, randomized studies identifying those who are best served by screening are yet to emerge, so that clinical judgment is necessary in selecting candidates for osteoporosis screening. Effectively advising the perimenopausal woman requires a knowledge of the epidemiology of osteoporosis, and of the risk factors, screening tests, and treatment modalities for this disease.

EPIDEMIOLOGY AND RISK FACTORS

Epidemiology. As the life expectancy of women reaches the mid-80s, osteoporosis takes on epidemic proportions, especially among Caucasian women in industrialized societies. In the United States, the prevalence of low bone density in older adults approaches 50%; a woman's risk for an osteoporotic fracture by age 80 is approximately 40% (several times greater than the risk for breast cancer). The risk for death after a hip fracture is nearly 25%. The disability and expense attributable to the consequences of osteoporosis are enormous and growing.

Risk Factors. The National Osteoporosis Risk Assessment Study examined risk factors of low bone mineral density (BMD) and the relationship of low BMD to fracture risk in a large population-based cohort of postmenopausal women (mean age 64 years). *Age* was the greatest risk factor. Women ages 70 to 74, 75 to 79, and older than 80 had a 9.5-fold, 14.3-fold, and 22.6-fold risk of osteoporosis, respectively. Other risk factors for osteoporosis included *body mass index* below the twenty-fifth percentile (<*23* kg/m^2), *maternal history of fracture,* and *personal history of fracture during adulthood.* Osteoporosis was associated with a fourfold increase in fracture rate (any site) at 1 year. After controlling for BMD, all of the above risk factors were independently associated with fracture risk. Other epidemiologic studies have found current *cigarette smoking* and nonuse of estrogen replacement therapy to be important predictors of risk. **Updated: 1/10/02**

Epidemiologic studies have identified major *risk factors*:

- Age
- Family history of osteoporosis in a first-degree relative
- Body mass index below the 25th percentile (<23 kg/m^2)
- History of fracture during adulthood
- Current cigarette smoking
- Nonuse of estrogen replacement therapy

In addition, a number of *contributing risk factors* have emerged. These include *lifelong inadequate intake of calcium, Caucasian race, inadequate physical activity, early menopause* (onset before the age of 45), and *excessive intake of alcohol.* All may predispose a woman to a lower bone mass and osteoporotic fractures with aging. Women in whom osteoporosis does not develop may have a larger skeletal mass, which can be increased through *physical activity* and *calcium supplementation.* Estrogen use and African-American race are protective factors. *Mild to moderate alcohol consumption* appears to decrease the risk of osteoporosis (although it does not influence fracture risk). **Updated: 1/10/02**

Medical conditions that are *secondary causes* of osteoporosis include *Cushing's syndrome*, exogenous *glucocorticoid* administration, prolonged *heparin* therapy, *thyrotoxicosis* (including excessive replacement therapy), *hypogonadism, hyperprolactinemia, anorexia nervosa*, and *hyperparathyroidism*. However, these diseases account for only a small percentage of cases of osteoporosis.

NATURAL HISTORY AND EFFECTIVENESS OF THERAPY

Natural History. The resorption and formation of bone are a continuous process throughout life. Under physiologic circumstances, the rates of these processes are equal and coupled. Skeletal mass is usually maximal by age 35 and declines in women after age 40 and in men after age 50, when the rate of new bone formation no longer equals the rate of bone resorption. The rate of decline in skeletal mass is most rapid in women within 2 years of menopause and averages 2% to 4% a year during the first 7 years after menopause. Bone mineral content may decline by 25% to 33% during this period. Afterward, loss continues, but at a slower rate (1% to 2% a year). The areas of greatest loss include the femoral neck and lumbar vertebrae, sites rich in *trabecular bone* and subject to future fracture. *Cortical bone*, comprising 80% of skeletal bone, is lost less rapidly.

The progressive decline in skeletal mass becomes clinically manifest when fractures are sustained spontaneously or after minimal trauma. A loss of height and developing kyphosis generally indicates vertebral compression fracture. Fractures most commonly occur in the sacral and lumbar vertebrae, hip, humerus, and wrist. The clinical course and frequency of fractures in individual patients are hard to predict.

Effectiveness of Therapy. (See also Chapter 164.) *Estrogen* replacement can prevent bone loss and even lead to skeletal accretion. Observational studies have consistently noted a 35% to 50% reduction in hip, wrist, and vertebral fractures in women who have used estrogen for at least 5 years after menopause. After 10 years of estrogen use, the risk for fracture decreases 75%. However, if estrogen is discontinued, bone loss rapidly ensues, and it is difficult to reverse the significant bone loss that occurs in the first few years of menopause. Beyond age 75, the effect of as many as 7 to 10 years of estrogen therapy started at the time of menopause is barely appreciable, which indicates that very prolonged estrogen therapy or restarting it in later years may be necessary. The bisphosphonate *alendronate* prevents bone loss and increases bone density at least as well as estrogen replacement. Fracture risk in osteoporotic patients is reduced by up to 50%. The selective estrogen receptor modulator *raloxifene* also halts bone resorption and modestly increases bone mineral density. *Calcium supplementation* with *vitamin D* helps preserve cortical bone mass but does not prevent bone loss to the degree that estrogen therapy does. The combination of calcium supplementation and *weight-bearing exercise* is more effective at stemming bone loss.

Utility of Bone Densitometry for Osteoporosis Screening. The chances for the development of significant osteoporosis and subsequent fracture cannot be adequately predicted by a review of clinical and epidemiologic risk factors. Measurement of bone mineral density is also required. Bone mineral density strongly correlates with the risk for osteoporotic fracture. The test of choice to measure bone mineral density is *dual energy x-ray absorptiometry* (DEXA), which provides rapid,

accurate screening with minimal radiation exposure. Because the bone mineral density can vary at different sites of the body, dual energy x-ray absorptiometry should optimally include separate determinations at the hip and spine. The bone density at the wrist is also predictive of fracture, providing a reasonable approximation of body bone mineral density; the study is less expensive and of interest as an economical alternative for mass screening. Nonetheless, direct assessment of bone mineral density at the hip and spine maximizes test sensitivity and is the most accurate assessment of osteoporotic risk.

Bone mineral density measurement is expressed as the number of standard deviations from the mean for normal young adults of the same sex (*T-score*) and as the number of standard deviations from the mean for persons of the same sex and age (*Z-score*). The World Health Organization diagnostic criterion for *osteoporosis* is a *T-score of less than -2.5*. *Osteopenia* is defined as a *T-score between -1.0 and -2.5*. A *Z-score of less than -1.5* suggests a *secondary cause* of osteoporosis. The risk for osteoporotic fracture increases twofold to fourfold for every standard deviation of reduction in bone mineral density.

Cost-effectiveness analysis suggests that prior to age 65, bone mineral density screening should be reserved for persons with one or more of the major risk factors for osteoporosis. In those with no risk factors at this age, the bone mineral density measurement is discretionary. After age 65, bone mineral density screening appears cost-effective for all women. Bone mineral density screening is also appropriate at any age for patients with an underlying medical condition that might cause osteoporosis (see above). Although many decision-analysis and cost-effectiveness studies of screening for osteoporosis have been performed, no data from long-term, prospective, randomized trials are yet available to confirm the value of screening. Clinical judgment and individualized decision making continue to be essential. If bone density measurement will affect clinical decision making, then screening makes sense for the individual patient. If it will not, then another compelling reason should exist.

CONCLUSIONS AND RECOMMENDATIONS

- Osteoporosis is a common affliction of postmenopausal women that results in important morbidity. Irreversible bone loss is most rapid in the early phases of menopause but continues indefinitely.
- Effective means to prevent postmenopausal bone loss are available; therapy with estrogen replacement, bisphosphonates, and possibly selective estrogen receptor modulators can halt bone loss and even stimulate modest amounts of remineralization.
- Clinical and epidemiologic parameters are limited in predicting low bone mass.
- Advances in the measurement of bone density have improved test accuracy and predictive value in the assessment of risk for osteoporotic fracture.
- Dual-energy x-ray absorptiometry involving bone mineral density measurement of the femoral neck is the screening test of choice for determining risk of hip fracture and is equivalent to other peripheral measures for determining risk of fracture elsewhere.
- Criteria for optimal patient selection remain to be fully defined, but the best available data and cost-effectiveness studies suggest that biannual screening begin after age 65 in those with no risk factors and at age 60 in women with at least one major risk factor.
- Whether earlier initiation of screening is beneficial in those with multiple major risk factors (e.g., low body mass index, nonuse of hormone replacement therapy, increasing age, family history of osteoporosis in a first-degree relative, history of fracture during adulthood, current cigarette smoking) cannot be made at present due to limitations in available data. Clinical judgment and customization of the screening recommendations are recommended. **Updated: 11/26/02**
- Screening is not recommended when the results will have no effect on decision making (e.g., persons already taking medication for osteoporosis prevention, refusing it, or unable to take it).
- Definitive benefit from screening plus prophylactic therapy remains to be demonstrated by large-scale, randomized, controlled trials.

CHAPTER 145 EVALUATION OF ACUTE MONOARTICULAR ARTHRITIS

Acute monoarticular arthritis calls for a prompt diagnostic evaluation because of the possibility of bacterial infection, which can lead to rapid joint destruction and septic sequelae. In certain noninfectious forms of inflammation, notably crystal-induced arthropathy, quick diagnosis and treatment are also beneficial. Most patients present for care on an outpatient basis, so that the diagnosis of monoarticular arthritis is an important responsibility of the primary physician.

PATHOPHYSIOLOGY AND CLINICAL PRESENTATION

The principal mechanisms of monoarticular arthritis can be broadly categorized as inflammatory and noninflammatory, with the inflammatory mechanisms subdivided into infectious and noninfectious.

Inflammatory Disease

Septic Arthritis. The arthritis of sepsis derives predominantly from hematogenous seeding of the synovium. Occasionally, it is caused by direct extension from a site of trauma or by osteomyelitis.

Disseminated Gonorrhea. Among previously healthy, sexually active patients, disseminated gonorrhea is the most frequent cause of joint infection. Women account for two thirds of cases. Pregnancy and menstruation appear to the increase risk for dissemination, which occurs in about 1% to 3% of persons with gonorrhea (see Chapter 137). An initial bacteremic stage is characterized by fever, polyarthralgias, transient scattered tendinitis, minimal joint effusion, necrotic skin lesions, blood cultures positive for organisms, and sterile joint fluid. This phase of the illness may be followed in several days by a septic joint stage, with monoarticular or occasionally polyarticular pain, marked joint swelling, and effusion. During the septic joint stage, gonococci can be recovered from the joint in about 50% of patients.

Nongonococcal Septic Arthritis. More than 80% of cases are monoarticular, with gram-positive organisms, especially *Staphylococcus aureus*, predominating (60% of infectious cases, most of them methicillin-resistant). *Streptococcus* species account for about 18%. *Gram-negative Enterobacteriaceae* also cause septic arthritis, particularly in IV drug abusers, immunocompromised persons, and the chronically ill. Joint sepsis is more likely in patients with altered host defenses (diabetes,cirrhosis, immunodeficiency), previously damaged joints (rheumatoid arthritis), or prosthetic joints. Fever, chills, and joint inflammation are usually prominent, but the presentation may be devoid of systemic symptoms, especially if the patient is debilitated or immunosuppressed. A larger joint, such as a knee or hip, is most likely to be involved. Sternoclavicular joint infection is characteristic of IV drug abusers. Articular destruction can be rapid. Within 10 days of nongonococcal infection, radiographic evidence of cartilaginous and bony damage may appear. Joint injury from gonococcal arthritis is less precipitous, so that more time is available for treatment. Permanent damage is uncommon in patients who are treated.

Lyme Disease. An acute oligoarthritis can develop months after the initial infection in untreated persons, with about 60% experiencing the problem (see Chapter 160). Large joints are typically involved, especially the knees. Intermittent attacks of acute arthritis lasting weeks to months are sometimes seen, as is chronic erosive arthritis. Swelling may be more prominent than pain.

Mycobacterial Infection. HIV-infected patients are at increased risk for mycobacterial joint infection, as are persons who have had repeated glucocorticoid injections into a joint. Often, periarticular bony disease develops in addition to joint inflammation. A chronic picture remains more common than acute inflammation.

HIV Infection. An acute monoarticular or oligoarticular arthritis may be part of a syndrome accompanying the onset of HIV infection. The lower extremities are the usual site of involvement (see Chapter 13).

Noninfectious Inflammatory Disease. The underlying mechanism is usually crystal-induced inflammation, but occasionally one of the immunologically mediated diseases may present as monoarticular disease.

Acute Gout. Gout is a common cause of acute monoarticular arthritis. Sodium urate crystals in the synovium incite a brisk inflammatory response after they are ingested by polymorphonuclear leukocytes. The condition is found most commonly among middle-aged and older men. Onset is rapid, peaking within 12 to 24 hours. The metatarsophalangeal joint of the great toe is the classic site, but the midfoot, ankles, knees, wrists, and olecranon bursae are other important locations. Sodium urate crystals are found in the joint fluid. They are needlelike and negatively birefringent under the polarizing microscope. Although the likelihood of a gouty attack increases with serum uric acid levels, uric acid levels are not diagnostically helpful except if extremely high. Alcoholic binges or the new use of thiazide diuretics may precipitate gouty attacks. A mild fever may even be present. Rapid response to colchicine helps differentiate crystal-induced arthritis from infection (see Chapter 158).

Pseudogout. Pseudogout results when crystals of calcium pyrophosphate induce joint inflammation, and it resembles gout pathophysiologically, although clinical features differ. Knees and wrists are the sites most commonly affected. Under the polarizing microscope, weakly positively birefringent rhomboid forms of calcium pyrophosphate are revealed in the synovial fluid. Chondrocalcinosis is usually present on radiography. Pseudogout tends to occur in older patients and seems to be associated with hyperparathyroidism, hemochromatosis, and severe degenerative joint disease.

Immunologic Disease. Immunologically mediated conditions typically cause polyarthritis but may present initially as a monoarthritis. These include rheumatoid arthritis, Reiter's syndrome, ankylosing spondylitis, psoriatic arthritis, the arthritis of inflammatory bowel disease, and the arthritis of sarcoidosis (see Chapter 146).

Noninflammatory Disease

Acute traumatic causes include juxtaarticular ligament or meniscus *injury*, frank bone *fracture* extending through to the joint space, or minor trauma in patients with impaired coagulation that results in *hemarthrosis*. A variety of mechanical disorders, collectively referred to as "internal derangements" of the knee, may produce chronic recurrent pain and noninflammatory effusion. *Osteoarthritis*, characterized by the degeneration of articular cartilage with adjacent bony sclerosis and proliferation, often produces chronic, gradually increasing joint symptoms but may present as an acutely painful joint with a noninflammatory or mildly inflammatory effusion.

DIFFERENTIAL DIAGNOSIS

The most immediately important entities in the differential diagnosis of acute monoarthritis are infection, crystal-induced arthropathy, and trauma. The gonococcus is the leading infectious agent, followed in frequency by gram-positive organisms (staphylococci, streptococci) and in compromised hosts by gram-negative coliforms. Gout and pseudogout are the important crystal-induced arthropathies.

As noted earlier, several polyarticular diseases may initially present with one acutely inflamed joint or with symptoms that are most pronounced in a single joint. These monoarticular presentations of polyarticular disease are seen in rheumatoid arthritis, Reiter's syndrome, ankylosing spondylitis, psoriatic arthritis, the arthritis of inflammatory bowel disease, and sarcoidosis.

Despite the wide range of diagnostic possibilities, it should be appreciated that recent series of monoarthritis have revealed that the most prevalent diagnoses are osteoarthritis, septic arthritis, gout, and pseudogout.

WORKUP

The first objective is to establish whether the joint is infected. Although examination of the joint fluid is the single most important diagnostic test, history and physical examination may provide useful information regarding the likelihood of infection and also its source.

History

Onset, associated symptoms, location, risk factors, and concurrent illness are essential items to check. Abrupt onset in conjunction with fever and chills points to a septic cause, as does a history of skin lesions, vaginal or urethral discharge, exposure to gonorrhea, tick bites, diabetes, concurrent rheumatoid arthritis, joint prosthesis, immunosuppression, HIV infection, IV drug abuse, and previous trauma. Acute trauma increases the probability of periarticular injury, internal derangement, and hemarthrosis. Prior attacks are indicative of gout and pseudogout. Alcohol abuse predisposes to gout, trauma, and infection. Inflammation in the first metatarsophalangeal joint points to gout, especially in an elderly male patient; however, in patients with diabetes, extension of osteomyelitis into the joint must be ruled out. Associated back pain and stiffness raise the possibility of one of the spondyloarthropathies. Age can be a helpful clue. Pseudogout is most common in older patients. Disseminated gonococcal infection, Reiter's syndrome, and ankylosing spondylitis are diseases of young people.

Physical Examination

All joints are carefully examined to ascertain the location and nature of the problem. Signs of inflammation are sought (increased warmth, swelling, redness, effusion). One needs to differentiate inflammation of the joint space from a periarticular process such as tendinitis, bursitis, or cellulitis, which can be mistaken for it. Sometimes this distinction is impossible to make, but preservation of range of motion despite pain in the area reduces the likelihood of true joint involvement. The probability of a periarticular process is increased by the finding of localized tenderness that does not encompass the entire joint space. Although painful limitation of motion suggests articular disease, tendinitis and cellulitis can also cause discomfort with movement.

Once it is suspected that joint inflammation is present, the focus shifts quickly to differentiating between infectious and noninfectious causes. The patient's temperature should be taken. Almost all patients with septic arthritis are febrile. Low-grade fever may also be noted in gout and rheumatoid arthritis, but a high fever suggests infection. The integument is noted for necrotic lesions on the extremities (indicative of gonococcemia), the splinter hemorrhages of endocarditis, manifestations of HIV disease (see Chapter 13), needle tracks, tophi, rheumatoid nodules, pitting of the nails and other psoriatic manifestations, erythema nodosum (seen with sarcoidosis and inflammatory bowel disease), and the keratoderma blennorrhagicum and circinate balanitis of Reiter's syndrome. The eyes are examined for conjunctivitis and iritis, the fundi for signs of endocarditis, the mouth for mucosal ulceration, and the heart for murmurs. The genitalia need to be checked for signs of gonococcal urethritis and cervicitis (see Chapter 136 and Chapter 137). The spine should be examined carefully for restriction of motion and tenderness, indicative of spondylitis.

Laboratory Studies

No "standard" laboratory workup exists for acute monoarticular disease. Appropriate test selection should be based on the clinical presentation; only conditions suggested by the history and physical are worth investigating further. Running a standard battery of "arthritis tests" is both wasteful and potentially misleading. A few guidelines for initial test selection have been suggested by the American College of Rheumatology:

- If trauma or focal bone pain is present, then the first study should be radiography of the area.
- If an effusion or other signs of inflammation are noted, then the test of first choice is joint aspiration with fluid cell count and differential to confirm the presence of inflammation.
- If no effusion or trauma is present, then testing for trigger points and tender points (see Chapter 159) is indicated to assess for tendinitis and fibromyalgia, respectively.

Examination of Joint Fluid. Aspirating and examining the joint fluid is the single most important diagnostic procedure in the evaluation of acute monoarticular arthritis when evidence of inflammation is found. Taking note of the appearance of the joint fluid may be of help in determining the cause of arthropathy. A turbid appearance to the fluid points to inflammation; blood suggests trauma, coagulopathy, pseudogout, or neoplasm; a clear, straw-colored fluid is seen with degenerative disease and minor trauma. With sepsis, one may aspirate frank pus.

The fluid should be sent promptly for *cell count* and *differential* while it is fresh, and separate samples should be put aside briefly to be sent quickly for microscopic examination for *crystals* and *organisms* and for culture if the initial fluid examination shows evidence of inflammation. A white blood cell count above *2,000/mm^3* is suggestive of an *inflammatory process.* A predominance of *neutrophils* (>75%) confirms an inflammatory process. In gout and septic joints, the white blood cell count often exceeds 50,000/mm^3. Crystal examination under a polarizing lens provides the most rapid and sure method of diagnosing gout and pseudogout. However, urate crystals can often be seen under the microscope with normal light; the crystals of pseudogout are harder to identify in this manner. The *glucose* concentration is often measured; it may be suggestively low in infection and rheumatoid disease.

The fluid in a case of suspected infection should be sent for *Gram's stain* in addition to culture. Gram-positive bacteria are seen in about 80% of the cases in which they are the responsible agent. *Enterobacteriaceae* show up on Gram's stain less frequently. *Neisseria gonorrhoeae* is rarely seen. It is most important to culture the joint fluid immediately onto proper media (including Thayer-Martin plates for detection of gonococci). Smears of the joint fluid may show organisms in the absence of a culture positive for organisms if antibiotics have already been taken. A repeated tap of the joint will improve the diagnostic yield of Gram's stain and culture if results of the first arthrocentesis are negative.

Other Testing. When joint fluid cannot be obtained, the *complete blood cell count* and *erythrocyte sedimentation rate* are moderately helpful in distinguishing inflammatory from noninflammatory disease, but clearly the initial results of the synovial fluid examination are the most helpful to guide further testing. If inflammatory joint fluid is sterile, a workup for connective tissue disease (see Chapter 146), Lyme disease (see Chapter 160), and sarcoidosis (see Chapter 51) must be considered. Reviewing the history and physical examination findings for pertinent clinical clues can help determine to what extent testing for each of these conditions should be performed. If the fluid is frankly bloody, then determination of the prothrombin time, partial thromboplastin time, and platelet count is in order. The finding of characteristic crystals obviates the need for *serum uric acid* or *calcium* determinations; values are often normal despite an acute attack of crystal-induced disease. The serum uric acid level is useful only if markedly elevated. *Blood cultures* are indicated when sepsis is suspected. Culturing other possible foci of infection, such as skin lesions, urethral discharge, and the cervix, should be considered if infection is a possibility. Testing the joint fluid by polymerase chain reaction analysis for evidence of *Borrelia burgdorferi* can be diagnostic when Lyme disease is a real concern, but test availability may be limited.

Serologic Studies. A host of serologic studies are routinely offered for the assessment of arthritis. However, they are rarely diagnostic of the cause of an acute monoarticular arthritis, and false-positives are common in the setting of acute inflammation. Nonetheless, they can be helpful when used carefully. Testing for *HIV antibodies* is indicated when evidence of immune compromise or high-risk sexual behavior is found (see Chapter 13). Testing for *antinuclear antibodies* (ANA) and *rheumatoid factor* can help in the diagnosis of connective tissue disease, but false-positives are very common, especially in the elderly and persons with other inflammatory conditions (see Chapter 146), so they should be ordered only when clinical suspicion is substantial. *Lyme antibody titers* add little to the diagnosis except in cases with strongly supporting clinical and epidemiologic evidence for *Borrelia* infection (see Chapter 160).

Radiography. *Plain films* are most useful when evidence of trauma or focal bone pain is present. Plain films may also reveal fracture, neoplasm, osteomyelitis, and chondrocalcinosis. A diagnosis of osteoarthritis cannot be based solely on the presence of osteoarthritic changes, but their absence makes osteoarthritis unlikely. Radiography in patients with an acute inflammatory arthropathy often shows little more than soft-tissue swelling, especially in early phases of the disease. Films are of little use unless a baseline study for later comparison is desired. *Magnetic resonance imaging* is overused, but the technology is worth considering when traumatic internal knee derangement is suspected and confirmation is required (see Chapter 152). *Bone scan* or magnetic resonance imaging is indicated if osteomyelitis is suspected.

Despite optimal efforts, many cases of acute monoarthritis elude diagnosis. In one study, one third of cases were never satisfactorily diagnosed. Fortunately, however, the majority of these patients improved, or at least did not get worse. If infection, trauma, and, less importantly, crystal-induced arthritis are ruled out, the evaluation can be approached less hurriedly.

SYMPTOMATIC MANAGEMENT

Until a diagnosis is established, the patient may feel better resting, immobilizing the joint, and administering ice packs. Antiinflammatory agents should be postponed for at least 12 to 24 hours so that cultures can grow and arthrocentesis can be repeated if the first result is nondiagnostic. If pain is unbearable and a diagnosis is not yet established, an analgesic without antiinflammatory effects (e.g., acetaminophen or codeine) may be used. After a second negative result of arthrocentesis, it is reasonable to institute antiinflammatory therapy even in the absence of a specific diagnosis provided all cultures are negative for organisms and the patient is deemed to be at very low risk for infection. More definitive therapy of acute monoarticular arthritis must be based on the underlying cause (see Chapter 137, Chapter 156, Chapter 158, and Chapter 160).

INDICATIONS FOR REFERRAL AND ADMISSION

A patient with septic arthritis requires hospital admission, treatment with IV antibiotics, and consultation with an infectious disease specialist. When a case of acute monoarticular arthritis remains undiagnosed but the white blood cell count is high, infection is a possibility and an infectious disease specialist should be consulted to consider an empiric course of IV antibiotics. The more chronic case that eludes diagnosis may benefit from a rheumatologic consultation. Closed synovial biopsy or arthroscopy may be needed.

CHAPTER 146 EVALUATION OF POLYARTICULAR COMPLAINTS

Polyarticular complaints are among the most frequent in primary care practice and are often associated with considerable loss of function. Although osteoarthritis accounts for many of the more obvious cases (particularly in the elderly), the differential diagnosis can encompass a bewildering array of conditions, both articular and nonarticular, inflammatory and noninflammatory (Table 146.1). Careful attention to the history and physical examination findings helps chart a logical course to minimize diagnostic error and cost and maximize patient benefit. In most instances, the workup can proceed in deliberate, sequential fashion, but its pace is best matched to that of the underlying illness. The initial evaluation should focus on answering the following basic questions:

Table 146.1. Differential Diagnosis of Polyarticular Pain

1. Are the patient's symptoms truly articular or nonarticular?
2. Is the arthritis inflammatory or degenerative?
3. Is the problem local or systemic?
4. How sick is the patient?

PATHOPHYSIOLOGY AND CLINICAL PRESENTATION

Pathophysiology

Polyarthritis can result from a degenerative, relatively noninflammatory process or from an inflammatory one. *Noninflammatory* forms of arthritis are, in most cases, the result of breakdown in joint cartilage and secondary mechanical disruption of the joint. This can be a primary process, or it can be associated with an underlying disease, such as hemochromatosis. Signs of inflammation are minimal, although occasionally a small joint effusion may be present. Other mechanisms of noninflammatory joint injury include synovial infiltration (amyloidosis), periosteal proliferation at the ends of long bones (hypertrophic osteoarthropathy), and ischemic injury (sickle cell disease).

Inflammatory arthritis develops as a consequence of the aggregation of inflammatory cells and their products in the joint space and synovium. Infection, gout, pseudogout, and the immunologically mediated diseases—rheumatoid arthritis, lupus, the spondyloarthropathies—all produce an inflammatory type of arthritis, characterized by joint swelling, warmth, redness, effusion, and tenderness. Joint constituents may be the targets of immunologic attack or may be caught up in a more generalized inflammatory process.

Periarticular disease involving muscles and tendons may also present as pain referable to joints, although it is not a true arthritis. Mechanisms range from autoimmune inflammatory processes to purported vasomotor instability.

Clinical Presentation: Inflammatory Polyarthritides

The hallmark of these conditions is synovitis, with manifestations of inflammation (erythema, warmth, swelling) encompassing the entire joint.

Rheumatoid Arthritis typically presents in subacute fashion with symmetric polyarthritis, although atypical forms includemonoarticular and asymmetric disease. The most common sites are the wrists, proximal interphalangeal (PIP) joints, and metacarpophalangeal (MCP) joints, but elbows, neck, hips, knees, ankles, and feet may also be involved. Extraarticular manifestations include vasculitis, pulmonary nodules or interstitial fibrosis, mononeuritis multiplex, Sjögren's syndrome, and Felty's syndrome (splenomegaly, anemia, thrombocytopenia). Fatigue may dominate the early clinical presentation and precede the onset of joint symptoms. Other systemic symptoms (fever, weight loss) are prominent in severe cases. Women are more often affected than men. Morning stiffness is almost universal, with Raynaud's phenomenon a common accompaniment. Rheumatoid factor (RF) is found in approximately 75% of cases and is associated with skin nodules and more aggressive articular and extraarticular disease. Tendinous inflammation and joint destruction may ensue, producing characteristic changes (subluxation, swan neck deformities of the fingers, ulnar deviation of the wrists). Because no single clinical feature or test finding is definitive, the diagnosis requires the presence of a constellation of findings (Table 146.2). Current criteria are believed to have a sensitivity and specificity of approximately 90%.

1. Morning stiffness for more than 6 weeks
2. Arthritis involving three or more joint areas for more than 6 weeks
3. Arthritis of hand joints for more than 6 weeks
4. Symmetric arthritis for more than 6 weeks
5. Rheumatoid nodules
6. Serum rheumatoid factor in elevated titers
7. Radiologic changes (bony erosion in or adjacent to involved hand or wrist joints)

*Presence of any four or more criteria is necessary for a diagnosis of definite rheumatoid arthritis.

Adapted from Arnet FC, Edworthy SM, Block DA, et al. The American Rheumatism Association 1987 revised criteria for the classification of rheumatoid arthritis. Arthritis Rheum 1988;31:315, with permission.

Table 146.2. Diagnostic Criteria for Rheumatoid Arthritis [a]

Systemic Lupus Erythematosus usually occurs in young women, with a high prevalence in blacks. Malar rash, symmetric polyarthralgias, and nondeforming arthritis are characteristic, as is multisystem involvement, but morning stiffness and joint destruction are not as prominent as in rheumatoid arthritis (RA). Both large- and small-vessel vasculitis may occur. Oral ulcers are common. Serositis leading to pleuritis, effusion, or pericarditis develops in about a third of patients with systemic

lupus erythematosus (SLE). Hematologic manifestations include leukopenia, immune thrombocytopenia, and hemolytic anemia. The most serious complications are glomerulonephritis and cerebritis. Results of testing for *antinuclear antibody* (ANA) by indirect immunofluorescence are positive in 95% to 99% of cases. *Antibody to native double-stranded DNA* (*anti-dsDNA*) is specific for lupus and is found in more than 70% of cases, especially those with renal involvement. *Antibody to the Smith antigen* (*anti-Sm*) is present in 30% and is also specific for SLE. Results of cardiolipin-based serologic tests for syphilis are false-positive. As with RA, no single finding or test is diagnostic for SLE; the presence of several characteristic features is necessary to confirm the diagnosis (Table 146.3).

1. Malar rash
2. Discoid rash
3. Photosensitivity
4. Oral or nasopharyngeal ulceration
5. Nonerosive arthritis
6. Pleuritis or pericarditis
7. Persistent proteinuria or casts
8. Seizures or psychosis
9. Hemolytic anemia, leukopenia, or thromboycytopenia
10. Antinuclear antibody
11. Anti-DNA antibody, anti-Sm antibody, or false-positive serologic test for syphilis.

*Presence of any four or more criteria is necessary for a diagnosis of definite SLE, although many authorities accept fewer criteria in clinical practice, particularly if an antibody test result is positive.

Table 146.3. Criteria for Diagnosis of Systemic Lupus Erythematosus[a]

Systemic Sclerosis (Scleroderma) initially presents as either hand arthralgias, mild inflammatory hand arthritis, or Raynaud's phenomenon. Florid joint inflammation is uncommon. Skin thickening, a hallmark of the condition, follows several months later. Two clinical variants are described. One is a very slowly progressive form in which visceral involvement does not become significant until after decades of activity. It is manifested by the CREST syndrome: subcutaneous calcinosis of the digits, Raynaud's phenomenon, esophageal dysmotility, sclerodactyly, and telangiectasia. In the more aggressive form, skin thickening progresses rapidly to extend to the proximal limbs and trunk (hence the term *scleroderma*), and the onset of visceral involvement is accelerated (i.e., kidneys, lung, heart, and gastrointestinal tract). The results of ANA testing are positive in most patients with diffuse organ system disease, and a speckled pattern is characteristic and disease-specific when it corresponds to *antibody* to the nuclear enzyme *topoisomerase* (*anti-Scl-70*).

Vasculitis may be a consequence of rheumatoid disease (e.g., RA, SLE) or an idiopathic necrotizing process that can lead to multisystem injury. Typically, vasculitis comes to attention after the appearance of palpable purpura, livedo reticularis, or skin ulceration, consequences of inflammatory injury to small dermal blood vessels (see Chapter 179). Multisystem involvement is characteristic, heralded by neurologic deficits, hematuria and proteinuria, abdominal pain, or asymmetric polyarthritis. The diagnosis is usually made by biopsy of an affected organ; skin is the most convenient.

Mixed Connective Tissue Disease is a term sometimes used to describe an indistinct clinical syndrome that contains features of systemic sclerosis, lupus, and Sjögren's syndrome. With time, the presentation usually evolves into one of these three conditions, so that some investigators have concluded that this is not a unique condition but rather an early, nonspecific clinical presentation.

Psoriatic Arthritis has both peripheral and axial forms. The peripheral form is asymmetric, oligoarticular, and often erosive. The distal interphalangeal (DIP) joints are most often affected, and the nails are pitted. Sausage-shaped digits and a "pencil-in-cup" radiologic appearance of the affected joints caused by erosion are found in advanced disease. Psoriatic skin changes (see Chapter 187) usually predate the onset of arthritis, often by months to years, but they can be subtle. The spondylitic form of the disease (associated with HLA-B27 positivity) may resemble ankylosing spondylitis, but the extent of spinal involvement is less.

Reiter's Syndrome is primarily a disease of young men. Oligoarthritis, nongonococcal urethritis, and ocular inflammation (i.e., conjunctivitis, iritis) are the defining features. The latter two features may be fleeting and nonconcurrent. Dermatologic features include circinate balanitis (shallow, painless ulcers of the glans penis) and keratoderma blennorrhagicum (a hyperkeratosis of the feet). Onset sometimes follows a recent bacillary dysentery or chlamydial urethritis, which has led to speculation that the condition represents an immunologic cross-response in genetically predisposed hosts. HLA-B27 positivity is common and is believed to be related to the pathogenesis (i.e., shared antigenicity with the infectious agents). Joint involvement is asymmetric and affects the lower extremities. Heel pain with plantar fasciitis and calcaneal periostitis is distinctive. Mild spondylitis is common. ANA is absent.

Ankylosing Spondylitis begins insidiously and affects young men most severely, producing inflammation of the spinal joints and connective tissue with subsequent calcification and ossification. Characteristic radiographic findings include sacroiliitis and a diffuse proliferation of syndesmophytes leading to spinal fusion. Peripheral arthritis does occur, more often in women. In men, it tends to develop only after spinal disease has become evident. Large proximal joints such as the hips or knees are the predominant peripheral sites. Uveitis and HLA-B27 positivity are found, but their presence is not necessary for the diagnosis to be made. The arthritis of inflammatory bowel disease has many of the same features (see also Chapter 147).

Polyarticular Gout of an acute nature almost always occurs in patients with a prior history of monoarticular or oligoarticular gouty attacks, although hyperuricemia is not always present. The acute arthritis may be migratory but usually is confined to the lower extremities. The diagnosis is made by the finding of urate crystals in synovial fluid (see Chapter 145). A chronic arthritis occurs in patients with tophaceous disease. Acute attacks may be superimposed (see Chapter 158).

Pseudogout, like gout, is mostly an acute monoarticular disease but is on occasion polyarticular. Patients are usually elderly, with degenerative disease of the knees. The finding of calcium pyrophosphate crystals in the synovial fluid is diagnostic, although cartilage calcification can be seen on radiography. A subacute form, referred to as "pseudorheumatoid" arthritis, has been described, characterized by morning stiffness, synovial thickening, an elevated erythrocyte sedimentation rate (ESR), and low titers of RF.

Gonococcal Arthritis is the bacterial arthritis most likely to present in polyarticular fashion. Fever is usually present, and a papulovesicular rash indicative of disseminated disease develops in about two thirds of cases. Initially, the patient may have diffuse polyarticular symptoms, and signs of tenosynovitis may be found in the wrists, fingers, ankles, and toes. These manifestations are followed by a purulent arthritis in a limited number of joints, usually confined to the wrists, knees, or ankles (see Chapter 137).

Acute Rheumatic Fever causes an acute migratory polyarthritis if streptococcal infection is not treated. Abrupt onset of arthritis and fever are the predominant manifestations in adults. Both synovitis and periarticular inflammation occur, especially in the knees and ankles. Erythema of the overlying skin may be noted. Anti-DNAase B titers are elevated.

Lyme Disease may begin with migratory polyarthralgias and progress to attacks of asymmetric oligoarthritis in large joints (especially the knees) beginning about 6 months after infection in untreated patients. Later, a chronic monoarticular or oligoarticular arthritis may follow. The knees are a common site of chronic involvement. *Erythema chronica migrans*, the diagnostic annular red lesion at the site of the tick bite, occurs in 50% to 80% of cases during the early phase of illness. The diagnosis of late disease can be difficult because serologic testing is imprecise (see below and also Chapter 160).

Acute Viral Hepatitis B and other viral infections may present with an immune polyarthritis, often in conjunction with urticaria. The condition is symmetric, affecting the proximal joints of the hands. Onset in hepatitis B is during the preicteric phase. The condition clears spontaneously (see also Chapter 70).

Subacute Bacterial Endocarditis also causes an immune-mediated polyarthritis similar to that noted with hepatitis B. Fever, petechiae, splinter hemorrhages, heart murmur, and hematuria may be seen.

Sarcoidosis can cause an acute arthritis of the knees, wrists, PIP joints, and ankles that is accompanied by fever and simulates arthritis with an infectious cause. Erythema nodosum, hilar adenopathy, and periarticular involvement help to differentiate the condition from those with other causes. A destructive arthritis develops in a few persons; it is asymmetric and relapsing.

Clinical Presentation: Noninflammatory Arthritides

These conditions produce joint pain with few of the manifestations of inflammation, although sometimes a small effusion or mild synovial thickening may be noted.

Osteoarthritis typically presents as deep, aching joint pain that is aggravated by motion and weight bearing and by periods of inactivity. The involved joint can be enlarged as a result of osteophyte formation, but swelling is usually inconsequential, as soft-tissue involvement and inflammation are minimal. In later stages, pain occurs on motion and at rest in conjunction with stiffness. Nocturnal pain after vigorous activity is common. Patients with advanced disease have pain on weight bearing and joint instability. Examination often reveals crepitus and discomfort on movement of the joint. Occasionally, slight warmth is noted in severely affected weight-bearing joints, but erythema and marked warmth are absent. Limitation of motion, malalignment, and bony protuberances from spurs are frequent findings. The joints most commonly affected include the DIP joints of the hands (with formation of Heberden's nodes), MPCjoint at the base of the thumb, hips, knees, and cervical and lumbosacral vertebral joints.

Hypertrophic Pulmonary Osteoarthropathy may lead to diffuse bony pain in the lower extremities that is worsened by dependency. New bone formation and periostosis are the source of discomfort. Articular and periarticular symptoms may be encountered. Clubbing is a hallmark, although it is not readily evident in about 25% of cases. Intrapulmonary disease is an important precipitant (see Chapter 45).

Hypothyroidism severe enough to cause myxedema is associated with symmetric peripheral joint swelling that can mimic RA. The white blood cell count in the joint fluid is low, and no clinical signs of inflammation are present. Nonarticular neuromuscular symptoms include myalgias and hand pain related to carpal tunnel syndrome.

Amyloidosis can cause swelling of large joints secondary to synovial infiltration. Because of the symmetric distribution and gradual onset, an immunologic cause of arthropathy may be suspected, but the joint fluid shows no signs of inflammation or immune hyperreactivity. Concurrent involvement of the skin, heart, liver, and peripheral nerves is characteristic. Carpal tunnel syndrome may be present.

Sickle Cell Disease sometimes produces a 2- to 3-week noninflammatory arthropathy affecting large joints that is characterized by swelling, tenderness, and effusion. The synovial fluid is noninflammatory.

Clinical Presentation: Nonarticular Disease

Polymyalgia Rheumatica develops gradually during weeks or months. Pain and stiffness of periarticular structures of the neck and shoulders is the presentation in two thirds of cases, with hip and thigh involvement accounting for the other third. Many patients have both shoulder and thigh involvement. Morning stiffness and pain with movement are highly characteristic; muscle strength is unimpaired. Synovitis has been documented histologically; muscle biopsy specimens are usually normal or show minor inflammatory infiltrates. Sometimes, low-grade fever, weight loss, and fatigue precede the onset of musculoskeletal symptoms. The condition is usually symmetric, but if asymmetric it may be mistaken for shoulder bursitis or hip arthritis. Most patients are elderly. The association with cranial arteritis makes this an important condition to recognize. Marked elevation of the ESR is characteristic. No serologic abnormalities are found (see also Chapter 161).

Myositis of any type may present as musculoskeletal pain and be confused with polyarthritis, although weakness is typically more prominent than pain. *Polymyositis* is the prototypical inflammatory muscle disease, characterized by proximal muscle weakness, soreness, and elevated levels of muscle enzymes. It may present as *dermatomyositis* in the elderly. *Eosinophilia–myalgia* syndrome is a serious myositis observed in association with ingestion of L-tryptophan preparations. Marked peripheral eosinophilia, muscle weakness and pain, and serum aldolase elevations comprise the initial presentation. Skin induration, pulmonary infiltrates, cardiac rhythm disturbances, and peripheral neuropathy may ensue.

Fibromyalgia Syndrome (Fibrositis, Fibromyositis) occurs predominantly in women. An inflammatory mechanism has been suspected (hence the "itis" designation) but never demonstrated. Characteristic manifestations include morning stiffness worsened by changes in the weather and heavy exercise, fatigue caused by disordered sleep, and tenderness at multiple symmetric *trigger points* concentrated in the upper back and neck. The musculoskeletal discomfort is typically diffuse and poorly localized, but exacerbations caused by extremes of joint motion may produce pain referable to the joints. All hematologic and serologic parameters are normal (see also Chapter 159).

Reflex Sympathetic Dystrophy Syndrome causes diffuse musculoskeletal discomfort, swelling, weakness, and limitation of motion. A single limb is affected, usually an arm. The limb is swollen and the skin shiny, often dusky in appearance and cool to the touch. Pain can be severe and burning. Periarticular structures are especially tender. Preceding trauma accounts for 50% of cases. A vasomotor mechanism is postulated.

DIFFERENTIAL DIAGNOSIS

The causes of polyarticular complaints can be divided into articular and nonarticular categories, and these can be subdivided into inflammatory and noninflammatory conditions (Table 146.1).

WORKUP

Overall Strategy

The initial assessment of the patient who presents with multiple joint symptoms is facilitated by addressing the following questions:

1. Is the underlying disease process inflammatory or noninflammatory?
2. Is the problem systemic or focal?
3. Is it truly articular or periarticular?
4. Is vital organ function or joint integrity endangered?

In the vast majority of cases, the answers to these questions can be provided by a careful history and physical examination, supplemented by a few basic blood tests or a radiographic study suggested by the clinical picture. Synovial fluid analysis is sometimes helpful if an accessible effusion is present. The laboratory workup is best used to modify one's initial clinical impression. Routinely ordering an "arthritis panel" of blood tests is wasteful, and it also risks the generation of false-positive results, which can have devastating consequences.

It is important to note that official criteria for the diagnosis of RA and SLE are designed more to ensure uniformity in epidemiologic and therapeutic studies than to diagnose disease in individual patients. The American Rheumatism Association criteria for RA emphasize chronicity and symmetry of polyarthritis, so they are less sensitive for use in early disease. The diagnosis of SLE by official criteria poses similar problems. For the individual patient, a diagnosis of one of these conditions should be considered if some, but not necessarily all, of the characteristic clinical features of the disease are present.

History

Differentiating Articular from Nonarticular Disease. Patients complain of pain, stiffness, and loss of function and often confuse neuropathic pain, bone pain, or myalgias with arthritis. The physician should attempt to identify the anatomic basis of the symptoms by asking the patient to specify exactly where the pain is located, what aggravates it, and what functional loss has occurred. For the most part, the symptoms of joint disease are well localized to the joint and bear a logical relation to its use. Nonarticular disease rarely has a specifically articular location and does not produce loss of articular function, although range of motion may be affected to some degree. After the location of the process has been established, the underlying disease mechanism should be elucidated.

Differentiating Inflammatory from Noninflammatory Disease. One inquires into the characteristic hallmarks of inflammation: redness, warmth, soft-tissue swelling, and tenderness. If such symptoms are localized to and encompass an entire joint, one has excellent presumptive evidence for synovitis and an inflammatory process. It is important not to mistake tenderness in a segment of the joint or a small effusion as evidence of inflammation. The response to antiinflammatory agents is

sometimes useful for differentiation, although most nonprescription agents, such as aspirin and other NSAIDs, also have analgesic activity that may provide nonspecific relief. Patients with RA reach for their aspirin as soon as they awaken and clearly feel worse if they miss a dose. The response in patients with osteoarthritis is much less dramatic.

Elucidation of a Specific Cause. The basic determinations of site and disease process help narrow the differential diagnosis and enable a more focused consideration. Attention to other elements of the history, such as distribution of involved joints, associated symptoms (including those suggesting systemic disease), and age and sex, facilitate identification of the cause.

Distribution and Temporal Pattern are of considerable diagnostic value, so that careful inquiry about all the joints affected and the sequence of involvement is necessary. Problems that at first appear monoarticular or asymmetric may turn out to be polyarticular or symmetric on further questioning. Several patterns are quite suggestive. Symmetric noninflammatory involvement of the PIP and DIP joints, without MCP or wrist involvement and without morning stiffness, argues for osteoarthritis. Asymmetric inflammatory disease of these joints points to psoriatic arthritis. Symmetric inflammatory involvement of the MCP, PIP, carpal, or metatarsophalangeal (MTP) joints supports a diagnosis of rheumatoid disease. Bilateral heel pain suggests Reiter's syndrome and the other spondyloarthropathies, as does back pain. Hip and shoulder girdle symptoms in an elderly patient with noninflammatory, nonarticular disease provide strong presumptive evidence for polymyalgia, whereas a vague distribution in conjunction with the presence of trigger points supports a diagnosis of fibromyalgia.

The temporal pattern deserves attention. A chronic, subacute, additive process is consistent with rheumatoid disease. The sudden, explosive onset of symmetric polyarthritis suggests an acute hypersensitivity reaction, such as that seen with early hepatitis B infection or penicillin allergy. A migratory pattern raises the possibilities of rheumatic fever, disseminated gonococcemia, Reiter's syndrome, and Lyme disease, among others.

Associated Symptoms aid in the diagnosis and may provide evidence for systemic involvement. A careful review of systems is essential. *Morning stiffness* is very suggestive of rheumatoid disease, which produces maximal stiffness after inactivity. In contrast, osteoarthritis is characterized by maximal symptoms with use. If some stiffness occurs with rest in osteoarthritis, it passes quickly with activity. Acute onset of fever points to an infectious origin or a marked hypersensitivity reaction, whereas low-grade fever may herald the onset of rheumatoid disease. The development of a *rash* may be diagnostic for such conditions as SLE, gonococcemia, Lyme disease, and vasculitis (see later discussion). New onset of *Raynaud's phenomenon* raises the possibility of scleroderma, SLE, or RA. A history of chronic or bloody *diarrhea* suggests inflammatory bowel disease. Symptoms of *urethritis* and *conjunctivitis* are suggestive of Reiter's syndrome. *Sleep disorder* and *chronic fatigue* point to fibromyalgia. Chronically *dry mouth* and *dry eyes* suggest Sjögren's syndrome, a common accompaniment of RA. Systemic involvement with SLE is evidenced by reports of nasopharyngeal ulcers, pleuritic chest pain, or mental status changes.

Age and Sex. Patients with SLE and RA are predominantly female, whereas those with Reiter's syndrome are predominantly male. The onset of rheumatic fever or ankylosing spondylitis nearly always occurs before age 40. The peak incidence for SLE is in the premenopausal period, although later onset is not rare. The incidence of RA is less dependent on age, with new onset occurring in elderly as well as young persons. Gout in women is mainly a postmenopausal disease; in men, it occurs at all adult ages. SLE is particularly common among black women.

Severity and effect on daily activity help assess the functional significance in addition to underlying cause. Joint pain awakening the patient at night indicates severe arthritis; alternatively, it may signify a bony or neuropathic process. Marked daily fatigue, the need for afternoon naps, weight loss, and fever all suggest active systemic illness. The assessment of the functional impact must take into account not only the severity of the condition but also the patient's premorbid level of activity and attitudes toward work and pain.

Past Medical History and Family History. Recurrent attacks and a genetic propensity are characteristic of many conditions. Gout may present as polyarthritis, but more often one uncovers a prior history of podagra or another form of acute monoarthritis in a lower extremity. A history of travel or residence in an area endemic for Lyme disease, in addition to a history of recent tick bite, should be elicited. The spondyloarthropathies, gout, and the Heberden's nodes of osteoarthritis all have a familial preponderance, which should be explored.

Physical Examination

The physical examination is basically a continuation of the same approach, with documentation of the pattern and type of joint involvement and the nature of any extraarticular disease. The myriad extraarticular manifestations of the arthritic diseases makes a detailed general physical examination mandatory. Certain aspects deserve emphasis.

Skin and Integument. Important dermal clues to underlying cause include the malar rash of SLE, annular erythema chronica migrans of Lyme disease, papulovesicular lesions with a necrotic center of disseminated gonococcemia, nail pitting and scaling of psoriasis, urticarial lesions of hepatitis B infection, and palpable purpura, ulceration, or livedo reticularis of vasculitis. In a patient with suspected Reiter's syndrome, the glans penis should be checked for the ulcers of circinate balanitis and the heels for the hypertrophic changes of keratoderma blennorrhagicum. One should carefully palpate around the elbows, Achilles tendons, and pinnae and search for rheumatoid nodules and tophi, which are specific indicators of RA and gout, respectively. The nails should be examined for pitting and clubbing. Nail pitting adjacent to erosive DIP arthritis can justify a diagnosis of psoriatic arthritis in the absence of any skin psoriasis. Fingertip atrophy with healed or active ulcers suggests severe Raynaud's phenomenon and should prompt a search for the calcinosis, subungual telangiectases, and skin tightening of scleroderma. The presence of the red, tender, subcutaneous lesions of erythema nodosum raises the possibilities of sarcoidosis and inflammatory bowel disease. Dry, doughy skin and loss of the outer third of the eyebrows are signs of hypothyroidism.

Head, Ears, Nose, Throat, Neck, Lungs, Heart. The anterior eye should be checked for conjunctivitis and iritis, which are suggestive of Reiter's syndrome and spondylitis (see Chapter 199), and the posterior eye for retinal hemorrhages, exudates, and ischemic lesions, which are consistent with systemic lupus and vasculitis. "Cotton-wool" exudates are the most common eye lesion in SLE. The oral and nasal mucosa should be examined for ulcers, which if painful suggest SLE and if painless suggest Reiter's syndrome. Thyroid evaluation may reveal a goiter. The chest is examined for signs of effusion, pleuritis, and pericarditis. Pleural and pericardial rubs are found in RA and SLE. Heart murmurs characterize rheumatic fever and SLE, mitral valve murmurs sometimes occur in SLE, and aortic regurgitant murmurs occur in the spondyloarthropathies. The abdominal examination includes checking for splenomegaly, which is found in a variety of rheumatic diseases, including RA and SLE.

Musculoskeletal Examination. One checks for signs of serositis, noninflammatory articular disease, and periarticular disease. As emphasized earlier, inflammatory joint disease involves the entire joint; tenderness, warmth, redness, soft-tissue swelling, and often an effusion are present. In contrast, noninflammatory disease is usually associated with only focal tenderness and few, if any, signs of inflammation, although a small noninflammatory effusion may be present. The distribution of disease is noted, as are any mechanical abnormalities, such as limitation of motion, instability, subluxation, or tendon injury.

A careful look at the periarticular tissues (tendons, bursae, muscles) is also indicated. Bursitis and tendinitis commonly mimic arthritis. Subacromial bursitis and bicipital tendinitis can be confused with shoulder joint disease (see Chapter 150), lateral epicondylitis (tennis elbow) and olecranon bursitis with elbow joint disease (see Chapter 153), trochanteric bursitis with hip disease (see Chapter 151), and anserine bursitis with knee disease (see Chapter 152). Muscle soreness and proximal muscle weakness raise the question of a myositis. Checking for pressure points in the upper back and neck is indicated in patients with suspected fibromyalgia syndrome.

Another important type of periarticular disease is that manifested by "frozen" joints and flexion contractures. Severe limitation of motion may occur in an intrinsically normal joint. Disuse because of neurologic disease or periarticular pain may lead to tightening of periarticular fibrous tissue and secondary contractures. The clinical presentation can be mistaken for that of arthritis, but normal radiographic findings in a joint and a lack of indicators of inflammatory arthritis, plus an awareness of a predisposing illness, lead to the correct diagnosis.

If a patient has hand stiffness or pain, a valuable screening test for finger joint and tendinous disease is "*curling.*" The patient is asked to extend the MCP joints and then maximally flex the PIP and DIP joints, but not to make a fist. Curling is normal if a patient can bring the fingertips into apposition with the palm. Any disease of the PIP or DIP joints interferes with curling, as does any inflammation along the dorsal extensor tendons.

For patients with a suspected spondyloarthropathy, *Schober's test* provides a useful assessment of lumbar mobility. Two marks are made on the patient's back while the patient is standing: one at the level of the posterior iliac spine and the other exactly 10 cm above the first. When the patient bends forward maximally, the two marks should be at least 15 cm apart. An abnormal Schober's test result is nonspecific, but if an abnormal result is combined with other evidence for a

spondyloarthropathy, it can advance the diagnosis.

Neurologic Examination. Evidence of peripheral neuropathy is sought by assessing motor and sensory function in the extremities, and the mental status is carefully evaluated in patients with suspected SLE and HIV infection (central nervous system involvement is a sign of serious disease).

Laboratory Studies

Approach to Testing. A large number of laboratory tests, both simple and esoteric, are routinely used in the evaluation of polyarthritic symptoms. Panels of tests are sometimes offered by laboratories as a means of "screening" for arthritic conditions. They range from a set of basic studies (e.g., ANA and RF titers, uric acid level, ESR) to elaborate panels that may include testing for anti-dsDNA, anti-Ro, anti-La, anti-Scl-70, anti-Sm, and anti-ribonucleoprotein. All such batteries of tests have been found to be wasteful, of little use diagnostically when ordered in the absence of clinical evidence, and a source of potentially misleading false-positive results. Nonetheless, test panels continue to be popular, even when the pretest probability of disease is so low that a positive test result will have almost no positive predictive value (see Chapter 2). Perhaps it is the desire to "rule out" disease that drives such testing (negative predictive value is high, but it is usually already very high before testing). Repeated studies demonstrate and expert panels reaffirm that the best means of diagnosing or ruling out "must-not-miss" conditions is a careful history and physical examination, complemented by thoughtfully selected tests that specifically address conditions for which at least some clinical evidence is present. Diagnostic confusion that persists at the end of the physical examination is rarely resolved by "pan-scanning" for arthritic disease. Careful test selectionand interpretation are especially important in the elderly because the frequency of abnormal test results in the absence of disease increases with age, especially with the most commonly ordered studies (e.g., ESR, uric acid level, ANA and RF titers); the false-positive rate can be as high as 90%. Test selection is guided by whether the clinical assessment suggests inflammatory or noninflammatory disease.

Suspected Inflammatory Articular Disease. In this setting, a determination of the *ESR* provides useful but nonspecific confirmation of inflammatory disease activity and can be followed as a measure of disease activity. A markedly elevated reading (e.g., >60 mm/h) suggests considerable inflammatory activity. A normal ESR in the setting of active joint symptoms reduces the probability of active inflammatory pathophysiology. However, the ESR is a relatively poor test for the detection of inflammatory disease that is in remission. A *complete blood cell count* can be obtained at the same time to check for hematologic involvement by the underlying disease process.

If symptoms are acute and new in onset, then tests for infectious causes should be considered. *Blood cultures* are essential if endocarditis or disseminated gonococcemia is suspected. Currently available *Lyme antibody* assays lack specificity, so their results are difficult to interpret (see Chapter 160) and less useful than a careful clinical assessment. DNA-based assays with polymerase chain reaction technology are not yet widely available and very expensive. Liver function testing (e.g., measurement of aminotransferases) may help confirm suspected viral hepatitis; hepatitis serology should follow if serum liver chemistries are abnormal.

If the duration of symptoms is more than 6 weeks, then the possibility of rheumatoid disease and other chronic forms of inflammatory joint disease need to be explored further, especially if the patient has systemic symptoms.

Rheumatoid factor is helpful if the pretest probability of RA is intermediate and further supporting evidence is sought. In general, 70% to 80% of all patients meeting strict criteria for RA are RF-positive. The higher the RF titer, the more likely the diagnosis of RA. RF negativity does not rule out RA; 25% of patients with RA are RF-negative. On the other hand, RF positivity does not rule in RA; it also occurs in other inflammatory conditions (e.g., SLE, subacute bacterial endocarditis, vasculitis, and even viral infection). Moreover, 5% to 15% of "normal" persons (the percentage increases with age) are RF-positive.

Antinuclear Antibody testing is very sensitive (99%) for the diagnosis of SLE, but specificity is lacking (50% to 85%). The test result can also be positive in other forms of connective tissue disease (sensitivity of about 50% for RA, and considerably higher for Sjögren's syndrome and progressive systemic sclerosis), in chronic hepatitis, and in elderly persons without any connective tissue disease. The higher the ANA titer, the more likely the diagnosis of lupus. A titer of 1:40 is usually listed as the criterion for a positive test result, but such a cutoff produces a 35% false-positive rate in a general medical setting. An ANA titer criterion of 1:160 reduces the false-positive rate to 5% while reducing sensitivity only minimally (to 95%). Titers of ANA fluctuate with time but do not necessarily parallel disease activity. The test is most useful in the setting of inflammatory polyarthritis and systemic symptoms. ANA negativity rules out SLE; however, the test is not specific enough for a positive result to rule in the condition, but it would justify further testing.

Follow-up Tests for Patients with a Positive Antinuclear Antibody Test Result . Because ANA positivity is a nonspecific finding, additional testing is required for patients with a positive test result. The specific nuclear constituents represented by the ANA titer function as convenient autoantigens. Testing for antibodies against these antigens often provides the desired specificity but should not be performed in the absence of characteristic clinical features (i.e., a reasonable pretest probability is required); otherwise, poor likelihood ratios (ratio of true-positives to false-positives) are likely to result. *Antibody to native dsDNA* occurs in up to 70% of patients with SLE and is specific for the condition and also predictive of an increased risk for nephritis. Testing for anti-dsDNA is used to confirm the diagnosis of SLE in patients with suspected disease and ANA positivity. *Antibody to Smith antigen* is similarly specific but is found in only 30% of patients with SLE. *Antibody to Scl-70* (a nuclear topoisomerase) is highly specific for *systemic sclerosis*, but its sensitivity is low (20%). In *Sjögren's syndrome, anti-Ro* and *anti-La* antibodies provide 60% to 70% sensitivity and more than 90% specificity. *Lip biopsy* is the definitive test, but it is often not necessary in the context of characteristic clinical and serologic findings.

Synovial Fluid Analysis is useful and indicated if a joint effusion is present and the diagnosis remains undetermined. One seeks to differentiate between inflammatory and noninflammatory disease (see Chapter 145), and also to check for crystal-induced arthropathy and investigate any suspected infection (see Chapter 145). A white blood cell count above 2,000/mm^3 with more than 75% polymorphonuclear leukocytes supports the presence of inflammation; a cell count below 1,000/mm^3 indicates noninflammatory disease. A count between 1,000 and 2,000/mm^3 is ambiguous. Often, one obtains a synovial fluid white blood cell count of 5,000 to 20,000/mm^3 without crystals, bacteria, or other distinctive attributes, which allows for little more than a designation of inflammatory arthritis, type unspecified.

Serum Uric Acid levels are obtained unnecessarily in most arthritis patients and too often serve as the primary basis for a diagnosis of gout. The definitive diagnosis is best made by observing urate crystals in the synovial fluid. A normal serum uric acid level does not rule out the diagnosis of gout, nor does an elevated level rule it in.

Radiography is usually of minimal diagnostic value in the early stages of inflammatory polyarthritis, showing little more than soft-tissue swelling. Films obtained during later stages may manifest more characteristic bony changes, but usually a diagnosis has already been established. However, early *sacroiliac films* are of value in suspected spondyloarthropathy because they may reveal sacroiliitis, a diagnostic finding. Another early radiologic change in spondyloarthropathy is squaring of the superior and inferior margins of the vertebral bodies. Only later do prominent syndesmophytes appear.

HLA-B27 Testing has not proved diagnostically useful. Although the prevalence of HLA-B27 antigen positivity in the seronegative spondyloarthropathies is high (³90%), the fact that positivity for HLA-B27 is seen in 6% to 8% of normal persons negates the utility of HLA-B27 testing in the diagnosis of this uncommon condition.

Urinalysis and Routine Chemistries . Urinalysis is essential to screen for glomerular injury in rheumatoid disease. Routine serum chemistries are less rewarding, although assessment of renal function by measurement of *blood urea nitrogen* and *creatinine* levels is indicated in patients with proteinuria or hematuria.

Suspected Noninflammatory Polyarticular Disease. In osteoarthritis, *joint radiographic findings* are abnormal by the time the patient becomes symptomatic and can confirm the diagnosis. However, degenerative changes are commonly found in asymptomatic joints also. Films of long bones can be obtained to confirm hypertrophic osteoarthropathy, but the diagnosis can usually be made clinically by the presence of clubbing. Suspected hypothyroidism can be confirmed by a *thyrotropin* (TSH) determination.

Suspected Inflammatory Nonarticular Disease. The *ESR* should be measured in patients with clinical evidence for polymyalgia rheumatica. A high rate supports the diagnosis; a low one reduces the probability. If headache, jaw claudication, visual disturbance, or a tender cranial artery is noted, then evaluation for cranial arteritis should proceed promptly (see Chapter 161). A *complete blood cell count* and *differential* are indicated in patients with suspected eosinophilia–myalgia; referral for skin and muscle biopsy is then appropriate if florid peripheral eosinophilia is noted. Suspected polymyositis is evaluated by measuring serum *creatine kinase* levels and, if they are markedly elevated, proceeding to consideration of *muscle biopsy.*

Suspected Noninflammatory Nonarticular Disease. The diagnosis of fibromyalgia is a clinical one. No associated laboratory abnormalities are found (see Chapter 159). Similarly, the diagnosis of reflex sympathetic dystrophy is predominantly clinical. Plain films of the hand may show a nonspecific but suggestive patchy

osteopenia.

INDICATIONS FOR ADMISSION AND REFERRAL

The diagnosis of polyarticular arthritis may remain uncertain for a long period. For the most part, the underlying condition is not immediately life-threatening, and the workup can take place in the outpatient setting during several visits. Short-term risk to the patient is posed primarily by extraarticular disease and infection. If any evidence of bloodstream infection, vasculitis, or involvement of the eyes, lungs, heart, kidneys, or nervous system is found, hospitalization and consultation should be promptly considered. The same recommendation pertains to persons with severe constitutional symptoms (e.g., disabling fatigue, fever, weight loss). Rheumatologic consultation is also appropriate if a patient with less serious illness remains without a diagnosis after the initial evaluation has been completed. A timely referral for consultation with a well-trained rheumatologist is likely to be far more productive than exhaustive serologic testing, with its attendant risks of false-positive results.

SYMPTOMATIC THERAPY

Treatment should be etiologic (see Chapter 155, Chapter 156, Chapter 157, Chapter 158, Chapter 159, Chapter 160, Chapter 161, Chapter 162 and Chapter 163), but the definitive diagnosis of an inflammatory polyarthritis may take time. Pending results, and provided infection has been ruled out, the patient bothered by symptoms of joint inflammation may be given either high-dose aspirin (up to twelve 325-mg tablets daily) or a generic NSAID preparation (e.g., 400 to 800 mg of ibuprofen four times daily).

CHAPTER 147 EVALUATION OF BACK PAIN

ALBERT G. MULLEY, JR.

INTRODUCTION

Back pain is a common complaint in primary care practice and one of the leading causes of disability. Most back pain is caused by musculoligamentous strain, degenerative disk disease, or facet arthritis and responds to symptomatic treatment. Disk disease is often responsible for recurring mild discomfort of the low back and episodes of severe back pain with sciatica. Occasionally, back pain may result from problems originating outside the spinal axis. Serious underlying problems such as tumor, infection, or vertebral compression fracture must be kept in mind. The prevalence of back pain requires that the primary physician be skilled in its assessment and conservative management and knowledgeable about the indications for referral and surgery.

PATHOPHYSIOLOGY AND CLINICAL PRESENTATION

Musculoligamentous Strain. Muscle fibers or distal ligamentous attachments of the paraspinal muscles may tear, usually at the iliac crest or lower lumbar/upper sacral region. Resultant bleeding and spasm cause local swelling and marked tenderness at the site of injury. The patient typically presents after a specific episode of bending, twisting, or lifting. The strain is usually severe and is associated with a feeling of something giving way in the lower back. The onset of pain in the lower lumbar area is immediate. Pain radiates across the low back, often to the buttock and upper thigh posteriorly. Radiation of pain into the lower leg is rare because usually no injury to the nerve roots has occurred.

Lumbar Disk Disease. The pathophysiology of disk disease remains incompletely understood but involves degenerative changes in the disk. It is thought that degeneration and attritional changes in the lower lumbar disks are caused by the concentration of stress at the lumbosacral level. Stresses resulting from the enormous longitudinal and sheer forces that are a consequence of upright posture are aggravated by bending strain. Injury, inflammation, and weakening of the disk annulus may occur and lead to localized back pain. Pain receptors in the longitudinal ligaments probably mediate the recurring attacks of local back pain. Eventually, the disk may become so weakened that it bulges circumferentially beyond the disk interspace. Less often, a focal or asymmetric extension beyond the interspace, termed a disk *protrusion*, develops. Extreme extension of the disk beyond the interspace has been called *extrusion*. Historically, the term *herniation* has been used to describe all these phenomena. It has been suggested that use of the more specific terms will sharpen our understanding of the relationship between disk disease and pain syndromes. Regardless of the vocabulary, compression and irritation of a lower lumbar or upper sacral nerve root may result, and the radicular symptoms of *sciatica* develop.

Sciatica is the symptomatic hallmark of nerve root irritation. Disk protrusion or extrusion is present in 95% of cases. It presents as sharp or burning pain radiating down the posterior or lateral aspect of the leg to the ankle or foot (depending on the specific nerve root involved). The pain may be worsened by cough, Valsalva's maneuver, or sneezing and is often accompanied by paresthesias and numbness. Weakness may also develop in the areas supplied by the irritated nerve root.

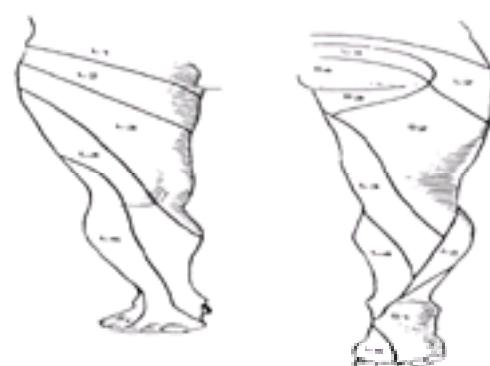
More than 95% of disk protrusions and extrusions occur at the L4-5 or L5-S1 level, with the L-5 and S-1 nerve roots affected, respectively. With S-1 root irritation, pain, numbness, and paresthesias involve the buttock, posterior thigh, calf, lateral aspect of the ankle and foot, and lateral toes. Calf atrophy can occur, the ankle jerk can be diminished or absent, and plantar flexion weakness may be noted. With L-5 root compression, pain radiates to the dorsum of the foot and great toe, and the only neurologic deficits may be extensor weakness of the great toe and numbness of the L-5 area on the dorsum of the foot at the base of the great toe (Fig. 147.1). In the rarer instance of high lumbar disk disease, pain radiates to the anterior thigh, and the knee jerk may be diminished or absent. Quadriceps atrophy and weakness may be found.


Figure 147.1. Dermatomes of the lower extremity. (From Finneson BE. Low back pain. Philadelphia: JB Lippincott Co, 1973, with permission.)

With lower lumbar disk disease, especially disk extrusion, lumbar paraspinal muscle spasm often occurs and limits lumbar motions. A list away from the side of the disk extrusion, so-called sciatic scoliosis, may develop, and often tenderness of the lower lumbar spine and sciatic notch is present. *Straight leg raising (SLR)* on the affected side is limited by back and leg pain that increases on ankle dorsiflexion at the extreme of SLR. With upper lumbar disk disease, reverse SLR often reproduces the back and anterior thigh pain (see later discussion).

The clinical course may begin with a several-year history of recurring mild mid-low back pain related to minor back strain, with symptoms clearing spontaneously within a few days. Attacks typically increase in frequency and severity at intervals of several months to several years. Finally, an episode of persistent pain accompanied by sciatica develops, often triggered by a seemingly trivial stress (e.g., bending over in the shower to pick up the soap).

Spinal Stenosis has become better appreciated as an important cause of chronic low back and lower extremity complaints. It occurs predominantly in elderly individuals with osteoarthritic spurring, chronic disk degeneration, and facet joint arthritis. Spinal stenosis is also found in young people who have a congenitally narrowed lumbar spinal canal. In either case, the changes narrow the canal and the neuroforamina, leading to root impingement and pain.

The characteristic symptom is pain that is worsened by standing, walking, or other activities that cause spinal extension and is relieved by rest, especially by sitting or lying down and flexing the spine and hips. Patients report pain in the low back, gluteal region, or lower extremities; often, it is bilateral. Numbness or weakness may accompany the pain in the legs. Because symptoms are often worsened by walking and relieved by sitting down and resting, they can mimic vascular insufficiency and are sometimes referred to as *pseudoclaudication*.

On examination, the spine demonstrates good range of motion and little focal tenderness. SLR is usually normal. Minor neurologic deficits (e.g., a diminished ankle jerk) may be present, but no pattern is characteristic.

Spondylolisthesis denotes forward subluxation of a vertebral body. In adults, the condition results from degenerative changes and arthritis of the facet joints, usually at L4-5 or L5-S1, with forward slippage of 10% to 20% of the diameter of the vertebral body. About 70% of patients with spondylolisthesis have chronic low back pain;

sciatica is infrequent. The pain is caused by strain imposed on the ligaments and intervertebral joints.

Vertebral Compression Fracture. In normal bone, this fracture requires severe flexion–compression force. It is acutely painful. Spontaneous vertebral body collapse, or pathologic fracture, is most commonly seen in elderly persons with severe osteoporosis (see Chapter 164), in patients taking long-term glucocorticoids (see Chapter 105), and in cancer patients with lytic bony metastases. Usually, the history is one of sudden back pain brought on by a minor stress. The discomfort is noted at the level of fracture, with local radiation across the back and around the trunk, but rarely into the lower extremities. The fracture is more likely to occur in the middle or lower levels of the dorsal spine, which helps differentiate the problem from lumbar disk herniations, 95% of which occur at the level of the L-4 or L-5 disk.

Neoplasms. The most common spinal tumor is *metastatic carcinoma*, which often presents with waist-level or midback pain of insidious onset, gradually increasing in severity and aggravated by activity. About 80% of patients are older than 50 years of age. Although only 30% give a history of previous cancer, in those that do, the probability of spinal metastasis is high. Approximately 90% report night pain and pain unrelieved by lying down or bed rest. A history of prior malignancy and insidious increase in midback pain that is not relieved by lying down is highly predictive of metastatic tumor.

Breast, lung, prostate, gastrointestinal, and genitourinary neoplasms often metastasize to the spine. Purely lytic lesions, which are often caused by renal or thyroid carcinoma, are seen occasionally. The disk spaces are spared. Disk space height is usually maintained, although collapse of the vertebral body as a result of destruction and weakening of bone is common. *Myeloma* is the most common primary bone tumor involving the spine. Early in its course, the tumor may be difficult to differentiate from compression fracture if osteoporosis is present.

Intraspinal tumors may present in the same manner as herniated disks. However, marked progression of neurologic deficits despite adequate conservative therapy is a clue to the existence of a tumor inside the spinal canal. *Extraspinal tumors* may eventually cause root impingement and simulate diskogenic sciatica. Tumors of the retroperitoneum, pelvis, and large bowel may extend to the roots. This is a very late development; metastases may occur earlier.

Infection. Back pain resulting from infection is rare but important to detect. An identifiable source is found in 40% of cases; possibilities include urinary tract infection, skin abscess, indwelling catheter, and IV drug abuse. *Vertebral osteomyelitis* is usually hematogenous in origin but may occasionally result from a spinal procedure, such as lumbar puncture, myelography, diskography, or disk surgery. It extends into the disk space in addition to affecting the vertebral bodies. Dull, continuous back pain is the usual presentation, often in conjunction with low-grade fever and spasm over the paraspinous muscles. Tenderness to percussion over the involved vertebrae is common, but fever is absent in up to half of cases. A compression fracture or an epidural abscess may ensue.

Epidural abscess develops in the context of bacteremia or osteomyelitis. The infection presents as back pain, focal tenderness, and fever. Fever and spinal tenderness are present in about 85% of cases. If the condition is not promptly treated, it may extend to compromise the local blood supply to the spinal cord and rapidly progress from spinal ache to major motor and sensory deficits within hours to a few days.

Ankylosing Spondylitis. This seronegative spondyloarthropathy has both peripheral and axial skeleton manifestations (see also Chapter 146). Spinal involvement is most prominent in young men. Morning spinal stiffness, symptomatic improvement with exercise, gradual onset, and persistence of pain for more than 3 months are characteristic but relatively nonspecific features. The mechanism of disease is unknown, but the incidence of HLA-B27 positivity is high, suggesting an immune pathophysiology. Some patients have a history of inflammatory bowel disease. Early clinical findings include morning back stiffness and diminished chest expansion. Spinal radiographic findings are often unremarkable in the early phases, but films of the sacroiliac joints may show narrowing of the joint space and reactive sclerosis ("sacroiliitis"). Eventually, the sacroiliac joint space becomes obliterated, and fusion follows. Squaring of the vertebral bodies is the first spinal radiologic manifestation, followed by the development of syndesmophytes. Similar although less florid changes may occur in the other seronegative spondyloarthropathies (see Chapter 146).

Psychogenic Disease. Patients with *depression* may present complaining of chronic low back pain. Often, they have a history of previous back problems or onset at the time of a minor injury, with the depression amplifying the presentation and prolonging the clinical course. Mild muscle spasm may be noted on physical examination. Characteristically, the intensity of the symptoms and degree of disability are much greater than the minor limitations found on examination would suggest. Multiple somatic symptoms are common (see Chapter 227). Other patients may have an underlying *somatizatior* disorder. Many of these patients appear refractory to therapy and are often unwilling to take an active role in their own treatment. Some even seem to derive a sense of legitimacy and self-worth from their suffering (see Chapter 230).

Malingering implies conscious deception for the sake of obtaining gain from being ill. Inconsistencies among symptoms and physical findings typify the malingerer. These often can be brought out by distracting the patient.

Cauda Equina Syndrome. Although the spinal cord ends at the L-1 level, the collection of nerve roots that make up the cauda equina are subject to injury by any process that compromises the spinal canal below the L-1 level. Massive midline disk herniation is the most common cause of cauda compression and a serious, although very infrequent, event that requires prompt attention. In contrast to the clinical presentation of simple root impingement, the presentation in cauda equina syndrome includes urinary retention in almost 90% of cases. Another characteristic feature is "saddle anesthesia" (reduction in sensation over the buttocks, upper posterior thighs, and perineum), reported by about 75% of patients. Both of these clinical findings are a consequence of sacral root compression, as is a decrease in anal sphincter tone, noted in about two thirds of cases. Sciatica and lower extremity motor and sensory deficits are prominent and often bilateral. Patients may report falling.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of back pain can be considered in terms of whether or not root pain is present (Table 147.1).

Conditions Commonly Presenting with Sciatica
Disk herniation
Spinal stenosis
Compression fracture
Epidural abscess
Vertebral osteomyelitis (late)
Compression fracture
Intraspinal tumor
Spinal metastasis
Spondylolisthesis (occasionally)

Conditions Usually Presenting without Sciatica
Musculoligamentous strain
Ankylosing spondylitis
Spondylolisthesis
Depression
Vertebral osteomyelitis (early)
Epidural abscess (very early)
Retroperitoneal neoplasm

Table 147.1. Important Causes of Back Pain

In primary care practice, about 85% of patients with back pain have musculoligamentous injury or degenerative change. Up to 5% have symptomatic disk protrusion or extrusion, with about half of these coming to surgery; 4% have compression fracture, 3% have spondylolisthesis, and another 1.5% have either tumor, infection, or ankylosing spondylitis. The prevalence of spinal stenosis remains unknown. Bulging disks at at least one level have been found on magnetic resonance imaging in half, and disk protrusions in 30%, of asymptomatic persons. Disk extrusions are much less common, occurring in only 1%.

WORKUP

Even with the advent of sophisticated spinal imaging techniques, the history and physical examination remain critical to the effective evaluation and management of back pain. The findings elicited are often diagnostic, and even if they are not, they can help guide test selection and ensure timely referral. Overreliance on imaging

studies often results in false-positive diagnoses.

History

In elucidating the basic features of back pain (i.e., quality, location, onset, radiation), one should also inquire specifically into symptoms potentially indicative of serious underlying disease (e.g., fever, progressive neurologic deficits, bilateral deficits, bladder dysfunction, saddle anesthesia, persistent pain unresponsive to bed rest). A history of recent injury and a prior history of cancer are other critical elements to be noted, as are previous therapy for back problems, recent lumbar puncture, concurrent infection, and prolonged use of high-dose corticosteroids.

The presence of sciatica helps narrow the differential diagnosis (Table 147.1).

Aggravating and alleviating factors may have diagnostic meaning. Morning stiffness in the back that is relieved by activity suggests ankylosing spondylitis or other inflammatory conditions. Worsening or onset of symptoms with standing or walking and relief with bending or sitting is characteristic of spinal stenosis, whereas worsening with sitting, driving, or lifting points to lumbar disk herniation.

The patient should be asked to describe the impact of the back pain on daily activities. Emotional and social stressors are sought if severity and duration of the symptoms appear disproportionate for the amount of organic disease present. Under such circumstances, it is important to check for depression (see Chapter 227) and manifestations of somatization disorder (see Chapter 230).

Physical Examination

Before examining the back, one should check the abdomen, rectum, groin, pelvis, and peripheral pulses for conditions that might mimic the symptoms of spinal disease. In addition, one looks for fever, skin abscess, breast mass, pleural effusion, prostate nodule, lymphadenopathy, joint inflammation, and other signs of systemic or malignant disease that may affect the spine. Thigh and calf circumferences are measured to detect evidence of atrophy, and joint motions of the lower extremities are tested.

Back Examination begins with the patient standing and the back uncovered. One checks for any abnormalities in symmetry, muscle bulk, posture, and spinal curvature. Flexibility is assessed, with any muscle spasm or spinal segments that do not move freely noted. A description of what limits back motion is more important than an estimation of degrees of motion, which is imprecise at best. The spine is palpated for focal tenderness suggestive of tumor, infection, fracture, or disk herniation. Sensitivity of the lower lumbar spine and sciatic notch is usually found with lower lumbar disk problems. Sacroiliac tenderness to deep palpation is sometimes present in ankylosing spondylitis, but the finding is nonspecific.

Straight Leg Raising (SLR) Test is an important component of the assessment for disk disease. The maneuver serves as a sensitive indicator of lower lumbar disk herniation, particularly in patients with sciatica. SLR testing is based on the observation that an L-5 or S-1 nerve root tethered by a herniated disk causes radicular pain if stretched. In the presence of a severely herniated disk, the additional root stretching causes impingement and pain, especially with an L5-S1 disk injury.

Straight leg raising is performed in the supine position with passive lifting of the patient's leg at the heel while the knee is kept fully extended. The test is performed both on the side of the reported sciatica ("*ipsilateral*" *SLR testing*) and on the opposite side ("*contralateral*" or "*crossed*" *SLR testing*). A test result is positive if the sciatica is reproduced as the leg is elevated between 30 and 70 degrees. Reproduction of the sciatica should not be confused with hamstring muscle tightness, which can also cause discomfort on SLR, especially as elevation approaches 90 degrees. (Elevation beyond 90 degrees exerts little additional stretch on the nerve root and is not of much meaning.) If severe pain is reported on elevation and resistance occurs, yet the leg can be raised another 20 or 30 degrees when the patient is distracted, the test result is "negative" and other causes of the pain should be sought, such as hamstring muscle tightness. Dorsiflexion of the ankle at the extreme of SLR may exacerbate the pain of disk herniation on SLR testing and is particularly useful if the SLR test result is equivocal.

The earlier the onset of pain during the test, the more specific the result and the greater the degree of disk herniation. Test sensitivity averages 80% for ipsilateral SLR; specificity is low (about 40%). The specificity of a positive contralateral SLR test result is considerably higher (75%), but the sensitivity is only 25%. A large disk herniation with an extruded fragment is an important cause of a positive contralateral SLR result.

Much less L-4 and minimal L-2 or L-3 movement occurs during SLR testing, so that it is less useful to detect disk herniation above L4-5. Femoral nerve sensitivity is usually present with higher lumbar (L-2, L-3, or L-4) root irritation. Flexing the knee with the patient lying in a prone position may reproduce the back and anterior thigh pain of upper lumbar disk herniation.

Neurologic Examination is most efficiently performed by concentrating on the areas of compromise suggested by the history. The patient with sciatica is most likely to have deficits in the territory of the L-5 and S-1 roots and should be tested accordingly. The person with back pain radiating to the anterior thigh and associated quadriceps weakness should be tested for L-4 function. A history of urinary retention requires a check of sacral root motor and sensory function.

Tests for *S-1 root* function (L5-S1 disk) include tiptoe walking, plantar flexion against resistance, ankle deep tendon reflexes, and lateral foot sensation. Loss of plantar flexion occurs only with severe disk herniation (low sensitivity, high specificity). Tests for *L-5 root* function (L4-L5 disk) include heel walking (an imprecise test), dorsiflexion of the ankle and big toe against resistance, and sensation on the anterior medial dorsal foot (Fig. 147.1). For a suspected upper lumbar disk lesion (*L-4 root*), one notes the knee deep tendon reflexes, quadriceps strength, and sensation about the medial ankle.

The sensitivity of any single neurologic test for the diagnosis of lumbar disk protrusion or extrusion is no greater than 50%, but it can be enhanced to almost 90% when clusters of findings are considered. The most accurate assessment of sensory function is attained by pinprick testing, most efficiently performed by limiting the examination to a few key distal dermatomal areas in the feet (Fig. 147.1) and noting any asymmetry of response. Responses in patients with psychological stress to neurologic testing and spinal examination may appear neuroanatomically inappropriate, but often they are diagnostically meaningful. Disturbances in strength or sensation that do not correspond to nerve root innervation patterns, inconsistency of responses to maneuvers, overreaction to palpation or passive movement, superficial or widespread tenderness, and pain on sham testing of spinal rotation (arms kept at sides while hips are rotated) are among the characteristic responses. The presence of three or more of these responses suggests considerable psychological overlay to the patient's back pain.

Laboratory Studies

For the majority of patients with low back pain, a careful history and physical examination usually suffice for diagnosis at the time of the initial office visit. The utility of imaging studies is limited to a few specific situations, many of which are also indications for referral or consultation (see later discussion).

Lumbosacral Spine Films. In most instances, the routine ordering of plain lumbosacral spine films in patients presenting with back pain is low in yield and neither cost-effective nor useful for decision making. The finding of normal disk spaces does not rule out disk herniation, and the finding of a narrowed disk space does not distinguish between disk rupture and asymptomatic degeneration. The presence of osteophytes extending from the vertebral bodies indicates little more than long-existing disk degeneration and attempts at repair.

Nonetheless, early radiography of the back is indicated in some situations, as when the physician suspects (a) malignancy (patient older than 50 years, focal persistent bone pain unrelieved by bed rest, history of malignancy); (b) compression fracture (prolonged corticosteroid therapy, postmenopausal woman, severe trauma, focal tenderness); (c) ankylosing spondylitis (young male patient, limited spinal motion, sacroiliac pain); (d) chronic osteomyelitis (low-grade fever, high sedimentation rate, focal tenderness); (e) major trauma; and (f) major neurologic deficits. Back pain localized to the high lumbar or thoracic region is also an indication for prompt spinal radiography because compression fracture and metastatic tumor are common in these areas. Plain films may be needed for patients seeking compensation for back pain and for those who desire reassurance, but they are of little use in early osteomyelitis (in which bony changes take 10 to 14 days to appear).

Computed Tomography and Magnetic Resonance Imaging. If severe symptoms persist for several weeks despite conservative therapy and disk herniation or other surgically correctable disease is suspected, then computed tomography (CT) or magnetic resonance imaging (MRI) may be useful. These are both very sensitive tests for the detection of lumbar disk disease or spinal stenosis and can provide anatomic detail of some surgical value. The cost of CT of the lumbosacral spine is less than the cost of MRI, but CT involves radiation exposure and does not provide the visualization of the entire spine or upper vertebrae that MRI does (desirable

features if the differential diagnosis includes intraspinal tumor and disk herniation at an upper level). Besides being costly, MRI often triggers a claustrophobic response, but no radiation exposure is involved. MRI is the best available test to detect early osteomyelitis and is also the noninvasive test of choice for spinal cord tumors, epidural abscess, and cord compression. In many instances, it obviates the need for myelography. CT provides excellent bony detail and shows changes in vertebral bodies caused by tumor and infection. MRI may reveal such pathologic findings even earlier than CT because it can detect marrow changes, which precede bony changes.

MRI and CT should be limited to patients who are either sufficiently symptomatic that surgical intervention must be considered or are suspected of having serious systemic disease. The high sensitivity of these tests for disk disease can produce misleading results unless the patient and clinician are aware that disk bulges and protrusions are extremely common (50% and 30%, respectively) in asymptomatic people.

Myelography has been largely replaced by MRI. It is best performed in conjunction with CT on patients with progressive neurologic deficits, especially those with findings suggestive of injury to the spinal cord (e.g., loss of sphincter control, bilateral numbness and weakness). The temptation to perform myelography in the patient with chronic refractory pain is strong, but the test should be reserved for patients with objective findings that are amenable to surgery or radiation therapy.

Radionuclide Scanning. The moderately high sensitivity of the technetium bone scan for osteomyelitis and metastatic disease and its wide availability make it a reasonable consideration for the patient presenting with any combination of fever, weight loss, persistent back pain, history of malignancy, concurrent infection, and markedly elevated sedimentation rate. Gallium scanning is sometimes useful in defining soft-tissue involvement by infection or abscess formation.

Immunoelectrophoresis of serum and urine samples diagnoses most cases of myeloma; crude screening with a complete blood cell count and determination of the erythrocyte sedimentation rate and serum globulin level is probably sufficient if clinical suspicion is not high. A diagnosis of myeloma must be suspected if back pain in an older person is accompanied by unexplained anemia and a very high sedimentation rate. However, such findings are quite nonspecific and may also be caused by a chronic inflammatory process.

Electromyography may be needed to document peripheral nerve deficits and help select patients who require myelography.

SYMPTOMATIC MANAGEMENT AND PATIENT EDUCATION

Acute Back Pain

Acute musculoligamentous strain, degenerative disk disease, and lumbar disk disease with or without sciatica are best managed conservatively. Bed rest was formerly a mainstay of treatment, but randomized trials have demonstrated that recovery is more rapid in patients who continue their ordinary activities within the limits permitted by pain than in those who go to bed.

Some patients are severely incapacitated by pain at rest as well as with movement. The acute discomfort usually persists for at least several days. Symptomatic measures consist of local application of heat or warm baths and the use of mild analgesics. Antiinflammatory agents have been shown to be effective in randomized trials and are preferred over narcotics for all but the first night or two of symptoms. Most so-called muscle relaxants are actually minor tranquilizers; they have little direct effect on muscles but can be of help to the patient who cannot sleep. The patient in pain should be advised to experiment to find the most comfortable position in bed. Lying supine with pillows behind the knees and a low pillow for the head usually suffices. Lying on one's side with the hips and knees flexed is sometimes quite comfortable; lying prone is usually not.

Even for patients with continuing pain and evidence of disk protrusion or extrusion, there is little evidence to support prolonged bed rest. Deconditioning with bed rest can contribute to physical and psychological morbidity.

Activity Prescription. For patients with disk protrusion or extrusion, a major goal is to avoid prolonged inactivity and the deconditioning that accompanies it. A reasonable activity program during the first week consists of walking for about 20 minutes three times a day, interspersed with several hours of bed rest. After the spine has healed sufficiently to allow sitting without pain, the patient can ease into a program of endurance exercises that may help prevent future back problems (see later discussion).

A reasonable program of back care should be discussed after recovery from acute symptoms allows gradual mobilization and resumption of normal activities. The patient must understand that pain is a normal protective response to injury or inflammation. Discomfort should be used as a guideline to determine the pace at which to increase activity. However, minor discomfort, stiffness, soreness, or mild aching should not interfere with progressive mobilization.

If symptoms recur or marked pain develops in relation to a specific activity or level of activity, the patient should temporarily limit activity for several days. If the patient undertakes a new or higher level of activity and pain increases within 24 hours, the activity should be halved each day until a tolerable level is reached and then gradually increased. The patient should be encouraged to progress as rapidly as symptoms permit.

Exercises and Back Care. Proper back care should become a way of life for the patient, even though acute symptoms subside with rest. The patient is advised to avoid activities that cause pain, and also potentially injurious actions such as repetitive bending, heavy lifting, and shoveling snow. Increasing evidence suggests that physical therapy programs designed to improve muscle strength and flexibility are effective, helping to maintain good posture and reduce the chances of recurrent injury. Instruction sheets are often useful to supplement instruction in the office (Fig. 147.2 and Fig. 147.3). Controlled trials have failed to confirm any benefit from the use of traction or braces in patients with disk herniation. In fact, it is of concern that restriction of movement may promote muscle weakness. A program of mild daily exercise with more vigorous endurance exercise two to three times a week is also encouraged and appears more useful than traditional isometric exercises. Brisk walking for 20 minutes once or twice a day, supplemented by swimming twice weekly for up to 30 minutes, fulfills such an exercise requirement. Stationary bicycling or jogging can be substituted for swimming.

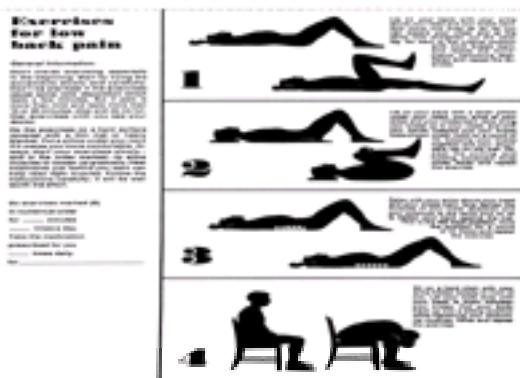
Figure 147.2. Sample instruction sheet describing care of the back. (Courtesy of McNeil Laboratories, Fort Washington, PA.)


Figure 147.3. Sample instruction sheet describing exercises for low back pain. (Courtesy of McNeil Laboratories, Fort Washington, PA.)

Spinal Manipulation by chiropractors and osteopaths may be the most common treatment for back pain. Metaanalytic study of randomized, controlled trials comparing spinal manipulation with other established therapies for acute and chronic low back pain finds that manipulation may offer some benefit, but no more than other moderately effective treatment modalities, such as back exercises, analgesics, physical therapy, and an educational program for back care. Manipulation is superior only to sham manipulation and other proven worthless treatments (see below). Of note, patients seen by either a physical therapist or chiropractor report being more satisfied with their care, suggesting a stong role for support and the laying on of hands. The safety of spinal manipulation in the setting of root compression, either by disk protrusion or extrusion or spinal stenosis, is not established. Most physicians advise patients with evidence of disk root impingement to avoid spinal manipulation therapy.

Persistent Pain or Worsening Neurologic Deficits

Patients with evidence of lumbar disk herniation who experience (a) persistent disabling root pain despite 4 to 6 weeks of comprehensive conservative therapy, (b) progressive neurologic deficits in the lower extremities, or (c) disruption of bowel or bladder control are strong candidates for surgery. *Disk excision (diskectomy)* by open surgery is mandatory and urgent for patients with massive disk herniation causing a cauda equina syndrome. It is also indicated in cases of major progressive neurologic deficit, calcified disk, extruded disk fragments that are not in continuity with the disk space, or pain caused primarily by bony abnormalities rather than by disk herniation. Relative indications for surgery include chronic disabling low back pain that persists after resolution of more acute symptoms, and frequent acute recurrences of severe back pain that the patient cannot prevent by following a careful program of back care.

Chymopapain disk injection is an option for patients who do not require an open procedure, although it is not indicated for backache alone. This naturally occurring enzyme acts to solubilize the nucleus pulposus, and in doing so, it decreases nerve root pressure with an effect very much like that of surgical disk excision. Hazards include possible nerve damage from the technique of lateral needle placement, diskitis, infection, and, in 1% to 2% of cases, an anaphylactic response. The incidence of complications is very low, and the drug is thought to be quite safe overall. However, many patients still experience back spasm and pain for several weeks after the treatment, so that the recovery period is about the same as that for surgery. Although enthusiasm for the procedure has waned, in experienced hands it still represents a less invasive means of treating disablingly painful disk herniation.

Some patients seek treatment from chiropractors, acupuncturists, and other paramedical practitioners. In a double-blinded, controlled study, *acupuncture* proved no better than placebo for the treatment of chronic back pain. No controlled studies of *chiropractic manipulation* for chronic back pain have been performed. *Injection of facet joints* with corticosteroids has been used in some patients with chronic back pain, under the presumption that a component of facet joint arthritis might be contributing to the pain. Controlled trials have shown it to be no better than placebo. The findings are similar for epidural injection to treat sciatica caused by a herniated nucleus pulposus. Despite initially enthusiastic reports, a controlled study also found *transcutaneous electrical nerve stimulation* (TENS) to be ineffective.

Chronic Refractory Back Pain in the Absence of Anatomic Deficits

Patients with chronic refractory back pain and no clear anatomic deficits pose one of the most difficult long-term management problems encountered in primary care practice. Persistence of symptoms may be encouraged by social factors such as *pending litigation* or *application for disability*. At other times, the patient's amplification of symptoms and refractoriness to treatment may be manifestations of an underlying *depression* or *somatization disorder* (see Chapter 227 and Chapter 230).

There are no simple solutions to the management of these patients. Many patients do not take an active role in their own treatment and frustrate the well-intentioned efforts of physicians while they continue to complain of discomfort. However, some important objectives can be achieved: identification and treatment of underlying psychopathology; avoidance of inappropriate tests, addictive medications, ineffective therapies, and unnecessary surgery; and preservation of the patient's capacity to function independently.

Addressing Underlying Psychopathology and Social Factors. If depression is encountered, it should be treated (see Chapter 227) regardless of whether it is the cause or result of the patient's condition. For the person with a suspected somatization disorder, therapeutic efforts are best directed at helping the patient to find ways other than suffering to achieve a sense of self-worth. Attempts to "cure" such persons physically actually remove their one source (albeit maladaptive) of personal value. Such efforts are bound to be sabotaged by patients unless they find something to replace their back pain (see Chapter 230). Patients with pending legal matters should be strongly encouraged to settle them as quickly as possible. If a disability determination is needed, it should be expedited. Arranging an independent evaluation may be best. This avoids jeopardizing the patient–doctor relationship, particularly if the physician does not feel comfortable certifying that the patient is physically disabled.

Protecting the Patient from Unnecessary Procedures and Narcotics. Patients with chronic refractory back pain are at considerable risk for invasive testing (e.g., myelography) and surgery, even though they may lack symptoms and signs that are considered proper indications for such procedures. The primary physician needs to protect such patients from unnecessary and potentially harmful interventions. One way to accomplish this objective is to arrange a consultation for the patient with an orthopedic surgeon or a neurosurgeon experienced in back problems, so that the patient does not feel the need to "shop around" for a willing surgeon.

Avoiding prolonged or repeated reliance on narcotics for pain control is a key management priority. A patient may repeatedly demand strong analgesic agents, but unless an acute and reversible cause of the pain is found, the use of narcotics should be avoided if at all possible. An assessment for substance abuse should be considered when a patient with back pain persistently requests narcotics (see Chapter 235).

Preserving Capacity to Function Independently. Establishing a strong doctor–patient alliance (see Chapter 1.1) and attending to underlying psychosocial issues are prerequisites to engaging the patient in a program of self-help. The caring, concern, and responsiveness that characterize a strong relationship help foster patient confidence and receptiveness. Even though symptoms may not disappear, it is often possible to keep the patient functioning independently through cultivation of the relationship and promulgation of a program of activity and exercise. Arranging regularly scheduled visits at intervals meaningful to the patient facilitates the sense of support and can forestall many anxious phone calls and unannounced office appearances.

PATIENT EDUCATION

The importance of patient education cannot be overemphasized for the person with back pain. Surveys of patients with back pain find that a lack of information is the greatest source of dissatisfaction with care. Patients suffering from a condition that suddenly disables them are extremely anxious and in need of detailed information about what has happened, what can be done, and what lies ahead. Even if the diagnosis has not been established, a review of the working differential helps one deal with the uncertainty of the situation. The use of a model of the spine greatly simplifies explanation and helps many patients better understand their condition. Patients with disk herniation can be reassured that the natural history of their condition is generally favorable, with most responding well to conservative therapy and very few suffering prolonged physical disability. Active patients are greatly relieved to know that jogging, stationary cycling, and swimming are not only possible but often desirable, and that reemergence of mild to moderate discomfort with resumption of activity is to be expected and is not a worrisome prognostic sign. At the same time, it is important to review with the patient the symptoms of serious neurologic injury that would necessitate prompt reporting and hospital admission. The rationale and anatomic basis for back hygiene measures and exercises also need to be reviewed to ensure compliance and proper implementation. A good outcome is greatly

facilitated by keeping the patient well informed.

INDICATIONS FOR ADMISSION AND REFERRAL

Patients with rapidly progressive neurologic deficits require prompt neurologic and surgical consultations. Urgent admission and referral are indicated if symptoms suggestive of cauda equina syndrome or cord compression develop (e.g., new bilateral neurologic deficits, urinary retention, sphincter incontinence, saddle anesthesia). The same is true for patients with acute vertebral collapse because spinal stability may be compromised by the fracture. Suspicion of osteomyelitis or epidural abscess is an indication for immediate hospitalization and infectious disease consultation. Particularly in patients with epidural abscess, treatment must be initiated early to be effective.

If back pain remains severe and intractable after 4 to 6 weeks of conservative therapy, or if an important neurologic deficit develops (e.g., foot drop, gastrocnemius–soleus or quadriceps weakness), then further evaluation and consideration of surgery are indicated and referral to an orthopedist or neurosurgeon with a particular interest in back problems can be helpful. Even if the patient does not have sciatica or neurologic deficits and is therefore not a candidate for surgery, the referral can serve to reassure the patient that a surgically correctable lesion is not being overlooked and that the efforts of the primary physician are appropriate.

CHAPTER 148 EVALUATION OF NECK PAIN

ALLAN H. GOROLL

INTRODUCTION

The primary physician is often faced with the patient who complains of a stiff neck; most of the time, the problem is musculoskeletal in origin. Although the majority of musculoskeletal causes are not serious, they can result in considerable discomfort. One should be able to provide symptomatic relief to the person with a minor neck problem and to identify the patient with a serious complication of cervical spine disease, such as root compression or cord injury, that requires surgical attention.

PATHOPHYSIOLOGY AND CLINICAL PRESENTATION

Neck Strain. The most common form of neck pain is caused by *cervical paraspinal muscle spasm*, usually secondary to minor strain or prolonged, unconscious muscle contraction associated with emotional stress. The problem is usually self-limited. Neck pain caused by minor muscle ligament strain is usually self-limited if aggravating activities are avoided. A relapsing clinical course is not uncommon. Muscle spasm also occurs with cervical degenerative disease (see below).

Severe neck strain is seen in *cervical hyperextension* ("*whiplash*") *injury*, typically sustained in an automobile accident. Sudden hyperextension of the neck followed by flexion results in musculoligamentous strain. Tearing of muscle fibers leads to bleeding, swelling, severe muscle spasm, and pain. Symptoms increase gradually during several hours, often becoming most severe the day following the acute event. The anterior or posterior ligaments of the cervical spine may be disrupted. Neurologic deficits are rare unless a cervical spine fracture is present that leads to root or cord compression. Refractory pain lasting more than 6 months may represent injury to a zygapophyseal joint, although other causes include the psychological stress of ongoing litigation and pending legal proceedings.

Degenerative Disease. Trauma or degenerative changes in the intervertebral disks or joint facets can be a source of neck pain and result in ankylosis or subluxation of the cervical spine, termed *cervical spondylosis*. Immobility and consolidation of the joint may ensue. Usually, the process is localized to the lower cervical levels, such as C4-5, C5-6, or C6-7. Degenerative changes and spurring at the cervical disk spaces are prominent. The condition presents as recurring neck stiffness and mild aching discomfort, with progressive limitation of neck motion over months to years. Lateral rotation and lateral flexion of the neck toward the painful side are limited; pain is precipitated or increased by such motions.

Cervical disk degeneration can lead to narrowing of the neural foramina that causes *root impingement* and pain. Pain radiates in the distribution of the affected nerve root, and paresthesias, numbness, and weakness may be associated. The C-5, C-6, and C-7 nerve roots are most often affected. C-5 root compression results in the development of pain, paresthesias, and numbness in the anterosuperior shoulder and anterolateral aspect of the upper arm and forearm; a decreased biceps jerk and weakness of elbow flexion are found on examination. Compression of the C-6 nerve root produces symptoms in the dorsoradial aspect of the forearm and thumb, whereas C-7 impingement is denoted by altered sensation in the middle of the hand. The brachioradialis tendon reflex is affected by conditions altering C-5 and C-6, and the triceps jerk by injury to the C-7 and C-8 roots.

Inflammatory Disease. *Rheumatoid* disease can produce neck pain; it is typically worse in the morning. Concurrent symmetric polyarthropathy and subluxation at C1-2 (identifiable on plain films of the neck in flexion and extension) are characteristic. In the *spondyloarthropathies*, neck pain occurs in the context of diffuse back and sacroiliac discomfort. The earliest radiologic signs are those of sacroiliitis visible on sacroiliac joint films; advanced disease produces syndesmophytes. In *polymyalgia rheumatica*, neck pain may accompany the aching discomfort and stiffness of the shoulders and hip girdle that predominate in this condition. Polymyalgia complicated by *giant cell arteritis* with carotid artery involvement can produce focal neck tenderness along one or both carotid arteries, sometimes referred to as *carotodynia*.

Malignancy. Tumor may infiltrate the spinal cord or the vertebral bodies and produce pain that is worse at night or while lying down. Cord involvement may be heralded by neurologic deficits in addition to the nocturnal pain.

Referred Pain. Neck pain radiating to the jaw is characteristic of *coronary ischemia*, which is usually precipitated or worsened by physical activity. Concurrent arm pain may simulate a cervical radiculopathy. *Esophageal* disease may produce pain referable to the neck; if a cancer of the esophagus extends into the prevertebral space, posterior pain may develop.

DIFFERENTIAL DIAGNOSIS

The musculoskeletal causes of neck pain include muscle strain, muscle spasm, cervical spondylosis, and cervical root compression. Lymphadenopathy, thyroiditis (see Chapter 104), angina pectoris (see Chapter 20), and meningitis are important causes of cervical pain that may be mistaken for a musculoskeletal problem.

WORKUP

History. Inquiry should focus on elucidating precipitating events, aggravating and alleviating factors (particularly specific neck movements), area of maximal tenderness, radiation of pain, presence of numbness or weakness in the extremities, course, past history of similar problems, and previous therapeutic efforts. One also should consider symptoms suggestive of coronary artery disease (see Chapter 30) or meningeal irritation.

Physical Examination. Physical examination must include full visualization of the neck, thorax, and upper extremities. Neck motions are assessed, including flexion–extension, left and right lateral flexion, and left and right rotation. The neck must be carefully palpated to identify the point of local tenderness, which gives the best indication of the structure involved. Careful examination of the upper extremities is also required and should include an evaluation of tendon reflexes, strength, sensation, range of motion, and pulses. Every patient with fever and neck pain should be tested for meningeal signs.

Laboratory Studies. In cases of nontraumatic neck strain, no studies are necessary. The only finding may be a loss of the normal lordotic curve. In cases of traumatic neck strain caused by a hyperextension injury, *cervical spine films* are required to rule out structural damage. Clinical evidence of root or cord compression is an indication for *magnetic resonance imaging* (MRI); *computed tomography* (CT) with *myelography* can be performed if MRI is not available or if surgery is contemplated. Degenerative disease and ankylosing spondylitis may be suggested by *plain films* of the *neck*, but in early spondylitis, plain films of the *sacroiliac joints* may be needed to detect early bony changes. MRI is not indicated for the assessment of degenerative disk disease unless neurologic compromise is noted because test specificity is poor (up to half of asymptomatic persons have disk herniations on MRI). Suspected tumor requires *bone scan* or CT if bony involvement is suspected, and MRI if marrow or cord compression is of concern.

SYMPTOMATIC MANAGEMENT

Most causes of neck pain are self-limited and resolve with time. However, the discomfort can be considerable, so that symptomatic measures are necessary.

Strain. Heat, ice, and gentle massage may ease muscle spasm. Although widely prescribed, most so-called *muscle relaxants* are actually minor tranquilizers marketed as relaxants; they are of limited value for prolonged use but can be useful on a short-term basis, especially in helping the patient to sleep. More useful and less expensive are therapeutic doses of an *NSAID* (e.g., aspirin, ibuprofen), supplemented for a few days by a small nighttime dose of a generic *benzodiazepine* (e.g., 5 mg of diazepam at bedtime). Prolonged benzodiazepine use is to be avoided (see Chapter 226). Strengthening and range-of-motion *exercises* are helpful. A soft

cervical collar may be used to rest sore neck muscles briefly, especially at night; however, prolonged wear should be discouraged, as it may lead to muscle weakening from disuse atrophy. No good evidence has been found that injecting anesthetic into the tender body of a muscle in spasm speeds resolution of the problem; injection may actually injure the muscle.

More severe strain, such as that resulting from whiplash injury, poses a more difficult management problem. Although patients prefer wearing a cervical collar acutely because neck movement is painful, use of the collar should be limited to the period of severe pain and eliminated when pain has eased. Prolonged use of a collar actually increases the duration of pain, limits the return of neck mobility, and slows the clinical course. Emphasis should be placed on return of neck function and range of motion. A strong educational effort regarding the goals of treatment and proper neck exercises helps considerably, as does advice to settle any litigation as quickly as possible.

Spinal manipulation if often performed for patients with chronic strain, but its utility, safety, and indications for use remain to be defined by properly designed prospective, randomized trials. In one of the few well-designed randomized trials to date that compares medical therapy, physical therapy, and manipulation in persons with nonspecific persistent neck pain of at least 2 weeks' duration, manipulation provided the best results at 7 weeks in terms of pain relief and functional status. However, such therapy was also associated with the highest rates of adverse effects, including increased neck pain for more than 2 days (18%), headache (28%), and pain or paresthesias in the arms (13%). Manipulation should be avoided when neurologic compromise or nerve root or cord impingement is a possibility. *Ultrasound* and *diathermy* treatments also provide subjective improvement beyond that derived from medical management, but often no more than placebo forms of these therapies. **Updated: 6/10/02**

Degenerative Disease. In cases of disk herniation associated with radiculopathy, symptomatic therapy is aimed at countering the inflammation and root compression responsible for pain. *Nonsteroidal agents* (e.g., generic ibuprofen or naproxen) are useful to treat inflammation, and a *cervical collar* helps minimize compression. Several weeks of continuous collar use may be necessary; the collar should be worn regularly until pain disappears. After pain lessens, the collar can be worn at those times when added support may be helpful, such as at night or when riding in a motor vehicle. A properly fitting collar holds the neck in gentle flexion (the neutral position); collars that produce excessive extension are to be avoided because they may aggravate root compression.

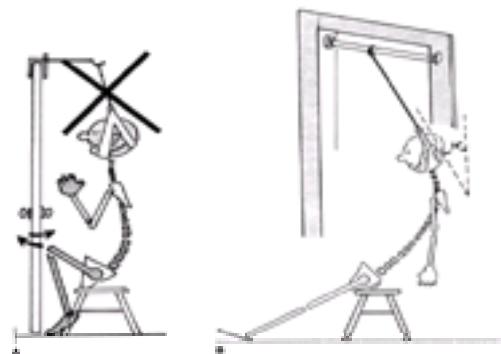
Home cervical traction is indicated for severe, chronic, or recurrent neck pain caused by cervical spondylosis or disk herniation associated with radiculitis. Sitting cervical traction is applied at home for 20 to 30 minutes, two to four times a day, with 6 to 10 pounds of weight. The cervical traction apparatus must be carefully aligned and pull slightly forward at an angle of about 20 degrees to follow the natural line in the neck (Fig. 148-1). Proper technique is essential for effective and safe use. *Spinal manipulation* is contraindicated because of its potential to worsen root or cord compression. Ultrasound and diathermy treatments are harmless but of little proven benefit and probably no better than other means of delivering local heat to an area of concurrent muscle spasm. *Surgical management* may be required in refractory disease, especially when neurologic compromise is present.


Figure 148-1. A: Ineffective home cervical traction with a door. The patient is too close to the door to obtain the correct angle for neck flexion. The door freely opens and closes and so does not permit constant traction. The patient cannot extend the legs or assume a comfortable position. This type of home traction is not recommended. **B:** Recommended home traction with a chinning bar and in the sitting position. (From Cailliet R. Soft tissue pain and disability. Philadelphia: FA Davis Co, 1977:129, with permission.)

INDICATIONS FOR ADMISSION AND REFERRAL

Meningeal signs are an obvious indication for urgent hospitalization. If significant weakness in the upper extremity or evidence of cord pressure is noted, then neurosurgical referral is indicated. Any signs suggestive of cord injury (hyperreflexia, upturned toe, incontinence or retention, bilateral neurologic deficits) are an indication for urgent neurosurgical consultation because the outcome is best when surgical treatment is early and definitive. If the patient has intractable chronic pain that is unresponsive to conservative measures, then consultation with a neurologist before the neurosurgical or orthopedic referral can sometimes be beneficial, especially to review the findings and discuss treatment options.

The patient with persistent neck pain is likely to request or ask about physiotherapy (e.g., diathermy, ultrasound, spinal manipulation). Careful review of the available data on these procedures with the patient can lead to an informed choice that is mutually satisfactory and minimizes risk and unnecessary expense. More beneficial to outcomes might be referral to a skilled physical therapist who, in a few sessions, can teach proper neck care and range-of-motion and neck-strengthening exercises.

CHAPTER 149 APPROACH TO THE PATIENT WITH MUSCLE CRAMPS

Muscle cramps are prolonged, involuntary muscle contractions that can be painful and difficult to manage but rarely reflect serious underlying disease. True cramps must be differentiated from ischemic pain, contracture, tetany, and dystonia. Fluid and electrolyte disorders, medication, and endocrinologic disorders must be considered in the evaluation, although they are uncommon precipitants. Patients come in requesting symptomatic relief from these painful episodes, which can be temporarily disabling.

PATHOPHYSIOLOGY AND CLINICAL PRESENTATION

True Cramps

True muscle cramping represents motor unit hyperactivity leading to prolonged, involuntary muscle contraction. Precipitants include unopposed contraction, electrolyte and volume shifts, and lower motor neuron disease. *Ordinary cramps* most commonly occur in the gastrocnemius muscle and the intrinsic muscles of the sole of the foot. Their *nocturnal* predilection appears to be related to unopposed plantar flexion of the foot in bed, which places the muscles of the calves and feet in their most shortened and therefore most vulnerable position. Without modulation by opposing muscles, the sustained contraction produces a cramp, which is experienced as sudden, severe calf pain; often, the muscle is palpable or visibly hardened. In many instances, a voluntary contraction triggers the cramp. Passive stretching relieves it.

True cramps may be precipitated by *volume* and *electrolyte shifts*, which accounts for the fact that they frequently occur during hemodialysis and can be relieved with administration of hypertonic dextrose. *Heat cramps* that occur during activity are a consequence of dehydration and sodium loss and respond to replenishment. *Hyponatremia* is a consistent feature of fluid-based muscle cramps, but hypokalemia is not, contrary to common belief. Cramps attributable to potassium-wasting diuretics are actually uncommon. Ordinary cramps are often a part of symptomatic *hypoglycemia*.

Muscle cramps are sometimes *drug-induced*, as may occur with nifedipine, b-agonists, and occasionally heavy alcohol use.

The cramp is a neural or electrical phenomenon, not primarily muscular. Electromyography shows fasciculations preceding the cramp. Cramps accompanied by clinically evident fasciculations are characteristic of *lower motor neuron diseases*, such as polio in the recovery phase, peripheral nerve injury, nerve root compression, and amyotrophic lateral sclerosis.

Other Forms of Muscle Cramping

Contractures also represent involuntary muscle contractions, but they are electrically silent and characteristically occur during exertion, not rest. They develop in persons who have inherited metabolic defects that impair the formation of adenosine triphosphate, which is needed for muscle relaxation. Most patients have McArdle's disease. Both hyperthyroid and hypothyroid disease may cause cramping. Exertional cramping has been seen in hyperthyroidism. In hypothyroidism, impaired muscle relaxation produces the "hung-up" reflexes that characterize the condition.

Tetany is a state of both motor and sensory hyperactivity, associated with muscle spasm and paresthesias. The muscles of the mouth, hands, and lower extremities are typically involved, and carpopedal spasm is a characteristic manifestation, as are Chvostek's and Trousseau's signs. Hypocalcemia, hypomagnesemia, respiratory alkalosis, and hypokalemia are known precipitants. In severe cases, seizures may ensue if the condition goes uncorrected.

Occupational cramp is a form of dystonia in which muscle contractures occur in persons engaging in fine motor activities that have taken years to perfect. The typical patient is a writer or pianist whose hands curl involuntarily when writing or playing is attempted.

DIFFERENTIAL DIAGNOSIS

See Table 149.1 for information on the differential diagnosis of muscle cramps.

```
True Cramps
    Ordinary (nocturnal)
    Heat-induced (volume depletion, hyponatremia)
    Hemodialysis (volume and electrolyte shifts)
    Lower motor neuron
    Drug-induced (nifedipine, β-agonists)
Dystonia
    Occupational (writer's cramp)
Tetany
    Hypocalcemia
    Hypomagnesemia
    Respiratory alkalosis
    Hypokalemia
Contracture
    McArdle's disease
    Thyroid disease

Adapted from McGee SR. Muscle cramps. Arch Intern Med 1990;150:511,
with permission.

Table 149.1. Differential Diagnosis of Muscle Cramps

WORKUP

History. A detailed description of the cramping is essential and should include the setting in which the episodes occur. Those that develop at night or in the context of hemodialysis, hypoglycemia, or heavy sweating during prolonged exertion are likely to be true cramps, as are those coincident with use of calcium channel blockers or b-agonists. Dystonic cramping is suggested by onset with occupation-related fine motor activity, and contracture by a lifelong onset with exercise. Associated symptoms should be reviewed for the paresthesias and carpopedal spasm of tetany, the weakness and fasciculations of lower motor neuron disease, and the cold or heat intolerance, skin changes, and related symptoms of thyroid disease (see Chapter 103 and Chapter 104). The location of the cramping is a less specific finding, but if calf pain is reported, one should include intermittent claudication in the differential diagnosis, particularly if pain is brought on by walking. A review of medications is always useful, but use of a potassium-wasting diuretic is not tantamount to an etiologic diagnosis because hypokalemia is rarely responsible for true cramps (although it should be considered in the differential diagnosis of tetany). Also potentially pertinent in suspected tetany is any distant history of thyroidectomy (with coincident removal of the parathyroid glands).

Physical Examination. If dehydration is suspected, the physical examination begins with a check of postural signs for a drop in blood pressure and rise in pulse. The skin is examined for signs of thyroid disease (see Chapter 103 and Chapter 104); the neck for evidence of thyroidectomy; the lower extremities for diminished or absent pulses, muscle wasting, and fasciculations; and the nervous system for focal weakness and absent or abnormal deep tendon reflexes. If tetany is a consideration, one can try to elicit the facial spasm of Trousseau's sign by tapping the facial nerve or the carpal spasm of Chvostek's sign by inflating the arm cuff above systolic pressure.

Laboratory Determinations can be of very limited value. For the majority of people who present with a clinical story of nocturnal muscle cramps, laboratory testing is

unlikely to provide additional information. Other situations do require a few simple tests. If the patient with ordinary cramps is diabetic and taking insulin, then testing for hypoglycemia is indicated (see Chapter 102). If severe dehydration and hyponatremia are suspected, then determinations of serum sodium, blood urea nitrogen, and creatinine levels can guide assessment and treatment. In the patient with possible tetany, levels of sodium, potassium,calcium, albumin (to interpret the calcium level), and magnesium must be checked. Consideration of thyroid disease is best pursued by obtaining a serum thyrotropin (TSH) determination. For the patient with fasciculations and possible lower motor neuron disease, a nerve conduction study may be required.

PRINCIPLES OF MANAGEMENT AND INDICATIONS FOR ADMISSION

Ordinary Cramps. To relieve an established cramp, one must passively stretch the contracting muscle and gradually contract the opposing one. In some cases, this can be accomplished by simply walking around, which produces a relative dorsiflexion of the foot.

Massage of the involved muscle sometimes helps. Conscious dorsiflexion at the first sign of a leg or foot cramp may abort it. Prophylactic stretching can also prevent attacks (see Chapter 18 for stretching exercise), as may positions in bed that prevent foot dorsiflexion. Swimming-induced cramps can be avoided by sacrificing the ideal kicking position of plantar flexion and maintaining a more neutral foot position.

Patients who have repeated attacks of nocturnal leg cramps seek a reduction in the frequency and severity of episodes. *Quinine sulfate* has been prescribed for decades for this purpose, but only recently have randomized, double-blind, controlled clinical trials been performed to assess its efficacy. Studies have shown that regimens with low to moderate doses (200 to 300 mg daily at bedtime) provide less benefit than those with higher doses (200 mg at supper, 300 mg at bedtime). This pattern suggests that response rates are related to the serum level attained, which can vary greatly with age of the patient and preparation used. The risk for serious side effects is quite small but increases with dose and serum level. Cinchonism (nausea, vomiting, tinnitus, hearing loss), visual impairment, and ventricular arrhythmias are the most important of these adverse effects and appear when serum levels exceed two to five times the average serum concentration. An immune thrombocytopenia, occasionally fatal, has also been reported.

Recently, a randomized, placebo-controlled, parallel-group trial, with more than 100 participants, demonstrated a substantial reduction in number of cramps and number of cramp-days with daily administration of 300 mg of *hydroquinine.* Side effects were mild and were noted by fewer than 10% of participants, and the treatment effect was sustained beyond the 2-week treatment period. The small but real risk for serious toxicity should temper one's uncritical use of quinine for this otherwise benign condition. However, for patients who are truly bothered by their symptoms, the evidence now justifies confidence in the effectiveness of quinine and its derivatives. A careful trial of quinine may be useful after the risks and benefits have been reviewed with the patient. Starting with small doses (200 to 300 mg daily at bedtime) is best, and the platelet count should be monitored periodically. Because of the evidence for a sustained effect, it is reasonable to interrupt treatment and reassess after 2 to 4 weeks.

Other drugs shown to be of some benefit include methocarbamol and chloroquine. Vitamin E is promoted in health food stores for the treatment of nocturnal cramps, but it has been found to be no better than placebo when tested in double-blind, placebo-controlled fashion. It may be found in combination with quinine. The calcium channel blocker verapamil has shown promise in preliminary study.

Patients with ordinary cramps related to dehydration and sodium depletion respond well to replacement therapy. Those with cramps as a consequence of hemodialysis are best treated with rapid volume expansion (infusion of hypertonic dextrose or saline solution). If hypoglycemia is responsible, then adjustment of the insulin regimen is needed (see Chapter 102). Altering the medication program may be necessary in cases in which b-agonists or calcium channel blockers are thought to be responsible.

Occupational Cramps are difficult to treat. Rest and occupational aids can be helpful; psychotherapy is not. Minor tranquilizers provide some short-term relief but little sustained benefit. Injection of botulinum toxin has been tried with some success.

Tetany requires urgent hospital admission and careful parenteral correction of the underlying electrolyte disturbances. For patients bothered by occasional muscle cramps, medication is not a serious consideration. For those who have frequent or prolonged cramps, prophylactic medication should be considered.

CHAPTER 150 APPROACH TO THE PATIENT WITH SHOULDER PAIN

JESSE B. JUPITER AND DAVID RING

The shoulder is a complex joint integrating three bones, four joints, and more than 15 muscles. The mobility of the shoulder exceeds that of all other joints, subjecting it to a wide range of stresses, both in normal activity and in occupational and recreational pursuits. Shoulder pain and dysfunction are among the more common musculoskeletal complaints encountered in office practice. Successful treatment necessitates an accurate diagnosis; common nonspecific diagnoses such as "bursitis" and "tendinitis" can be misleading and delay appropriate therapeutic measures. Besides being capable of identifying the cause of shoulder pain, the primary physician needs to know how and when to utilize exercises, antiinflammatory agents, and joint injection to provide safe and effective symptomatic relief.

PATHOPHYSIOLOGY AND CLINICAL PRESENTATION

Injury or degenerative change in the rotator cuff, bicipital tendon, or acromioclavicular joint can produce pain localized to the shoulder joint. Characteristically, focal tenderness is present and pain is aggravated during shoulder movement. Patients report difficulty in dressing, combing their hair, or reaching up. Degenerative disease of the glenohumeral joint is uncommon; symptoms include mild stiffness, crepitus, and low-grade, aching discomfort related to vigorous or sustained use. Pain originating in or about the shoulder may be referred to the upper arm or radiate to the neck, elbow, or forearm; it does not follow a specific cervical root distribution. Although pain originating in the neck may radiate to the shoulder, it is brought on by neck motion rather than by shoulder movement and is usually not affected by shoulder position. However, poorly localized sensitivity to touch extending into the shoulder may vaguely simulate shoulder disease (see Chapter 148).

Rotator Cuff Problems are the single most common source of shoulder pain seen in a primary care practice, particularly among older patients. The tendons of the cuff are subjected to considerable mechanical stress. Degenerative and attritional changes taking place over time in the tendons lead to structural weakening. The role of "impingement" of the rotator cuff between the greater tuberosity and acromion is debated. Early on during this process, the tendons become inflamed and the diagnosis of rotator cuff tendinitis is appropriate. As the degenerative process advances, failure of the tendons near their insertion into the proximal humerus may result in a *tear*. Such tears are not usually associated with specific traumatic events—they are the result of cumulative degenerative failure of the tendon. It is important to identify large tears of the rotator cuff promptly. Fatty degeneration of retracted rotator cuff muscles that occurs within a few months of a large tear makes the results of repair much less predictable.

The diagnosis of *rotator cuff tendinitis* should be applied with caution to patients younger than 40 years of age. In younger patients, rotator cuff tendinitis is usually secondary to some other process, such as instability. A tear of the rotator cuff tendon in a younger person—most commonly a tear of the *subscapularis tendon*—is typically a high-energy injury. Such tears are rare but should not be missed. Careful physical examination can verify that the rotator cuff is intact. Any doubt merits referral to an experienced shoulder surgeon.

Most patients with rotator cuff problems are older than age 40. Pain over the deltoid, especially during overhead activities and internal rotation, plus weakness of shoulder elevation and external rotation, are diagnostic features. It is very common for pain from the rotator cuff to be referred to the lateral arm. Superior shoulder pain suggests acromioclavicular joint problems. Muscle atrophy suggests a large tear.

Biceps tendinitis of the shoulder is a diagnosis that is now rarely made in isolation. Inflammation of the tendon of the long head of the biceps is a common component of rotator cuff degeneration.

Glenohumeral Joint Problems. The glenohumeral joint has little inherent stability; stability is heavily dependent on static capsuloligamentous and dynamic musculotendinous restraints. Two general categories of glenohumeral instability comprise the majority of such problems: traumatic unidirectional instability and atraumatic multidirectional instability.

Traumatic dislocation of the glenohumeral articulation almost always results in anterior dislocation of the humeral head from the glenoid articular surface of the scapula. Posterior glenohumeral dislocations are rare and are usually related to a seizure or electric shock injury. Traumatic posterior dislocations are often fracture dislocations of the glenoid articular surface.

Traumatic anterior dislocation nearly always disrupts the anterior attachment of the glenoid labrum to the glenoid articular surface (Bankart lesion). The labrum is a ring of fibrous cartilage that helps deepen the relatively shallow glenoid articular surface and is the site of attachment of the all-important glenohumeral ligaments. The likelihood that a patient who has had one traumatic anterior dislocation of the shoulder will have recurrent dislocations is related to the age of the patient at the time of the first dislocation. Of patients younger than 20 years at the time of first diagnosis, as many as 80% will have another dislocation. Older patients are less likely to have a recurrent dislocation, but tearing of the rotator cuff is common and must be identified. Recurrent anterior dislocation usually requires surgical treatment consisting of reattachment of the anterior portion of the labrum to the glenoid margin in addition to tightening of any redundant anterior capsule.

Atraumatic instability is usually related to laxity of a number of capsular restraints. In many cases, the patient may have a connective tissue disorder. Other patients, such as competitive swimmers, have multidirectional instability as a result of repetitive microtrauma. This type of instability usually responds to a program of specific exercises intended to strengthen the dynamic muscular stabilizers of the shoulder. Athletes may also need to modify their technique; a good coach or trainer can be useful in this regard.

Patients who can actively and voluntarily dislocate their shoulder should be approached with caution. Often, a subtle underlying psychiatric condition is present. Cases in which the voluntary dislocation is habitual—often, the patient has derived some attention or reward from the ability to dislocate a shoulder—can be difficult to manage. This should be distinguished from situations in which the voluntary dislocation is positional—the patient can reproduce the instability by placing the arm in certain position but is averse to doing so.

Adhesive capsulitis, or *frozen shoulder syndrome*, is a characteristic symptom complex of pain and tenderness located diffusely about the anterior and posterior regions of the shoulder joint capsule. Active and passive motions of the glenohumeral joint are limited to a small, pain-free arc. Glenohumeral motion slowly decreases during several weeks. The condition is often refractory to most forms of treatment, yet motion usually improves with time. The challenge for the clinician is to rule out the presence of an underlying rotator cuff, instability, or neurologic problem.

Osteoarthritis of the glenohumeral joint is very uncommon. It causes symptoms at rest that are exacerbated by shoulder use. The patient may note a "grinding" sound with motion. Muscle atrophy, "bone-on-bone" crepitation, and diminished motion are noted on examination. Rheumatoid arthritis frequently involves the glenohumeral joint and usually gives a picture of symmetrical bilateral inflammatory changes.

Acromioclavicular Degenerative Lesions. Degenerative changes are seen in patients who do heavy labor or engage in contact sports. Pain arises with activities above and in front of the body and localizes to the acromioclavicular joint; tenderness is maximal over the joint and does not radiate.

Infection. The patient with a shoulder joint contaminated by an improperly performed injection presents with marked swelling, redness, and fever.

Referred Pain. Shoulder–hand syndrome (also referred to as *reflex sympathetic dystrophy* or *sympathetic maintained pain*) follows myocardial infarction, stroke, trauma, and a host of other events. The characteristic features are the persistent burning pain of "causalgia," diffuse tenderness, immobilization of the shoulder, and vasomotor changes in the hands. *Gallbladder disease* is suggested by pain at the tip of the scapula in conjunction with upper abdominal pain and tenderness. With

diaphragmatic irritation, pain may be referred to the trapezius area running from the shoulder to the lateral aspect of the neck.

DIFFERENTIAL DIAGNOSIS

The causes of shoulder pain can be considered in terms of the structures that comprise the shoulder (Table 150.1). The vast majority of nontraumatic shoulder complaints are related to tendinitis.

Rotator Cuff
 Calcific tendinitis
 Subacromial impingement
 Biceps tendinitis
 Tear
 Adhesive capsulitis
Glenohumeral Joint
 Instability
 Dislocation
 Arthritis
 Infection
Acromioclavicular Joint
 Arthritis
Referred
 Cervical spondylosis
 Myocardial ischemia
 Shoulder–hand syndrome (reflex sympathetic dystrophy)
 Diaphragmatic irritation
 Thoracic outlet syndrome
 Gallbladder disease

Table 150.1. Important Causes of Shoulder Pain

WORKUP

History

One should inquire about previous trauma or an inciting event, location and radiation of pain, specific limitations of movement, associated neurologic deficits, aggravating and alleviating factors, previous history of shoulder problems, and therapies utilized. It is important to be sure that no symptoms suggestive of angina, gallbladder disease, or diaphragmatic irritation are present. Pain resulting from myocardial ischemia usually originates in the precordial region but may present as shoulder or neck pain radiating into the arm. Relief with rest or administration of nitroglycerine supports the diagnosis. An occupational history is occasionally revealing, especially if the patient has engaged in heavy labor or sports.

Patients with symptoms suggestive of shoulder disease describe a combination of pain, loss of mobility, and weakness. Pain associated with activities above the horizontal level suggests subacromial impingement or acromioclavicular joint arthritis. Pain occurring at night when the patient attempts to sleep with the arm overhead is characteristic of rotator cuff problems. Calcific tendinitis can be a cause of severe acute shoulder pain.

Overuse syndromes are commonly associated with sporting activities involving throwing or use of a racquet or an occupational history of wallpapering, painting, or carpentry. A past history of shoulder dislocations might suggest glenohumeral instability.

General Physical Examination

Before proceeding to the examination of the shoulder, it is important that the physician carefully check the neck, chest, heart, and abdomen for sources of referred pain. Cervical disease is often mistaken for a shoulder problem. Cervical root compression is readily distinguished from intrinsic shoulder disease by the elicitation and reproduction of pain on neck motionto the side of the complaint. Brachial plexus injury causing shoulder pain is associated with tenderness on deep pressure over the neurovascular bundle and scalene muscles of the supraclavicular fossa. The chest is checked for effusion, pleural rub, and poor diaphragmatic movement. If the heart is examined while the patient is in pain, one can listen for transient auscultatory signs of ischemia (e.g., fourth heart sound, single second sound, mitral regurgitant murmur from papillary muscle dysfunction). The abdomen is palpated for tenderness in the right or left upper quadrant, which may signal subdiaphragmatic disease.

Shoulder Examination

The patient is comfortably seated and sufficiently disrobed to permit evaluation and comparison of both shoulders. Close *inspection* from both front and back may demonstrate asymmetry or deformity. For example, supraspinatus muscle atrophy would suggest either a rotator cuff tear or suprascapular nerve disease. The patient is instructed to place the involved shoulder *actively* through a *full range of motion*, along with similar movements of the contralateral limb for comparison. This includes forward flexion, extension, abduction, and internal and external rotation. Internal rotation is best recorded as the level at which the patient can reach posteriorly, such as the buttock or thoracolumbar junction. The scapula is observed as the patient flexes the shoulder forward against resistance. Winging of the scapula can be the result of serratus anterior muscle palsy.

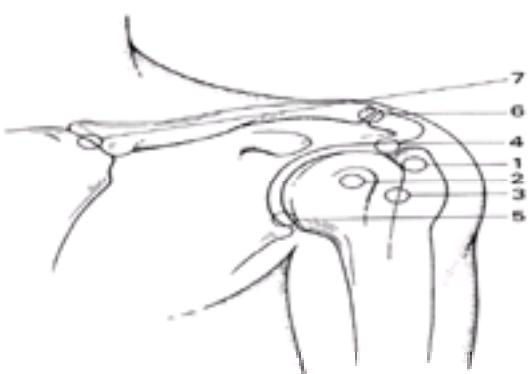
The patient is instructed to point out specific *sites of tenderness* (Fig. 150.1). Palpation by the examiner routinely should include the anterior aspect of the acromion, the acromioclavicular joint, the bicipital groove (which is best palpated with the humerus in about 10 degrees of internal rotation), the greater tuberosity, and the cervical spine. With the examiner's hand on the joint, the shoulder is passively put through a *range of motion* (Fig. 150.2). Limitations are noted, in addition to any palpable crepitation.


FIG. 150.1. Trigger points. Palpable "trigger points" during the examination reveal the site of disease, corroborate the history, and indicate the type of therapy. *1*, The greater tuberosity and site of supraspinatus tendon insertion. *2*, Lesser tuberosity, site of subscapularis muscle insertion. *3*, Bicipital groove, in which the bicipital tendon glides. *4*, Site of the subdeltoid bursa. *5*, Glenohumeral joint space. *6*, Acromioclavicular joint. *7*, Sternoclavicular joint. (Redrawn from Cailliet R. Shoulder pain. Philadelphia: FA Davis Co, 1973, with permission.)
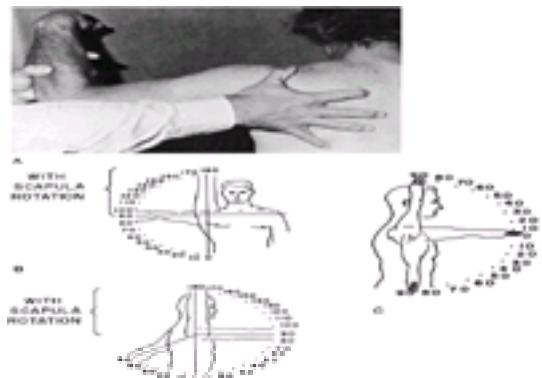

FIG. 150.2. A: Stabilization of the scapula during testing of glenohumeral joint motion. **B**: Normal range of adduction–abduction of the shoulder with and without scapular rotation. **C**: Normal range of external–internal rotation with upper arm at 90 degrees and elbow held at right angle. **D**: Normal range of flexion–extension of the shoulder with and without scapular rotation. (From Katz WA. Rheumatic diseases. Philadelphia: JB Lippincott Co, 1977.)

A manual *muscle test* is helpful, in particular for comparison with the uninvolved shoulder. Inability to "shrug" the shoulder suggests trapezial muscle weakness, whereas weakness of forward flexion is associated with derangement of the rotator cuff (the supraspinatus, infraspinatus, and teres minor muscles). A *sensory* and *deep tendon reflex* examination of the upper extremity should be included in the routine shoulder evaluation.

Diagnostic Maneuvers

Several specific maneuvers are diagnostically helpful and provide a means of quick and reliable diagnosis in the office.

Wright's Maneuver, in which the radial pulse is evaluated at the wrist with the shoulder in external rotation and abduction, may uncover an underlying *thoracic outlet syndrome*. The result of this test is considered positive if shoulder and arm symptoms are reproduced and the radial pulse is obliterated with the shoulder in this position.

Impingement Signs. *Neer's test* is performed with the examiner standing behind the patient and bringing the involved arm to the maximum degree of forward flexion with one hand while the other functions to depress the patient's shoulder girdle. If pain is elicited in the deltoid area or beneath the acromion, inflammation of the rotator cuff tendons and *impingement* of the greater tuberosity of the humerus against the undersurface of the acromion is likely. *Hawkins' sign* tests the shoulder with internal rotation at 90 degrees of forward flexion in the plane of the scapula. Results of these tests can be confirmed if an injection of 5 mL of lidocaine (Xylocaine) into the subacromial space relieves the symptoms—the so-called *impingement test*.

Tests for Rotator Cuff Tears. Large rotator cuff tears are identified with a series of specific tests. To test the posterior portion of the rotator cuff, or infraspinatus, the arm is placed at the side with the elbow maintained against the trunk. The forearm and hand are then brought passively into maximum external rotation. The patient is asked to maintain the arm actively in this position. An external rotation lag is defined as the difference between the maximum active and passive external rotation and may indicate a tear of the infraspinatus tendon.

The integrity of the anterior cuff (subscapularis tension) can be tested in either or two ways. The *lift-off test* involves maximum passive internal rotation of the arm behind the back so that the dorsum of the hand "lifts off" from the hip/back area. If the patient cannot maintain this position actively, the subscapularis tendon may be torn. For the belly press sign, the patient is asked to place the hand flat against the abdomen with the elbow held forward in this plane. The patient is then asked to maintain the hand against the belly as the examiner pulls the hand anteriorly. A posterior swing of the elbow reflects an attempt to maintain the hand against the belly by means of extension rather than internal rotation of the shoulder, in which case a tear of the subscapularis tendon may be present.

The supraspinatus is more difficult to isolate. Long-standing tears are associated with atrophy noted in the supraspinatus fossa of the scapula. Weakness of resisted abduction may be noted with the shoulder held in 90 degrees of abduction.

Tests for Acromioclavicular Joint Disease. In the *cross arm adduction test*, symptoms are reproduced when the patient brings the involved arm across the body so that the *hand grasps the contralateral shoulder*. The result can be confirmed by having the patient repeat the maneuver after the acromioclavicular joint has been injected with 1 mL of lidocaine; a 25-gauge needle is used to enter the joint. Patients who report a feeling of imminent shoulder dislocation when the shoulder is positioned in 90 degrees of abduction and maximum external rotation—a *positive apprehension sign*—may have anterior shoulder instability. Confirmatory evidence is obtained by repeating the test with the patient supine and placing posterior pressure over the proximal humerus—the *relocation test*. The uncomfortable sensation of impending dislocation should be diminished if it is caused by anterior instability.

Multidirectional laxity is sought in an examination of other stabilizing structures. The patient is tested for laxity of the superior glenohumeral ligament by applying axial traction to the arm held at the side in external rotation. If the gap between the acromion and humeral head is larger than that seen during testing of the opposite side—a positive sulcus sign—the superior glenohumeral ligament may be lax. Forward flexion and posterior translation of the arm may reproduce symptoms of posterior instability. Repeating the sulcus sign in internal rotation also tests the posterior capsule.

Laboratory Studies

Radiographs of the shoulder are mandatory in the initial evaluation. A *standard anteroposterior view* is helpful in ruling out underlying bone tumor, infection, or arthritis of either the glenohumeral or acromioclavicular joint. The anteroposterior view with the shoulder in *internal* and *external rotation* can best identify calcification. Well-circumscribed, organized calcification reflects chronic calcification of degenerated tendons and is not particularly important. Patients who have acute, severe pain may be noted to have a more diffuse, disorganized pattern of calcification, which suggests acute calcific tendinitis. An *axillary view* is mandatory if dislocation is suspected; it most clearly defines the relation of the humeral head to the glenoid fossa and is also helpful in the assessment of glenohumeral arthritis. In patients with chronic or recurrent dislocations, an indentation into the humeral head (or Hill-Sachs lesion) may be apparent. Cervical spine films are needed if neck motion reproduces the shoulder pain or root compression symptoms are observed (see Chapter 148).

Shoulder arthrography has been used to identify a suspected rotator cuff tear and is still popular with some physicians, particularly for the diagnosis of full-thickness tears of the rotator cuff. Dye is injected directly into the glenohumeral joint, and the joint is then mobilized. Extravasation of dye from the joint into the subacromial space is highly suggestive of a complete tear of the rotator cuff.

Magnetic resonance imaging provides a noninvasive means of assessing the integrity of the rotator cuff and in some instances obviates the need for arthrography to detect a tear. It can also provide information about the size of a tear, the degree of retraction, and the status of involved muscles (i.e., whether or not they have been replaced by fat). Although useful for the assessment of a rotator cuff tear, magnetic resonance imaging is costly and is not indicated as part of the initial evaluation of shoulder pain.

If infection is suspected in the joint or joint capsule, *aspiration, Gram's stain*, and *culture* are urgent so that definitive therapy can be initiated without delay (see Chapter 145). If a peripheral nerve deficit is discovered on neurologic examination, *electromyography* may help to characterize the lesion better. Testing for referred pain is indicated only in the presence of a suggestive history and corroborating physical findings.

SYMPTOMATIC THERAPY

Rotator Cuff Tendinitis. If a large tear of the rotator cuff is not suspected, the tendinitis can be managed with a program consisting of avoidance of exacerbating activities, an *NSAID* (e.g., 375 mg of naproxen twice daily or 600 mg of ibuprofen three times daily), and exercises to strengthen the rotator cuff. The exercises are best taught and supervised by a trained therapist. Commonly, a set of rubber bands providing increasing levels of resistance is used to exercise specific tendons and

enhance their strength and performance.

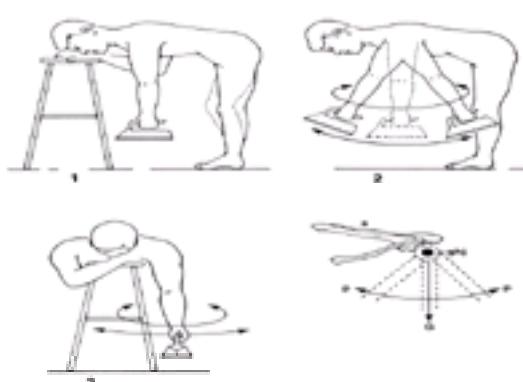
If motion is restricted, the program should include specific exercises for restoring shoulder mobility. *Pendulum exercises* aid in maintaining joint mobility. With the patient bending forward at the waist, the arm is allowed to dangle and swing in forward-to-back, side-to-side, and circular patterns (Fig. 150.3). Additional exercises, such as "wall climbing" (Fig. 150.4), are included as the pain subsides. The patient must be counseled to expect some mild discomfort with these exercises, as they are designed specifically to stretch the joint capsule. These exercises are performed for periods of 5 to 10 minutes, three to four times each day.


FIG. 150.3. Active pendular glenohumeral exercise (Codman exercises). *1,* The posture to be assumed to permit the arm to "dangle" freely, with or without a weight. *2,* The arm moves in forward and backward sagittal plane, in forward and backward flexion. A circular motion in the clockwise and counterclockwise directions is also made in increasingly large circles. *3,* The front view of the exercise shows lateral pendular movement, actually in the coronal plane. The lower right diagram shows the effect of gravity, *G,* on the glenohumeral joint, *ghj,* with an immobile scapula, *s.* The *p*-to-*p* arc is the pendular movement. (Redrawn from Cailliet R. Shoulder pain. Philadelphia: FA Davis Co, 1973, with permission.)
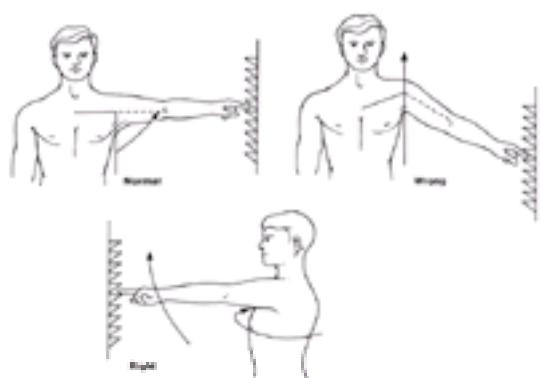

FIG. 150.4. Correct and incorrect use of "wall-climbing" exercise. The wall-climbing exercise frequently is performed improperly. The normal arm climbs with normal scapulohumeral rhythm. If a pericapsulitis is present, the wall climb in abduction is performed with "shrugging" of the scapula, and nothing is accomplished. The wall climb should be started with the patient facing the wall and gradually turning the body until at a right angle to the wall. (Redrawn from Cailliet R. Shoulder pain. Philadelphia: FA Davis Co, 1973, with permission.)

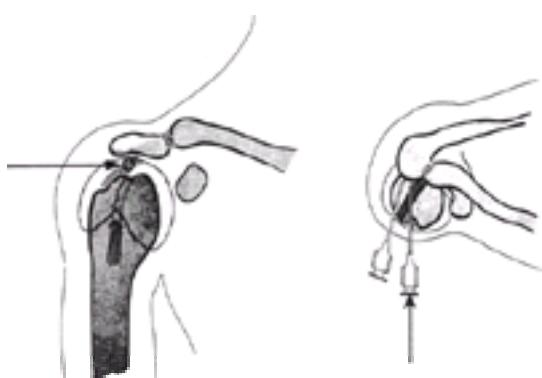
When the inflammation in the tendon is so severe that exercises are not possible, or in the case of severe acute calcific tendinitis, subacromial *injection* of a *corticosteroid* and local anesthetic is often helpful. The subacromial joint can be entered by advancing the needle under the lateral edge of the acromion process. After the skin has been initially infiltrated with a few milliliters of lidocaine, the subacromial space is injected with 5 to 10 mL of lidocaine and 40 mg of methylprednisolone (Depo-Medrol, usually 1 mL) or an equivalent steroid (Fig. 150.5). Steroid injection may acutely worsen symptoms after the anesthetic wears off, but improvement is likely to follow within 48 hours. To avoid precipitating capsular atrophy, injections should be given no more often than once every 6 to 12 months and limited to a total of three. Care must be taken not to inject into the tendon; the goal is to deliver medication into the area around it. Repeated steroid injection within a few months of the initial injection should not be attempted by the primary care physician because of the deleterious biochemical effects of glucocorticoids on connective tissue. Orthopedic referral is indicated when symptoms do not respond or when a large tear is suspected.


FIG. 150.5. Site of injection in acute calcific tendinitis. **A:** Region of supraspinatus insertion in the suprahumeral space. The region is palpable immediately below the overhanging acromion and over the greater tuberosity just lateral to the bicipital groove of the humerus. **B:** Insertion of needle viewed from above. Two directions of entrance are shown, with the *arrow* depicting that shown in the anterior view. (From Cailliet R. Soft tissue pain and disability. Philadelphia: FA Davis Co, 1977:161, with permission.)

In patients with calcific tendinitis, pulsed *ultrasound* treatments help to reduce calcification and improve the patient's functional status and quality of life over the short term. However, the fact that no long-term benefit has been noted in comparison with placebo shows that recurrence is common if the underlying cause of tendinous injury is not alleviated.

Torn Rotator Cuff. Spontaneous healing of a torn rotator cuff is unlikely. Despite this, many patients with a partial tear or a small complete tear respond to an exercise program designed to strengthen their shoulder rotator muscles. Repetitive steroid injections have no place in this disorder because the cortisone, if anything, retards healing and accelerates the deterioration of the tendons. Large tears require prompt surgical treatment. In may not be possible to reconstruct very large or massive tears and large tears associated with retraction and degeneration of the muscle.

Adhesive Capsulitis is difficult and often frustrating to treat; the course is prolonged, and the chances for full recovery are unpredictable. The hallmark of treatment is an *active exerciseprogram.* The patient is instructed to precede each session with the application of local heat, either by using a heating pad or taking a warm shower, for 15 to 20 minutes. Initially, one begins by lying supine and, with the contralateral hand, bringing the involved shoulder into forward flexion. External rotation exercises are also begun; one holds a broom handle in both hands and moves from internal to external rotation. The patient should be encouraged to use the shoulder as much as possible in the normal activities of daily living. It is worthwhile for a physical therapist to keep a weekly or monthly log regarding the shoulder motion because improvement is slow and usually occurs in small increments; objective signs of improvement help to lessen patient frustration. *Forceful manipulation*

of the shoulder is rarely indicated, and in fact *operative caspsulotomy* may be safer. Recently, this procedure has been performed with the arthroscope, but the indications for operative intervention are uncertain. Most people achieve a functional range of motion through a concerted, patiently applied exercise program.

Glenohumeral Arthritis. In the conservative treatment of glenohumeral arthritis, whether secondary to osteoarthritis or inflammatory arthritis, *NSAIDs* and *exercises* are used to maintain a functional range of motion. The patient can be instructed to do the same exercises as for adhesive capsulitis on a daily or twice-daily basis at home. Exercises directed at maximizing existing muscle strength are also prescribed, preferably with the supervision of a physical therapist. Improvements in total joint arthroplasty have offered a functional alternative to many patients whose condition is refractory to medical management. Cortisone injections of the glenohumeral joint also provide relief, and the number of injections that can be administered is unlimited. Injection of the glenohumeral joint can be difficult and is best performed by an orthopedic surgeon.

Acromioclavicular Arthritis. Antiinflammatory medications and modification of activity are often helpful in reducing the inflammatory component of arthritis of the acromioclavicular joint. At times, an injection of *corticosteroid* and lidocaine may help but can be remarkably difficult to administer because of the small size and accessibility of the joint. Injection of this joint may be best left to the orthopedic specialist. Rarely, surgery is required, which consists of partial distal clavicular excision.

INDICATIONS FOR REFERRAL

Shoulder dislocation or instability, fractures about the shoulder, advanced acromioclavicular or glenohumeral joint arthritis, rotator cuff tears, and infection are best referred early to the orthopedic surgeon. Refractory rotator cuff tendinitis also is an indication for referral if resolution is not obtained with appropriate conservative treatment.

PATIENT EDUCATION

Emphasis should be placed on the importance of active participation in the treatment program. Many patients seek only relief from pain and expect oral or injectable medication to suffice. Thorough recovery entails actively performing the exercises of the treatment program, which must be carefully taught, often with the help of a physical therapist. Repeated pain and limitation of function are bound to ensue if the exercise program is not taken seriously.

CHAPTER 151 EVALUATION OF HIP PAIN

ROBERT J. BOYD

Hip pain can be a major source of misery for both patient and family. The joint is essential to locomotion and weight bearing and is frequently subject to trauma and chronic mechanical stress.

In the assessment of hip pain, the degree of pain and disability must be determined in addition to the underlying cause because surgery is now a practical therapeutic option for disabled patients whose pain is refractory to conservative measures.

PATHOPHYSIOLOGY AND CLINICAL PRESENTATION

The hip is supplied by the obturator, sciatic, and femoral nerves. Pain originating in or around the hip can be felt in the groin or buttock, with radiation to the distal thigh and anteromedial aspect of the knee. Occasionally, pain from the hip may be felt only in the thigh and knee. Pain occurs in the distribution of the L-2 and L-3 roots and rarely is referred to the lower leg or foot. Conversely, pain caused by a problem outside the hip may be referred to the hip if the lesion irritates the femoral, sciatic, or obturator nerve or the nerve roots. Problems outside the hip include herniated disks in the high lumbar region, spinal stenosis, retroperitoneal or pelvic tumor, and femoral hernia; patients who have aortoiliac insufficiency may also present with hip and buttock pain (see Chapter 147).

Hip pain may be focal or diffuse, depending on the extent to which the joint and surrounding structures are involved in the pathologic process. For example, bursitis is characterized by focal pain and tenderness over the site of the bursa; synovitis is more diffuse, involving the entire joint capsule. Stiffness, limitation of motion, limp, and crepitus are frequent accompaniments of pain. Swelling is usually not evident and is difficult to detect because the joint is buried deeply in soft tissues.

The major mechanisms of hip disease include cartilaginous degeneration, synovial inflammation, tendinitis and consequent bursitis, fracture, and ischemia.

Osteoarthritis. The hip is a major site of degenerative joint disease, with the elderly being the most affected. Obesity is also a risk factor, particularly in women. The onset is often insidious, beginning with minor aching or stiffness that may be unilateral or bilateral. Symptoms are characteristically exacerbated by prolonged standing, walking, or stair climbing. Stiffness is noted when the patient gets up after sitting for long periods. The hip begins to loosen up at first with moving about, but discomfort then worsens with continued activity. As osteoarthritis gradually progresses, it results in decreasing hip motion, increasing stiffness, and increasing pain. A limp may develop as the joint architecture is disrupted, and weight bearing becomes painful. The course of the disease is usually marked by spontaneous exacerbations and remissions.

On physical examination, the patient with substantial disease characteristically holds the hip in flexion, external rotation, and adduction. An antalgic gait, Trendelenburg's sign (buttock falls when the patient stands on the opposite foot), which is indicative of abductor weakness), and limitation of hip motion with or without crepitus may be present. Pain, muscle spasm, and guarding occur when the examiner attempts to take the hip through the full range of motion. Buttock atrophy may involve the gluteus maximus posteriorly and the gluteus medius more laterally. With severe degenerative arthritis of the hip, a marked flexion deformity may develop, and pain may be felt in the hip joint even at rest (see also Chapter 157).

Rheumatoid Arthritis. The hips are rarely affected in rheumatoid disease until other joints have become involved. Pain is characteristically bilateral and associated with morning stiffness, which lessens with activity. During flares of the disease, the hip joint is tender to palpation, and capsular fullness and thickening may be felt if effusion or chronic synovitis is present. Flexion contractures occur in advanced cases (see also Chapter 156).

Ankylosing Spondylitis is unique among the spondyloarthropathies in that the hip is sometimes affected. Concurrent sacroiliac and spinal involvement is usually present and in itself may cause pain radiating into the hip or buttock (see also Chapter 146 and Chapter 147).

Hip Fracture. At greatest risk is the frail, elderly person with a history of frequent falls and osteoporosis. The femoral neck and intertrochanteric region are common fracture sites. Loss of normal surface architecture may be associated with acute joint deformity, severe pain, guarding, and restriction of flexion and external rotation. Active straight leg raising is impaired. Competitive long-distance runners are at risk for stress fracture of the femoral neck.

Septic Arthritis. Joint infection in the hip most often follows hematogenous seeding (see Chapter 145). Because the joint is deep-seated, the ordinary signs of infection may not be readily evident. Fever, hip or knee pain (caused by referral of pain), and inability to bear weight are early symptoms. The thigh is often held in flexion, and a bulging, tender joint capsule may be palpable.

Idiopathic Avascular Necrosis. Also referred to as "aseptic" necrosis of the femoral head, this condition has an ischemic pathophysiology. It occurs in patients who take high daily doses of glucocorticoids, alcoholics, patients with hemoglobinopathies, and those who work under conditions of increased atmospheric pressure. The mechanism of steroid-induced disease involves the proliferation of intramedullary fat, tissue hypertension, and compromised perfusion of bone. Patients report the gradual onset of focal pain and limitation of movement. Diagnostic radiographic changes include wedge-shaped areas of increased density and segmental collapse of the femoral head.

Bursitis. Inflammation of the bursa occurs as a consequence of trauma or spread of an inflammatory process. Focal pain with tenderness develops over the bursa. *Trochanteric bursitis* is felt on the lateral aspect of the hip, posterior to the trochanter. Symptoms are increased by direct pressure or hip flexion and internal rotation. Pain may worsen at night and radiate down the leg to the knee. It may occur in runners who jog on uneven surfaces and those with one leg slightly shorter than the other. *Iliopectineal bursitis* causes pain on flexion and tenderness localized to the lateral border of Scarpa's triangle. *Ischiogluteal bursitis* presents with buttock pain that is worse during prolonged sitting, occurs at night, and occasionally radiates down the leg posteriorly, simulating sciatica.

Polymyalgia Rheumatica. A disease of the elderly that is often mistaken for depression, arthritis, or bursitis, polymyalgia is characterized by bilateral aching of the hips, thighs, and shoulders in conjunction with a very high sedimentation rate. It has a strong association with cranial arteritis (see Chapter 161). Joint structures and passive range of joint motion are usually preserved.

Pigmented Villonodular Synovitis. This uncommon granulomatous disease of the synovium presents with slowly progressive pain and limitation of movement. Radiographic films show large cystic areas about the hip joint, which distinguish the condition from degenerative joint disease.

Referred Pain. Any pelvic, abdominal, or retroperitoneal process irritating the obturator muscle can cause pain that is referred to the hip. Such pain is worsened by internal rotation of the hip joint.

DIFFERENTIAL DIAGNOSIS

Hip pain is usually caused by degenerative joint disease. Other important causes include joint infection, avascular necrosis of the femoral head, bursitis, polymyalgia rheumatica, and rheumatoid arthritis. On occasion, ankylosing spondylitis or villonodular synovitis is responsible. Pain may be referred to the hip from a lumbar or pelvic problem, such as a herniated disk in the high lumbar region, retroperitoneal tumor or abscess, or obturator or femoral hernia. Aortoiliac insufficiency may present with exercise-induced hip and buttock pain.

WORKUP

History. One should ascertain the onset, location, and radiation of the pain in addition to inciting and alleviating factors and the presence of numbness or weakness. It is particularly important to inquire directly about trauma, involvement of other joints, morning stiffness, relation of pain to activity, response to rest, steroid or alcohol use, and current infection or fever. A few pitfalls regarding the history should be mentioned. For example, stiffness by itself is a nonspecific finding because it may occur both with degenerative disease and with rheumatoid involvement of the hip. The response to continued activity may be of more help diagnostically; stiffness usually worsens in degenerative disease and lessens in rheumatoid arthritis. Bilateral cramping hip and buttock pain that comes on with walking and is relieved by rest may actually be a sign of vascular insufficiency rather than of joint disease.

Physical Examination. The hip should be examined for deformities such as flexion or adduction contractures, which are seen with rheumatoid disease, and for fixed external rotation, which suggests a fracture of the femoral neck. Gait is also important to check. The hip is then put through the full range of passive motion to detect crepitus, limitation of movement, flexion contracture, muscle spasm, or guarding. The normal range of hip flexion–extension is from -20 to 90 degrees with the knee straight and from 0 to 120 degrees with the knee flexed. Normal adduction–abduction is from -20 to 90 degrees; normal internal–external rotation is from -50 to +50 degrees. One of the first movements to be limited in hip disease is internal rotation with the hip hyperextended. Palpation of the joint and individual bursae for focal tenderness and swelling is important for detecting a localized inflammatory process.

The circumference of the thigh should be measured at a fixed distance from a bony reference point, such as the tibial tubercle of the knee, the anterior superior iliac spine, or the midpatella. Atrophy is suggestive of intrinsic hip disease.

Femoral pulses should be palpated for diminution and auscultated for bruits. Pelvic and rectal examinations are helpful in searching for tumors, which may cause referred pain. The back should be examined for evidence of L1-2 or L2-3 disk herniation (see Chapter 147). Neurologic assessment of the lower extremities is needed to test for weakness, sensory loss, and reflexes.

Laboratory Studies. Hip *radiography* is essential in the assessment of hip pain. Radiography may be diagnostic of degenerative joint disease, rheumatoid arthritis, avascular necrosis, or fracture. Weight-bearing films help one judge the severity of degenerative hip disease by disclosing the extent of joint space narrowing. Sacroiliac and spine films are indicated if ankylosing spondylitis is under consideration (see Chapter 146 and Chapter 147). *Magnetic resonance imaging* is the most sensitive test for avascular necrosis of the femoral head, showing expansion of intramedullary fat before bony changes become visible. It also is more sensitive than standard radiography in the detection of stress fracture of the femoral neck.

A complete blood cell count, determination of the *sedimentation rate*, and *rheumatoid factor* analysis may be useful if a rheumatoid disease is being considered (see Chapter 146). If a septic joint is suspected, aspiration for cell count, Gram's stain, and culture is urgent (see Chapter 145).

SYMPTOMATIC THERAPY AND INDICATIONS FOR REFERRAL

Degenerative Disease. Simple treatment measures for relief of an acute exacerbation include daily periods of bed rest, analgesics (e.g., 500 mg of *acetaminophen* four times daily), limitation of sitting, and crutch or cane support. *NSAIDs* offer little benefit over pure analgesics when no signs of concurrent synovial inflammation are present. Moreover, NSAIDs increase both cost and the risk for NSAID-induced gastric injury, and may even speed the rate of joint degeneration. *Glucosamine* is heavily promoted for osteoarthritis, but evidence of efficacy from properly designed trials is lacking (see also Chapter 157).

After acute symptoms lessen, the patient can begin a program to improve functional capacity. It should include avoidance of activities that specifically aggravate pain, daily mild exercise (walking short distances as tolerated) preceded by acetaminophen, cane support if necessary, weight reduction if obese, and specific daily range-of-motion and strengthening exercises, preferably taught by a physical therapist. Rest periods of 1 hour twice daily with local heat applied to the hip may be helpful if discomfort occurs after exercise. Even modest degrees of weight reduction can be remarkably helpful in alleviating pain and disability.

If conservative measures fail to control symptoms and the patient is active, *surgery* may be needed. Because results of *hip reconstructive* procedures are now quite good and the procedure entails a relatively low risk, referral for consideration of surgery need not be delayed indefinitely if symptoms are disabling and not well controlled by conservative measures. The need for reconstructive surgery must be a joint decision of patient, primary physician, and orthopedic surgeon. Despite the relative safety of surgery, expectations for outcomes need to be realistic and the amount of rehabilitative work necessary must be clearly understood (see also Chapter 157).

Bursitis. NSAID therapy (e.g., 500 mg of naproxen twice daily for 1 to 2 weeks), in conjunction with reduced activity, often suffices. The jogger who has been running on uneven surfaces should change to another running surface. A *heel lift* may help the person whose legs are not the same length. If pain does not respond and if tenderness is well localized to the bursa overlying the bony prominence of the greater trochanter, a *local steroid injection* into the bursa can be attempted to provide relief. The bursa and trochanter are identified by having the patient lie in the lateral decubitus position with the involved hip exposed; the physician palpates for focal tenderness over the bony prominence of the greater trochanter. After 2 mL of 2% lidocaine has been mixed with 1 mL (40 mg/mL) of methylprednisolone (Depo-Medrol), 1 to 2 mL of the mixture is injected into the tender area overlying the bony prominence with a 25-gauge needle, inserted until it just touches the periosteal surface of the bone and then drawn back ever so slightly for the injection. Primary physicians who are unfamiliar with the technique of injecting a hip bursa should refer the patient to an orthopedist or rheumatologist.

Rheumatoid Disease. Polymyalgia rheumatica responds dramatically to low-dose steroids (see Chapter 161), and rheumatoid arthritis to high-dose aspirin or NSAIDs (see Chapter 156).

Hip Fracture and Septic Arthritis are indications for immediate hospitalization.

CHAPTER 152 EVALUATION OF KNEE PAIN

The knee joint is frequently the site of trauma, degenerative disease, and rheumatologic conditions. Disability can be considerable because of the inability to bear weight. The primary physician is called on most often to treat minor acute injuries or chronic knee pain that limits mobility. Occasionally, an acute monoarticular arthritis is encountered. The popularity of skiing, jogging, and long-distance running has markedly increased the prevalence of acute and recurrent knee complaints.

PATHOPHYSIOLOGY AND CLINICAL PRESENTATION

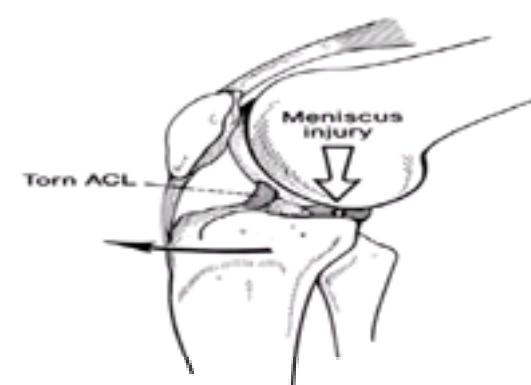
Degenerative disease, trauma-induced derangements of soft tissue, and inflammatory processes are the predominant mechanisms of knee pain in the adult. The pain is characteristically worsened by weight bearing and may radiate into the anterior thigh, posterior calf, or pretibial region. An inflamed joint capsule produces diffuse pain. The site of pain is characteristic of the underlying problem (Fig. 152.1). Locking of the joint suggests a loose body or torn meniscus. Hip disease occasionally presents as knee pain (see Chapter 151).


FIG. 152.1. Cruciate ligament tear with associated meniscal damage.

Degenerative Disease. Changes often originate in the medial joint compartment and patellofemoral joint, related in part to mechanical stresses. The entire joint may be painful, but often the discomfort is localized to the anterior and medial portions of the knee. Prolonged standing or walking may precipitate or worsen symptoms. Mild stiffness is common on first arising in the morning and on getting up after a long period of sitting. It initially improves on moving about, but worsens with continued activity. Symptoms gradually progress but may take many years to become disabling. Considerable degenerative change and joint destruction can occur before serious knee pain develops. Small effusions may appear after prolonged weight bearing, but few other signs or symptoms of inflammation occur.

Rheumatoid Disease. Rheumatoid arthritis commonly affects the knees. Pain, swelling, and morning stiffness are characteristic. Symmetric polyarticular involvement is the rule, with joints in the hands, feet, ankles, and wrists often affected. Symptoms wax and wane; the course is chronic (see Chapter 156). Other rheumatoid diseases can produce a similar picture (see Chapter 146).

Acute Monoarticular Arthritis. The knee is a frequent site of septic arthritis, gout, pseudogout, early rheumatoid arthritis, rheumatic fever, palindromic rheumatism, and disseminated gonorrhea. Acute onset of unilateral swelling, pain, and generalized tenderness is the usual presentation (see Chapter 145). Motion is limited, and muscle spasm is prominent.

Knee Sprain. Ligamentous injury caused by excessive joint strain is extremely frequent. Sprain injuries ranging from minor tears of a few fibers to complete tears of entire ligaments result in a loss of joint stability. Mild sprains produce tenderness and local swelling without joint effusion or loss of joint stability. Moderate sprains are associated with pain when the joint is stressed, voluntary restriction of movement, some joint instability, and swelling secondary to an effusion. Severe sprains involve a total loss of integrity and immediate swelling, marked joint instability, severe pain, and a large effusion. The collateral and cruciate ligaments are frequently injured in contact sports. Ligamentous injuries are uncommon in joggers.

Tearing of the *anterior cruciate* ligament is a common sports-related knee injury; it accounts for the vast majority of sprains suffered in skiing. Typically, it occurs in the setting of sudden noncontact deceleration that causes valgus twisting of the knee. A "pop" is heard, and marked swelling ensues within a few hours because of intraarticular bleeding. The resulting subluxation of the tibia compresses the meniscus between the tibia and femur and may cause the cartilage to tear (see Fig. 152.1 and below). Initially after an anterior cruciate tear, the knee may function reasonably well, but instability develops on resumption of sports activity.

Degeneration or Tear of a Meniscus. An acute tear occurs as a consequence of excessive weight bearing, twisting, or valgus or varus stress and may be associated with the partial or complete disruption of collateral or cruciate ligaments. Usually, a history of acute trauma and immediate swelling, resulting from tissue disruption and bleeding, is elicited. A torn anterior cruciate ligament is a common precipitant of meniscal tear. If cartilaginous fragments become trapped, they cause the knee to lock. If swelling does not develop until the next day, damage islikely to be confined to the meniscus and not involve the ligament. Such swelling is caused by a reactive joint effusion. Chronic internal derangements caused by degeneration or tear of the meniscus produce recurrent pain and swelling, and a knee that gives way, catches, or locks.

Chondromalacia Patellae. Degeneration of the posterior patellar cartilage is the cause of this condition. Dessication, thinning, fissure formation, and ultimately erosion of the cartilage occur. Mechanical factors are suspected, although unproven. Chondromalacia is the most common cause of knee pain in joggers and is believed to be related to overtraining. The patient presents with retropatellar aching that is worsened by standing up, climbing stairs, or any other form of bent-knee strain. Stiffness may develop after inactivity, but usually no locking or giving way of the knee is noted. Pain is reported in the peripatellar region and lateral aspect of the knee and can be reproduced by applying pressure against the patella with the knee actively extended. Palpable grating can be elicited at the patellofemoral joint with flexion and extension of the knee. Radiographic findings are normal until late stages, when the posterior surface of the patella becomes irregular and marginal osteophytes develop.

Baker's Cyst. Rupture of one of these popliteal fossa cysts can cause acute inflammation with pain, swelling, and limitation of knee flexion. The inflammation may extend down into the calf and simulate thrombophlebitis. Baker's cysts usually communicate with the knee joint space and most commonly occur in patients with osteoarthritis or rheumatoid disease. An unruptured cyst causes only mild aching and stiffness. Trauma may initiate a rupture.

Prepatellar Bursitis results from repeated trauma—hence the name "housemaid's knee." Swelling, tenderness, and occasionally erythema over the prepatellar bursae are present. The presentations of bursitis of the suprapatellar and infrapatellar bursae are similar, with findings localized to the bursal site.

Villonodular Synovitis is a granulomatous inflammatory condition of the synovium that lines the joints, bursae, and tendon sheaths. The cause is unknown. It affects young adults, predominantly men, and presents with unilateral pain, persistent swelling, intermittent knee locking, and occasionally a palpable mass. Diagnosis requires arthroscopy or surgical exploration.

DIFFERENTIAL DIAGNOSIS

The list of conditions that can cause knee pain is extensive and includes polyarticular disease in addition to processes confined to the knee. A clinically useful classification system groups causes of knee pain according to whether the pain is acute or chronic, and whether the distribution is symmetric or asymmetric and monoarticular or polyarticular (Table 152.1).

	Asymmetric Involvement				Symmetric Involvement			
	One Knee Only		One Knee Plus Other Joints		Knees Only		Systemic Polyarthritis	
	ACUTE	CHRONIC	ACUTE	CHRONIC	ACUTE	CHRONIC	ACUTE	CHRONIC
Sprain	Osteoarthritis	See Chapters 145, 146	Rheumatoid arthritis	Osteoarthritis	See Chapter 146			
Strain	Baker's cyst		Juvenile RA	Chondromalacia patellae				
Acute gout	Chronic gout		Early phase of other rheumatoid diseases	Bursitis				
Meniscal tear	Chondromalacia patellae		Trauma	Rheumatoid arthritis				
Early rheumatoid disease	Bursitis			Juvenile RA				
Gonococcal arthritis	Meniscal injuries			Chronic gout				
Septic arthritis				Neuropathic joints				
Reiter's syndrome				Hemophilia				
Bursitis								
Pseudogout								
Patellcomic rheumatism								
Ruptured Baker's cyst								
Hemophilia								
Sickle cell disease								
Rheumatic fever

Table 152.1. Differential Diagnosis of Knee Pain

WORKUP

History

Besides ascertaining the quality and location of pain, alleviating and aggravating factors, and associated symptoms such as swelling, redness, and warmth, the physician must determine whether the problem is acute or chronic, symmetric or asymmetric, and monoarticular or polyarticular. By combining a careful description of the problem with a characterization of its pattern and chronicity, one can quickly focus the evaluation onto a relatively limited set of conditions having similar clinical presentations (Table 152.1).

Acute Unilateral Knee Pain. One should inquire about trauma, jogging, locking, giving out, swelling, pain on climbing stairs, concurrent fever, purulent vaginal or urethral discharge, rash, recent streptococcal infection or sore throat, heart murmur, morning stiffness, and urethritis or conjunctivitis (see Chapter 145). Any prior history of gout, sickle cell disease, or hemophilia should be ascertained. When swelling is localized, it is important to determine the exact site because it may be a clue to bursitis or a Baker's cyst. A history of knee locking suggests meniscal tear with lodging of cartilaginous fragments in the joint space. Reports of the knee giving out point to anterior cruciate disruption.

Chronic Unilateral Knee Pain. Questioning should cover previous or recurrent trauma, as may occur occupationally; pain associated with prolonged walking, standing, or climbing stairs; knee locking; crepitus; focal swelling; and recurrent acute episodes or exacerbations.

Acute Bilateral Knee Pain. When both knees are involved acutely, then the focus of inquiry should be on the symptoms of rheumatoid disease (see Chapter 146) and recent trauma.

Chronic Bilateral Knee Pain. The questioning can be similar to that for chronic unilateral disease, but rheumatoid symptoms should also be considered (see Chapter 146).

Polyarticular Presentations. When other joints are also involved, inquiry into symptoms of infectious and rheumatologic conditions is essential (see Chapter 146).

Physical Examination

A complete physical examination must be performed because many systemic illnesses can present with knee pain. Skin and integument are examined for rash, clubbing, psoriatic changes, rheumatoid nodules, pallor, alopecia, and tophi. The conjunctivae are noted for erythema and petechiae, the oral cavity for aphthous ulcers, lymph nodes for enlargement, the chest for signs of consolidation and effusion, the heart for murmurs and rubs, the abdomen for organomegaly and tenderness, the pelvis for vaginal discharge and adnexal tenderness, the urethra for discharge, and the penis for balanitis. In addition, a thorough check of all joints and complete neurologic testing should be performed.

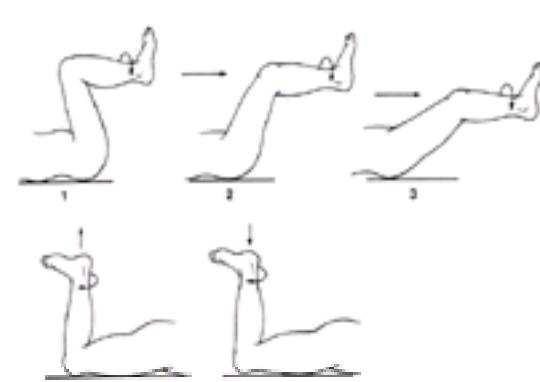
Examination of the knee should begin with a careful inspection for distortion of normal contours and irregular bony prominences at the joint margin. It is important to check for muscle atrophy. Measurements of the knee, calf, and thigh circumferences can help quantify the loss of muscle mass. The presence of an effusion needs to be determined. This is done by noting an increased knee circumference at midpatella and feeling for a distended, fluctuant capsule with a fluid wave and ballotable patella. The joint line should be palpated for localized joint line tenderness suggestive of a meniscal tear. The *McMurray* and *Apley tests* are performed for suspected meniscal injury (Fig. 152.2). The bursal regions should be assessed for focal tenderness and swelling indicative of bursitis.


FIG. 152.2. Meniscus signs (examination). *1,2,3*, McMurray test. The patient is supine with knee flexed, heel touching the buttocks at the start. The leg is internally rotated to test the lateral meniscus or externally rotated to test the medial meniscus. Then the knee is fully extended. A painful click occurs if a meniscus lesion is present. The test is more meaningful in the first phase of knee extension. Limited extension does not indicate a lesion of the anterior meniscus. *4,5*, Apley test. The patient is prone. The leg is internally or externally rotated with simultaneous traction. Pain indicates a capsular or ligamentous lesion. Pain caused by rotation with downward pressure indicates a meniscus lesion. (Redrawn from Cailliet R. Knee pain and disability. Philadelphia: FA Davis Co, 1973, with permission.)

Range of motion needs to be determined. The knees normally extend symmetrically 180 degrees and may hyperextend an additional 5 or 10 degrees. Knee flexion is also symmetric and limited to 135 to 170 degrees by contact with posterior soft-tissue or by striking of the heel against the buttock. Collateral and cruciate ligaments should be examined for stability. Collateral ligaments are tested by applying mediolateral valgus–varus strain with the knee in full extension and in 15 to 20 degrees of flexion (Fig. 152.3).

FIG. 152.3. Testing for lateral instability of the knee by fixating the lower femur with one hand and forcibly abducting and adducting the joint while grasping the leg. (From Katz WA. Rheumatic diseases. Philadelphia: JB Lippincott Co, 1977.)

Anterior cruciate ligament stability is best assessed by the *anterior drawer test*, which is performed with the knee relaxed and flexed to about 25 degrees. One gently pulls the tibia anteriorly while the femur is held in a fixed position and notes the amount of anterior displacement of the tibia relative to the femur. Patients who describe a knee that repeatedly gives out may have anterior cruciate instability, which can be assessed by testing for pivotal shift. The validity of these tests has been confirmed by arthroscopic study. They are important parts of the examination of the injured knee.

Laboratory Studies

No set of laboratory studies is "routinely" used to assess knee pain. In cases of trauma, *radiography* is needed to rule out fracture, and stress films are indicated to determine joint stability. Knee films are also indicated for suspected degenerative or chronic rheumatoid disease. Weight-bearing films best demonstrate the degree of joint obliteration. *Magnetic resonance imaging* (MRI) has enhanced the diagnosis of disease in the soft tissues of the knee. Its sensitivity for the detection of meniscal tear exceeds 90% (better than that of arthrography), and for cruciate tear it reaches 95%. However, MRI remains expensive. The test is best reserved for instances in which the clinical findings are not sufficient to establish a diagnosis and an invasive diagnostic procedure would otherwise be necessary. *Fiberoptic arthroscopy* remains the gold standard for the diagnosis of problems in the soft tissues of the knee. Acute monoarticular effusions require prompt *arthrocentesis* for Gram's stain and cultures to rule out a septic process. Joint fluid is sent for determination of the white cell count, differential, and glucose level and is examined for crystals (see Chapter 145). With polyarticular presentations, testing for inflammatory joint disease must be considered (see Chapter 146).

SYMPTOMATIC THERAPY AND INDICATIONS FOR REFERRAL

For the patient with a knee injury, *acute pain* responds best to restriction of weight-bearing activities and the use of crutches. A *knee brace* is applied to provide support and prevent further injury by limiting the range of motion. Only absolutely necessary walking is allowed, and kneeling, squatting, and stair climbing are forbidden. *Aspirin* may be helpful symptomatically when used in pharmacologic doses of 2 to 4 g/d. Otherwise, any one of the other *NSAIDs* is a reasonable alternative (e.g., 375 mg of naproxen twice daily or 400 mg of ibuprofen three times daily). Once swelling subsides and the full range of motion without pain returns, rehabilitation can begin. One starts with isometric *quadriceps* and *hamstring exercises*. These help prevent muscle atrophy, weakness, and thinning of ligamentous tissue. If the problem is one of acute severe injury and pain, especially if the knee gives way or locks and joint instability or internal derangement is suspected, prompt orthopedic referral is essential. Arthroscopy may be needed.

Patients who have *chronic knee pain* associated with osteoarthritis have been shown to benefit from both *aerobic exercise* and *resistance exercise* in randomized trials. In a recent trial, the benefit for aerobic exercise was modestly better than that for resistance exercise, but either was better than an education program without exercise. No evidence of more rapid disease progression was found with either form of exercise. These approaches should complement other measures for the general treatment of osteoarthritis. NSAIDs have not be shown to be superior to non-narcotic analgesics, such as acetaminophen, for providing control of chronic pain caused by osteoarthritis of the knee. Although glucosamine is popular, its effectiveness has not been demonstrated in well-designed studies; moreover, it is expensive (see also Chapter 157).

CHAPTER 153 APPROACH TO MINOR ORTHOPEDIC PROBLEMS OF THE ELBOW, WRIST, AND HAND

JESSE B. JUPITER AND DAVID RING

INTRODUCTION

As the physician of first contact, the primary care practitioner encounters a host of minor upper extremity complaints that may be causing the patient considerable discomfort. Quick recognition and proper treatment can save the patient an unnecessary referral and allow for prompt symptomatic relief.

ELBOW PAIN

The evaluation of elbow pain requires a careful correlation of the presenting symptoms with the specific anatomic site. The elbow is particularly subject to overuse syndromes, inflammatory conditions, and localized nerve entrapments. A careful history and physical examination are often all that is required to reach an accurate diagnosis and formulate a treatment plan.

Lateral Epicondylitis ("Tennis Elbow") Lateral epicondylitis ("tennis elbow") denotes inflammation at the common tendinous origin of the extensor muscles of the forearm, in particular the extensor carpi radialis brevis, on the humeral lateral epicondyle. It is the result of repetitive overuse, as occurs when tennis players use backhand strokes or people knit. The common denominator is a strong grasp during wrist extension. The patient describes pain on the lateral aspect of the elbow. The physical examination reveals tenderness over the lateral epicondyle (Fig. 153-1), pain during resisted wrist extension with the elbow extended, and reproduction of symptoms during resisted extension of the elbow with the forearm in pronation and the wrist in palmar flexion. Radiographic findings are normal. It is often difficult to distinguish a radial nerve entrapment syndrome from lateral epicondylitis.

Figure 153-1. Technique of palpating the lateral epicondyle to elicit "point" tenderness, typical of "tennis elbow." (From Katz WA. Rheumatic diseases. Philadelphia: JB Lippincott Co, 1977.)

The management of epicondylitis consists of reducing the inflammatory component, strengthening the involved muscle, and understanding and avoiding the precipitating factors. It may take several weeks for pain to disappear. Any painful activity is best avoided, including racquet sports, handshake, forceful use of the arm in hammering or unscrewing jars, and use of a screwdriver. There is no certain way to prevent recurrences of epicondylitis related to playing tennis, but proper stroking of shots with a firm wrist and proper elbow positioning may be helpful. *Forearm bands* are often tried but usually are of limited value; however, sometimes they allow play when mild pain is present.

Systemic *antiinflammatory medication* (e.g., 375 mg of *naproxen* twice daily or 600 mg of *ibuprofen* three times daily for 1 week) often provides relief of symptoms and may help abate the process. Local steroid injection may eventually be needed, although results may not be very dramatic. Injection is best reserved for refractory cases. The area of well-localized tenderness is carefully identified and injected with 1 mL of 2% lidocaine (Xylocaine), then with 20 mg of dexamethasone. If symptoms recur after an initially successful injection, the patient may request additional injections. Repeated steroid injection incurs some risk of tendon and fascial rupture and may be associated with other problems, such as discoloration or atrophy of the overlying skin. We rarely administer more than three injections and prefer to space the injections at least 4 to 6 months apart.

Physical therapists can teach patients a set of exercises they can perform at home to stretch and condition the involved muscles. They may also recommend friction massage, ultrasound, and other modalities. Many patients obtain relief from such alternative modalities, but few data are available to support their use.

In most cases, a program of rest, application of ice, NSAIDs, and physical therapy is successful in reducing symptoms and permitting a return to function. In the unusual recalcitrant case, operative treatment may be considered.

Medial Epicondylitis ("Golfer's Elbow") Medial epicondylitis ("golfer's elbow") is similar to "tennis elbow" but involves the common forearm flexor origin at the humeral medial epicondyle. Occasionally seen in golfers, it more commonly is associated with certain manual or household activities. The pain is localized to the region of the medial epicondyle and is reproduced by forcefully extending the elbow against resistance with the forearm in supination and the wrist in dorsiflexion. Radiographic findings are normal. Treatment is the same as for lateral epicondylitis. The possibility of a median or ulnar nerve entrapment syndrome should be considered.

Olecranon Bursitis. The clinical presentation is a painful swelling over the posterior aspect of the elbow. The swollen bursa is usually fluctuant and can be transilluminated. Localized trauma or repetitive local pressure associated with certain occupations is the most common cause, but this bursitis can also be a manifestation of such inflammatory conditions as rheumatoid arthritis, gout, or sepsis. Patients with septic bursitis commonly report a history of antecedent trauma and cellulitis of the skin, followed by localized swelling, redness, and tenderness about the elbow. Almost all cases of septic olecranon represent spread from a contiguous soft-tissue infection. Gram's stain of the bursal fluid is positive for the causative organism in about 50% of instances. *Staphylococcus aureus* is the most common isolate, found in 80% of cases; streptococcal species account for most of the remainder. The presentation of septic bursitis in the immunocompromised patient is similar.

Unless sepsis is suspected, one should avoid aspiration or corticosteroid injection because of the possibility of introducing infection. The use of antiinflammatory medication and a sling as needed and local protection to avoid pressure are the basic treatment approaches. The presence of septic bursitis should be confirmed with needle aspiration and analysis of the fluid for cell counts, Gram's stain, culture, and sensitivities. Treatment with aspiration followed by organism-specific parenteral antibiotics is usually effective. On rare occasions, operative debridement may be required.

Nerve Entrapment Syndromes. Pain in the elbow or forearm may be secondary to compression of the ulnar nerve in the cubital tunnel, the posterior interosseous nerve in the proximal forearm, or even the median nerve in the forearm or wrist. With ulnar nerve compression, pain may be felt beneath the medial epicondyle, and the patient may experience numbness in the pinky and ring finger. Intrinsic muscle weakness is also commonly noted on examination. The presentation of posterior interosseous nerve compression is similar to that of tennis elbow, but symptoms are reproduced by extension of the middle finger against resistance (see also Chapter 167). The treatment of ulnar nerve compression can be as simple as avoidance of leaning on the elbow and nighttime use of a splint that holds the elbow in

extension. Use of a protective pad may help. If entrapment is accompanied by muscle atrophy or does not respond to simple measures, referral is required.

Arthritis

The elbow is not a common site for osteoarthritis, but arthritis may be found in association with prior fracture or dislocation. In contrast, elbow involvement is common in rheumatoid arthritis. On examination, limitation of motion, swelling, and pain are common findings. Radiographs demonstrate the extent of joint space involvement. Antiinflammatory agents provide good relief (see Chapter 156).

Septic Arthritis. Most cases are the result of blood-borne infection, manifested by the rapid onset of pain, diffuse joint swelling, and erythema. Systemic symptoms are common. It is important to rule out underlying conditions such as diabetes mellitus, steroid treatment, or rheumatoid arthritis. If sepsis is suspected, arthrocentesis for Gram's stain and culture of the joint fluid is required (see Chapter 145). The differential diagnosis of an acute monoarthritis includes gout and pseudogout (calcium pyrophosphate deposition), both of which can be difficult to distinguish from infection before aspiration and fluid analysis have been performed. Treatment of confirmed infection includes operative debridement and IV administration of organism-specific antibiotics.

HAND AND WRIST PAIN

Carpal Tunnel Syndrome. Carpal tunnel syndrome is an important cause of work disability and is often blamed on repetitive motion. However, such activity may be only a precipitant rather than the cause. In many cases, an underlying, often undiagnosed, medical condition renders the patient susceptible. Leading causes include hypothyroidism, inflammatory joint disease, osteoarthritis of the wrist, and recent trauma. Typically, the patient reports nocturnal symptoms, including hand and wrist pain and paresthesias that are often relieved by shaking the hand. Numbness is common, affecting the middle or three radial fingers and occasionally the thumb. A number of systemic conditions are associated with carpal tunnel syndrome, including diabetes mellitus, hypothyroidism, inflammatory arthritis, and pregnancy.

Clinical findings can be helpful in the diagnosis. With the aid of a diagram to help patients specify their hand symptoms, the history was found to have a sensitivity of 64% and a specificity of 73%. The physical examination is not much more sensitive or specific but may reveal suggestive findings. For example, altered sensibility may be noted in the thumb, index, and long fingers and the radial side of the ring finger; one may find changes only in one or two digits. Thenar (base of the thumb) muscle atrophy is present in prolonged or profound median nerve compression. *Tinel's sign*, elicited by tapping over the median nerve at the wrist crease, consists of "electric shocks" or paresthesias in the median nerve distribution. *Phelan's test* is performed by having the patient maintain the wrists in palmar flexion for 1 minute. The test result is considered positive and consistent with carpal tunnel syndrome if the patient's symptoms are reproduced. A negative result of Phelan's test or the absence of Tinel's sign does not necessarily rule out the presence of carpal tunnel syndrome. Reported sensitivities and specificities for Tinel's sign and Phelan's test range from 47% to 90%.

Definitive diagnosis can be made by *nerve conduction study* and *electromyography* (EMG). Testing is indicated if the diagnosis is unclear or if the condition persists and some numbness or weakness appears. In a patient with carpal tunnel syndrome, EMG and nerve conduction study demonstrate an increase in motor or sensory latency, which is helpful in documenting the location and degree of nerve compression. Correlating the clinical findings with the neurophysiologic test results is necessary for an accurate diagnosis because as many as 50% of asymptomatic patients may have abnormal results on nerve conduction or EMG studies.

Updated: 10/8/02

Conservative therapy for carpal tunnel syndrome consists of wrist splinting, control of any underlying systemic metabolic disorder, and occasional local injection of corticosteroids. A firm canvas or plaster *wrist splint* worn during sleep prevents wrist positions of extreme dorsiflexion or palmar flexion, which tend to increase the local compression within the carpal tunnel. In those patients with a significant flexor tenosynovitis, an *injection of corticosteroids* (e.g., 0.5 to 1 mL of dexamethasone plus 1 to 2 mL of lidocaine) directly into the carpal tunnel may be of value. The injection is placed just proximal to the transverse retinacular ligament in the wrist. If a paresthesia is elicited, a more superficial needle placement is made to avoid injecting into the nerve. Steroid injection has been found in randomized, controlled studies to provide long-term relief to a majority of patients and obviate the need for surgery in most. *Surgical intervention* is considered if symptoms persist longer than 3 months, if an associated thenar muscle atrophy develops, or if the motor or sensory latencies on the EMG and nerve conduction studies are extremely prolonged. A randomized controlled trial has demonstrated that in persons with idiopathic moderately severe disease, open surgical carpal tunnel release is superior to splinting over the long term. Predictors of a poor outcome with conservative therapy alone include age over 50 years, presence of symptoms for longer than 10 months, constant paresthesias, triggering of flexor tendons, and positive Phalen test in less than 30 seconds.

De Quervain's Tenosynovitis. On the dorsal aspect of the wrist, the extensor tendons to the hand and wrist course through six well-defined compartments. The first dorsal compartment contains the abductor pollicis longus and the extensor pollicis brevis and is located just proximal and radial to the anatomic "snuff box." A relatively common disorder is a nonspecific subacute or chronic inflammation of these tendons within the first dorsal compartment. Pain is exacerbated by use of the thumb and is reproduced when the patient, with the wrist in ulnar deviation and palmar flexion, grasps the thumb with the adjacent digits (Finkelstein's test). This test differentiates tendinitis from any underlying arthritis. The usual aggravating factor is excessive repetitive work with the hand, such as needlepoint, knitting, or peeling vegetables.

Most patients respond to nonoperative treatment consisting of splinting and steroid injection. An injection preparation such as that described for carpal tunnel syndrome is carefully placed within the first dorsal extensor compartment, which has a somewhat more radial and volar location than one might think. Care is exercised to inject just above the abductor pollicis longus. A removable plaster or Orthoplast splint holding the wrist and thumb in slight dorsiflexion and radial deviation is worn for 10 to 14 days except for bathing. Oral NSAIDs may also be of use. Failure to respond should be considered an indication for surgical referral.

Trigger Finger. Tenosynovitis also commonly involves the flexor tendons to the digits or thumb at the level of the metacarpophalangeal joints just proximal to the first annular pulley of the flexor tendon sheath. Snapping of the digit (triggering) with use and locking, or the inability to extend the proximal interphalangeal joint, are the characteristic presenting symptoms. Often, the patient perceives the triggering to be at the level of the PIP joint. A palpable thickening of the flexor tendon may be felt at the level of the metacarpophalangeal joint in the palm.

Treatment consists of splinting, corticosteroid injection, and NSAIDs. The steroid–lidocaine combination is injected just proximal to the distal palmar crease, where the first annular pulley of the flexor sheath is located. Such treatment is effective in almost 90% of cases, and the risk for serious adverse reactions is minimal.

Ganglion Cysts. Ganglionic cysts are the most common mass occurring in the hand or wrist and may be found in a number of sites, including the dorsum of the wrist, where the origin is the scapholunate ligament. Another common location is on the radial volar surface of the wrist directly adjacent to (and not to be confused with) the radial artery. Ganglia are thought to be outpouchings of the wrist capsule and contain fluid very similar to joint fluid. Their origin (stalk) is in the wrist joint, which explains the high incidence of recurrence when treatment methods such as aspiration or the traditional home remedy of striking the cyst with a heavy object (e.g., a Bible!) are used.

Most ganglia require no treatment. Aspiration with a large-bore (16- or 19-gauge) needle is helpful if the diagnosis is in doubt; however, even with steroid injection, the recurrence rate is high. Surgical treatment is indicated if the cyst is painful, the appearance is unsatisfactory, or the exact nature of the mass is a concern.

Mucous Cysts. Mucous cysts, associated with degenerative arthritis of the interphalangeal joints of the digits or thumb, are outpouchings of joint fluid similar to wrist ganglia. Radiographs show joint space narrowing and, often, marginal spurs or osteophytes. Osteophytes alone are the cause of the so-called Heberden's node at the distal interphalangeal joint and Bouchard's node at the proximal interphalangeal joint.

Arthritis. Degenerative joint disease commonly affects the carpometacarpal joint at the base of the thumb (see Chapter 157). Most often affecting women, the condition is associated with localized pain, decreased dexterity, and diminished grip strength. Pain and crepitation can be elicited if the examiner grasps the thumb metacarpal and compresses it onto the trapezium (grind test). Radiographic changes may vary from mild joint space narrowing to complete joint space loss and the presence of osteophytes and loose bodies.

Once recognized, mild to moderate arthritis of the trapeziometacarpal joint of the thumb can be effectively managed with NSAIDs and a molded splint worn 4 to 6 hours daily. The splint extends beyond the metacarpophalangeal joint but leaves the wrist free (a short opponens splint). It should be custom-made by a trained occupational therapist.

The hand involvement in *rheumatoid arthritis* can vary from minimal pain and swelling to extensive deformity and joint destruction. Treatment includes pharmacologic

and physical therapy (see Chapter 156). Tendon rupture is not uncommon; its occurrence should prompt early referral.

Hand Infections. Hand infections are potentially serious conditions, especially if they occur in a closed compartment. Presentations vary. Infection around the fingernail is termed *paronychia* and is usually caused by gram-positive organisms. Antibiotics and warm soaks suffice in mild, well-localized cases, but any spread requires referral for incision and drainage. A *felon* is a more worrisome problem because it is an infection in a closed compartment, the pulp space of the tip of the digit. The pulp is swollen, exquisitely tender, and erythematous. If not corrected, the edema can compromise arterial supply and lead to necrosis of the fingertip. Treatment includes incision, drainage, and administration of antibiotics. Early referral to a hand surgeon is essential for definitive treatment. A less troublesome infection, seen mostly in hospital personnel and children, is *herpetic infection* of the fingertip, which is characterized by the appearance of small vesicles along the pulp. It clears spontaneously, although the patient is infectious until the vesicles clear.

In *infectious flexor tenosynovitis*, the patient presents with a digit that is symmetrically swollen, painful along the entire flexor sheath, flexed, and tender on passive extension of the distal joint. Prompt recognition and, in many cases, surgical intervention are critical to preserve ultimate tendon function.

Puncture wounds, in particular human bites, may result in extremely virulent infection. Prompt and aggressive wound care, with the puncture site left open, and antibiotic treatment may abort a more serious and destructive process. Animal bites, especially from dogs and cats, can transmit *Pasteurella multocida*, which in most instances is extremely sensitive to penicillin (see Chapter 196.1).

SUMMARY

Localization of symptoms provides the keystone for evaluation. The examiner should attempt to determine the precise area of tenderness. A thorough functional examination (active and passive motions of the wrist, digits, and thumb; sensory testing with light touch and pinprick; determination of specific flexor and extensor tendon function) should be part of every assessment of the patient with a hand problem. Standard anteroposterior and lateral radiographs are generally advisable in most cases. EMG and a nerve conduction study are part of the workup for peripheral nerve compression.

Nonspecific tenosynovitis and mild to moderate degenerative arthritis generally respond to antiinflammatory medication and simple splinting (discussed earlier). The patient with a hand infection, fracture, nerve compression, or mass should be referred to a hand specialist.

CHAPTER 154 APPROACH TO MINOR ORTHOPEDIC PROBLEMS OF THE FOOT AND ANKLE

JESSE B. JUPITER AND DAVID RING

Foot Problems
Ankle Disorders

Patients often consult primary physicians for advice and help regarding foot or ankle problems. Although some patients require orthopedic referral for more detailed investigation and treatment, many can be substantially helped by the nonorthopedist physician who is knowledgeable about the diagnosis and treatment of common foot and ankle complaints. Such disorders are extremely prevalent and can incapacitate a patient. The primary care physician should be familiar with the basic types of foot and ankle complaints, so as to be able to treat minor conditions effectively and refer appropriately those problems that require the skills of an orthopedic surgeon.

FOOT PROBLEMS

Foot disorders are a major cause of disability in the work force. Although often the result of normal activity, foot pain can also be precipitated by structural deformity or systemic disease. Environmental factors, such as shoe type and weight-bearing surface, add to the development and progression of symptoms.

Anatomically, the human foot has 26 bones, comprising one fourth of those in the entire skeleton, along with 100 or more ligaments, 12 extrinsic muscle insertions, and 19 intrinsic muscles. During gait, more than two times the force of body weight is borne by the foot. In normal gait, the foot assumes several roles, including that of a shock absorber, a mobile adapter to accommodate uneven surfaces, and a rigid lever to propel the limb. Limitation or excess of these primary functions places the foot at risk for acquired mechanical trauma, with the prime candidates being the flat (pes planus) and high-arched (pes cavus) feet. Foot disorders are conveniently considered by anatomic zones: digits, forefoot, and hindfoot (Table 154.1). Office assessment is facilitated by familiarity with the location and manifestations of common foot problems (Fig. 154.1).

Table 154.1. Common Causes of Foot Pain

FIG. 154.1. Sites of common foot problems.

Digital Problems

Problems referable to the toes usually are related to deformities. Most digital problems present as sagittal plane deformities. The three types are *hammer toe, mallet toe,* and *claw toe.* Pain with or without a "corn" (clavus) is usually the primary complaint. Toe contractures develop secondary to muscle imbalances or are shoe-induced; they can be flexible or rigid. Shoes (prescription or commercial) that provide adequate room in the toe box area are the first line of treatment. If the contractures are flexible, digital splints may be helpful. In persistent or progressive disease, surgery may be necessary if foot pain compromises daily activity.

Forefoot Problems

First Metatarsophalangeal Joint. The most common deformity of this joint is the *hallux valgus*, or *bunion.* It presents as a painful swelling on the dorsomedial aspect of the first metatarsal head, associated with lateral drift of the toe. The deformity or foot–shoe incompatibility may be the presenting complaint, but just as frequently, the patient presents with secondary adjacent problems, such as hammer toes or metatarsalgia. Hyperpronation (flat feet) and inappropriate shoes (high heels, pointed toe box) contribute to the development of the painful bunion, particularly in women.

On examination, a tender bursa is often present over the inner side of the head of the first metatarsal. The great toe itself may deviate laterally and at times is not even passively reducible. Radiographs may show the underlying cause to be an increased angle between the first and second metatarsals (normal, 10 to 12 degrees). This deformity is also commonly seen in patients with rheumatoid arthritis.

Properly fitted shoes (commercial or custom-made), bunion shields, and orthotic devices can afford symptomatic relief to many patients. Surgical intervention may be required to correct the structural deformity.

Hallux limitus, or *hallux rigidus*, is characterized by limited or total loss of dorsiflexion of the first metatarsophalangeal (MTP) joint and a dorsal "bunion." The patient usually has pain while walking or problems with shoe fitting.

Physical examination reveals markedly limited mobility of the first MTP joint, especially on dorsiflexion (normal, 50 to 80 degrees passively). Pain and crepitation are usually present. Radiographs reveal changes associated with degenerative joint disease, such as joint space narrowing, osteophytes, and sclerosis. Chronic gouty arthritis may resemble this condition.

The initial treatment should be directed at limiting the stresses on the joint. An orthotic device with an extension under the great toe (Morton's extension) and a shoe

with extra depth should be prescribed. Limiting joint motion by stiffening the outer sole of the shoe (full-length steel shank) may also help. Surgery involving either debridement of osteophytes (so-called cheilectomy) or joint resection, replacement, or fusion is indicated if conservative treatment is unsuccessful.

Sesamoid Disorders. The first MTP joint contains two sesamoid bones (medial and lateral) that articulate on the plantar aspect with the first metatarsal and serve, to some degree, as a fulcrum in normal joint mobility. Excessive or abnormal stress about this area can lead to pain and inflammation (*sesamoiditis*), *cartilage injury*, or *sesamoid fracture*. A history of trauma may not be obvious, but sesamoid injuries are not uncommon among ballet dancers, joggers, aerobic dancers, and the like.

Localized pain and swelling are present on careful examination (plantar palpation). Radiographs should include, in addition to standard anteroposterior and lateral views, a sesamoid axial view, which is crucial for an accurate diagnosis. If a fracture is suspected, one must remember that bipartite (or multipartite) sesamoids are normal variants; a bone scan may be helpful in the diagnosis of fracture.

Treatment is directed toward providing rest and reducing the weight-bearing stresses in this area. A stiff-soled, low-heeled shoe with a full-length shank and soft innersole may be all that is required to reduce stress on the sesamoids in mild cases. Orthotic devices may be of additional help. Infrequently, excision of the involved bone is required.

Lesser Metatarsophalangeal Joints. The fifth metatarsal equivalent of the bunion is the *bunionette*, which also presents as a painful deformity and foot–shoe incompatibility. The lateral aspect of the fifth metatarsal head is tender, with a local bursal swelling. Radiographs may show the primary defect to be an excessive angle between the fourth and fifth metatarsals or an enlarged fifth metatarsal head. Alteration of shoe gear (i.e., wider or stretched) usually helps, although surgical correction may be necessary.

Metatarsalgia. True metatarsalgia is pain with weight bearing in the vicinity of the lesser metatarsal heads. Although the term is commonly used for any pain pattern in this area, it more accurately reflects an absence of other underlying conditions, such as interdigital neuroma, metatarsal stress fracture, MTP joint arthritis, or osteochondritis. The metatarsals are tender to pressure, and the plantar aspect of the foot (with the patient lying in the prone position) may reveal a protrusion in an otherwise flat forefoot surface. Hypermobility may also be found in the neighboring metatarsals. Often, a callus develops directly beneath the involved metatarsal, creating additional discomfort.

A variety of conservative methods are employed to disperse weight away from the involved metatarsal, including soft innersoles, molded shoes with innersoles, metatarsal bars, and orthotic devices. In some situations, as in deforming rheumatoid arthritis with dorsal dislocation of the MTP joints, surgical intervention (metatarsal head resection) is necessary and most rewarding.

Interdigital (Morton's) Neuroma. Burning pain and cramping, most often involving the third and fourth toes, are characteristic symptoms of this lesion. Classically, the patient is a woman who reports that symptoms are aggravated by wearing closed shoes and relieved by removal of the shoe and forefoot massage. The third intermetatarsal space is supplied by a common nerve trunk, receiving branches from both the medial and lateral plantar nerves. Compression and irritation of this trunk in a fibroosseous ring formed by the metatarsal heads, the deep transverse intermetatarsal ligament, and the plantar weight-bearing surface are implicated in this lesion.

By compressing the forefoot and pushing up in the distal third intermetatarsal space, a "click" may be felt (Mulder's sign) and the patient's symptoms reproduced. Relief is sometimes achieved through the use of wider shoes, a metatarsal bar, soft insoles, orthotic devices, NSAIDs, or local anesthetic and steroid injections. Quite often, surgical excision is required.

Metatarsal Stress Fractures. Functional overload in a lesser metatarsal (usually the second or third metatarsal) may result in a march or fatigue fracture. The onset of symptoms is sudden and often without a history of trauma. Palpation of the metatarsal shaft elicits pain over the site of injury. Between 4 and 6 weeks after injury, swelling can be palpated, reflecting the presence of a healing callus. Initially, radiographic findings are negative, but a bone scan may confirm the diagnosis early on.

Healing is uneventful if one avoids rigorous activities and wears a stiff-soled, low-heeled shoe. Occasionally, a standard wooden postoperative shoe and an Unna's boot compressive wrap are helpful in providing a more comfortable gait.

Hindfoot Problems

Plantar Heel Pain is seen in both young and old patients and can be disabling. It is often mistakenly attributed to "heel spurs," most of which are asymptomatic and unrelated to the pain.

Plantar Fasciitis classically causes pain with the initial step taken on getting out of bed in the morning. Pain often diminishes as the foot "stretches out," only to recur after periods of inactivity. Overuse syndromes, such as conditions caused by jogging, can contribute to small tears near the origin of the plantar fascia, with subsequent focal pain and localized inflammation. Characteristically, tenderness can be elicited along the medial plantar aspect of the foot, approximately three finger breadths distal to the posterior heel. Pain is increased with forced dorsiflexion of the digits during the examination. Although radiographs often demonstrate a plantar spur at the anterior inferior aspect of the calcaneus, this is usually not the cause of the symptoms.

Initial treatment focuses on tendo Achilles stretching exercises and modification of activities, application of ice, administration of NSAIDs, and use of a heel cushion to provide symptomatic relief. Patients often wonder why they should do exercises for their calf when the problem is in their foot. It must be explained that a continuous fascia sleeve extends from the calf muscles into the foot and that the stretching exercises will relieve the point of stress at the heel. If these measures are not effective, a trial of 1 to 2 months of cast immobilization can be tried—a form of enforced complete rest. Local steroid injections can be considered but should be used sparingly. Rupture of the plantar fascia can be a more difficult problem to address. Rarely, surgical release of the plantar fascia is required, but the operative results are not consistently good.

Intracalcaneal Bursitis. In contrast to plantar fasciitis, this entity presents with an aching sensation in the direct *midplantar* aspect of the calcaneus that generally increases with the duration of weight bearing. Symptoms are more pronounced as the day progresses. Examination reveals *point tenderness* directly under the midportion of the calcaneus. Localized warmth and swelling may be present. This localized lesion is most likely an inflamed bursa directly beneath the calcaneus. Therapy includes local modalities, such as ice, massage, NSAIDs, and steroid injections. A soft heel pad, heel cup, or appropriately fabricated orthotic device to relieve direct impact on this region should be added.

Neurologic Heel Pain. Local or more *proximal nerve entrapment* is an important cause of heel pain. For example, an entrapment of the medial calcaneal branch of the posterior tibial nerve in the region of the inferior calcaneus can mimic symptoms of inferior calcaneal bursitis. In this situation, however,one can elicit a proximal radiation of pain upward toward the region of the tarsal tunnel beneath the medial malleolus. The presence of Tinel's sign should be sought on examination. If local steroid injection is not effective, release of the medial calcaneal branch, or tarsal tunnel release, may be required.

As the posterior tibial nerve courses behind the medial malleolus and enters the fibroosseous tarsal tunnel, local compression of the nerve caused by local trauma (sprain, fracture), a space-occupying lesion (varicosity, lipoma), or repetitive hyperpronation can result. Symptoms include paresthesias, dysesthesias, and nocturnal pain along the plantar aspect of the foot or anywhere along the distribution of the medial or lateral plantar nerves. Results of nerve conduction studies are not consistently abnormal in this "*tarsal tunnel syndrome*." A foot surgeon should be consulted, although conservative treatment with orthotic devices and local steroid injections may preclude the need for surgical release.

Lastly, neurologically related heel pain can be the result of a *radiculopathy* secondary to a herniated lumbosacral disk. Careful examination of the low back and neurologic testing, including assessment of sensory and reflex function, should be performed, especially if the cause of the pain is not readily apparent.

Posterior Heel Pain. Two bursae are present at the posterior heel: a superficial bursa lying between the Achilles tendon and skin and a deep bursa located between the tendon and the calcaneus. *Posterior calcaneal bursitis* results from structural and functional abnormalities of the hindfoot or the wearing of inappropriate shoe gear with a firm, unyielding heel counter. Pain can be elicited by compression of the heel cord just anterior to its attachment and with passive dorsal and plantar flexion of the ankle. Several systemic inflammatory conditions (rheumatoid arthritis, ankylosing spondylitis, and Reiter's syndrome) can produce a similar clinical picture, as can a tear of the Achilles tendon and posterior calcaneal exostosis (see later discussion).

The recommended treatment of acute posterior calcaneal bursitis begins with local measures, such as application of ice in the first 24 hours, followed by moist heat, NSAID medication, and rest. With a more chronic condition, a heel lift or orthotic device to control heel motion and adjustments of the heel counter of the shoe should be considered.

Exostosis. Posterior calcaneal exostosis ("pump bump") is most commonly seen in young women, presenting as a tender enlargement about the lateral dorsal aspect of the posterior calcaneus. Pain is aggravated by a firm heel counter. A thickened bursa may overlie a true exostosis of the calcaneus, which can be seen on a lateral radiograph. The treatment of the acute, bursal inflammation parallels that for other types of heel bursitis, already described. Resection of a posterior bony exostosis is reserved only for those cases in which symptoms cannot be effectively controlled conservatively.

Achilles Tendinitis, a common affliction of athletes, reflects inflammation or small tears near the insertion of the Achilles tendon (or paratendon). Discomfort worsens during athletic activity, with subsequent swelling and stiffness. On examination, tenderness to palpation of the tendon (often extending proximally) is noted in association with a palpable fusiform swelling. In acute cases, the first line of therapy is rest, even to the point of plaster immobilization. A heel lift, ultrasound, antiinflammatory agents, heel cord stretching, and orthotic devices are helpful in the chronic phase.

Systemically Related Foot Disorders

The foot can mirror systemic disease. Disorders of the macrovasculature or microvasculature can be the underlying cause of a variety of foot problems, including ulcers and necrosis. Neurologic disorders can compromise both form and function of the foot. Systemic or metabolic disorders, including atherosclerosis, diabetes mellitus, gout, and rheumatoid arthritis, may all have profound effects on the foot and require medical in addition to orthopedic, vascular surgical, or podiatric treatment (see Chapter 34, Chapter 102, Chapter 156, and Chapter 158).

Runner's Foot

The stress of repeated impact sustained during athletic endeavors such as jogging predisposes the foot to significant mechanical trauma. All the specific entities discussed previously occur among runners. Just as important is the biomechanical influence of the foot on the rest of the lower extremity. For example, the hyperpronated "flat" foot can cause excessive strain on the posterior tibial muscle and also increase the torque on the entire lower extremity, so that medial knee pain is felt after prolonged jogging. If one does observe significant hypermobility or hyperpronation, it is best to support the foot mechanically with a molded orthotic device. A rigid, cavus-type foot deformity prevents normal pronation with stance. When engaged in running, the foot may lose its capacity to act as a shock absorber. Increased shock is transmitted up the entire lower extremity, even to the region of the lower back. Patients with this type of foot deformity may complain of leg, knee, and hip discomfort.

ANKLE DISORDERS

Ankle Sprain. A sprain is the most common ankle injury. Lesions range from minor ligamentous damage to complete tear or avulsion of the bony attachment, fracture, and dislocation. Sprain occurs when stress is applied while the ankle is in an unstable position, causing the ligaments to overstretch. During plantar flexion, the joint is least stable and most susceptible to eversion or inversion forces. Such stresses are encountered during running or walking over uneven surfaces. Evaluation is facilitated by early presentation because the event producing injury is likely to be remembered and swelling is confined to the site of injury.

All too often, ankle sprains are considered minor injuries requiring little medical attention, even though experience has proved this concept to be misleading. Although many sprains heal with no residual disability, some do not. All reflect some degree of injury to one or several ligaments and may be classified as *first-degree* (involving stretching of ligamentous fibers), *second-degree* (involving a tear of some portion of the ligament with associated pain and swelling), and *third-degree* (involving complete ligamentous separation).

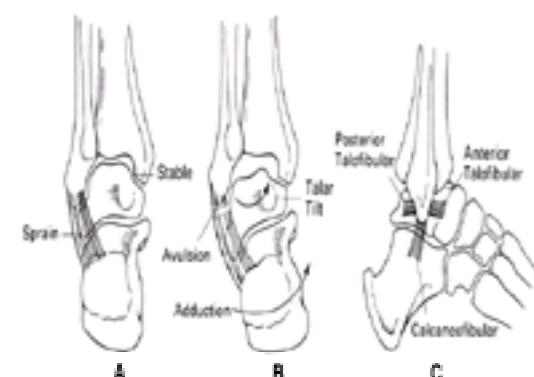
An *inversion injury*, the most common type of sprain, causes damage to the lateral ligaments. There is often a history of inversion during plantar flexion; a snap or tear may have been heard or felt. However, the history of injury is often inaccurate and may not be helpful in the evaluation of the extent of ligamentous damage. A careful physical examination is needed to identify the site and degree of injury, with the examiner's fingertips used to check the anterior capsule and medial and lateral ligaments (Fig. 154.2). Although significant edema commonly accompanies ligamentous injury, complete ligamentous and capsular disruption may produce remarkably little edema because of extravasation into the surrounding soft-tissue planes.


FIG. 154.2. Lateral ligamentous sprain and avulsion. **A:** Simple sprain in which the ligaments remain intact and the talus remains stable within the mortice. **B:** Avulsion of the lateral ligaments; the talus becomes unstable and tilts within the mortice when the calcaneus is adducted. **C:** Lateral ligaments of the ankle. The anterior talofibular and calcaneofibular ligaments are the ligaments most frequently involved in inversion injuries. (Redrawn form Cailliet R. Foot and ankle pain. Philadelphia: FA Davis Co, 1968, with permission.)

A useful indicator of significant injury is the *anterior draw sign.* The sign may be elicited by grasping the distal tibia in one hand and the calcaneus and heel in the other and sliding the entire foot forward. This is done first with the ankle in neutral position and then with 30 degrees of plantar flexion. Up to 2 mm of shift is normal. With disruption of the anterior or lateral ligaments, one sees 4 mm or more of anterior shift, as the fibers of the anterolateral ligaments lie in an anteroposterior direction. Passive inversion of the ankle produces pain. Swelling invariably occurs, usually anterior to the lateral malleolus at the onset; ecchymoses are common. Simple strain does not result in joint instability, but with a sprain, the joint loses stability and the talus tilts if the calcaneus is adducted (Fig. 154.2), producing a gap between the talus and malleolus on the lateral aspect of the ankle. If swelling or pain interferes with evaluation, a radiographic assessment after nerve block may be needed to determine joint instability.

Radiography is useful in most cases of moderate to severe injury, helping to identify any associated skeletal injury in addition to assessing the degree of ligamentous damage. Three standard views are obtained: anteroposterior, lateral, and mortice (an anteroposterior view with the ankle in 20 to 30 degrees of internal rotation). In addition, a stress view is obtained (with the help of local anesthesia, if necessary) to check for talar tilt. A tilt of more than 15 degrees is suggestive of lateral ligament injury; more than 25 degrees of tilt is diagnostic. One must always compare the tilt of one foot with that of the other to rule out underlying ligamentous laxity.

Control of swelling is the first and immediate priority of management because effusion and hemorrhage further stretch and distend the joint and predispose to adhesions. An elastic bandage, ice water, and elevation are often helpful in controlling edema. The ankle should be placed in ice water for 15 to 20 minutes and then elevated. An ice pack can substitute for immersion. Cold application is repeated every few hours. Radiography can be performed after taping, application of ice water, and elevation. A bulky, conforming, nonconstricting soft dressing may be applied.

The soft dressing or elastic bandage is used for 1 to 2 weeks to control swelling and provide stability. When the ankle is splinted, it should be kept in neutral or slightly everted position to avoid tightening the heel cord and other posterior structures. Partial weight bearing is accomplished by use of a crutch until pain subsides.

Non–weight-bearing exercises are started within 2 to 3 days of injury; these include active plantar flexion, dorsiflexion, toe flexion, inversion, and eversion.

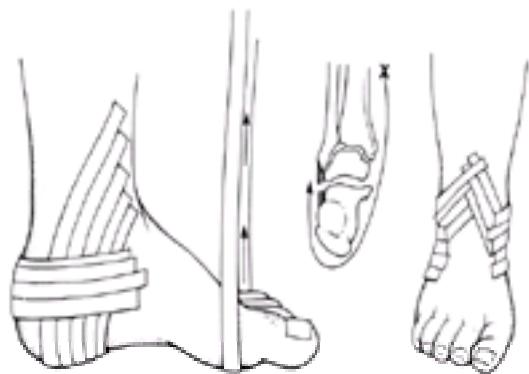
After pain subsides and swelling resolves, full weight bearing can be resumed, often with the use of a functional plastic "sprain brace." These braces are commercially available in a number of designs; all function to support the ankle against inversion and eversion stresses while, at the same time, allowing dorsiflexion and plantar flexion of the ankle. Running should be postponed another 1 to 3 weeks depending on the severity of injury. With mild ligamentous laxity of the ankle and repeated minor sprains, proper taping to support the lateral structures is indicated for athletic activity that involves contact, running, or jumping, particularly on uneven ground. Tape strips are applied from medial aspect to the lateral aspect of the ankle (Fig. 154.3) to hold the heel and ankle in eversion and provide support. Exercises to strengthen the ankle evertors and high-laced leather supportive shoes may also be helpful.


FIG. 154.3. Taping a sprained ankle. The purpose of taping the ankle is to prevent further stretching of the injured ligaments until healing has occurred. The ankle must be inverted or everted to place the strained ligament at rest. The center figure depicts an avulsed lateral ligament. The tape here begins from inside and then runs under the foot to finish on the outer leg, holding the heel everted. The horizontal strips minimize rotation of the forefoot. (Redrawn from Cailliet R. Foot and ankle pain. Philadelphia: FA Davis Co, 1968, with permission.)

Ankle sprain is a serious injury; if torn ligaments result in marked ankle instability (determined by examination under anesthesia or stress radiography), cast immobilization for 4 to 8 weeks is indicated. Serious sprain requires prompt orthopedic referral to maximize chances for healing and restoration of joint stability.

CHAPTER 155 APPROACH TO THE PATIENT WITH ASYMPTOMATIC HYPERURICEMIA

Asymptomatic hyperuricemia became commonplace when physicians began using chemistry panels that routinely included measurement of the serum uric acid. Hyperuricemia is defined as a serum uric acid concentration that exceeds the mean by at least two standard deviations. The mean (as determined by colorimetric assay, the most commonly used method) is 7.5 mg/dL for men and 6.6 mg/dL for women. By statistical definition, 2.5% of the population is hyperuricemic. The consequences of being hyperuricemic and the need for lowering the uric acid level have been subjects of debate. Some authorities have advocated prophylactic therapy in the hope of preventing acute gout, chronic tophaceous gout, stone formation, and renal failure. Others question the cost-effectiveness of such an approach and even the relationship of hyperuricemia to some of the adverse consequences attributed to it. The primary physician must decide if and when to treat the asymptomatic patient with an elevated uric acid level.

PATHOPHYSIOLOGY AND CLINICAL PRESENTATION

Uric acid is the end-product of purine metabolism. Humans have no pathway for the further breakdown of uric acid; it must be excreted by the kidneys or the serum level will rise. The pathogenesis of hyperuricemia involves either the overproduction or underexcretion of urate, or both. It is estimated that one third of hyperuricemic patients are overproducers, another third are underexcreters, and the remainder have a combined deficit.

Overproduction of uric acid is especially marked in patients undergoing treatment for myeloproliferative and lymphoproliferative malignancies and in those with severe psoriasis. Rapid cellular turnover results in the production of massive amounts of nucleic acid metabolites that are converted to uric acid. Overproduction may also develop from an increase in purine synthesis *de novo*, as occurs in patients with inborn errors of metabolism. Contrary to popular belief, excessive dietary intake of purine-rich foods is rarely responsible for hyperuricemia because dietary sources of purine make up only 10% of the uric acid pool. However, excessive intake of alcohol (>100 g of ethanol per day) results in increased urate synthesis, especially if the patient does not eat anything at the time of alcohol consumption.

Underexcretion of uric acid occurs in association with an overall decrease in the glomerular filtration or a defect in the tubular secretion of urate; uric acid is also underexcreted if another substance competes with urate for tubular secretion. A compromise in renal blood flow secondary to aging or atheroscleroticdisease reduces renal urate excretion. Hyperuricemia has been noted in hypertensive patients. Although some instances may be a consequence of hypertensive renovascular injury, epidemiologic analysis suggests that most cases are caused by thiazide use. In addition to thiazides, low doses of aspirin reduce renal urate excretion. Excretion falls in patients with an increased proximal tubular reabsorption of sodium, which has been linked to hyperinsulinism and might account for the oft-noted, poorly understood relation between hyperuricemia and atherosclerotic cardiovascular disease. However, careful reexamination of the epidemiologic data linking hyperuricemia to an increased risk for cardiovascular disease reveals no independent causal relationship, but rather an association with thiazide use for the treatment of hypertension, a major cardiovascular risk factor. Fasting that results in ketosis seems to be capable of transiently reducing urate excretion and raising the serum uric acid.

Well over 90% of hyperuricemic patients present asymptomatically. Most are persons who have been subjected to multiphasic screening. Half of newly discovered patients in the Framingham study were taking thiazides, and just under 3% had elevations secondary to a concurrent illness, such as myeloproliferative disease.

PRINCIPLES OF MANAGEMENT

Prophylactic therapy might be indicated if lowering the uric acid level could prevent acute gout, chronic gouty arthritis, gouty nephropathy, or urolithiasis. For years, it was assumed that such complications are a direct result of untreated hyperuricemia, so that many clinicians treated asymptomatic hyperuricemic patients with urate-lowering drugs. The statistical relationship between hyperuricemia and atherosclerotic disease was also a concern, one that has now been eliminated.

Prevention of Acute Gouty Arthritis. Population studies (Framingham, Normative Aging, Sudbury) have confirmed that the higher the serum uric acid level, the greater the chance of an attack of acute gout; they have also confirmed that the urate concentration is the predominant determinant of risk. However, the oft-quoted 90% risk reported in the Framingham study represented a 12-year cumulative incidence figure and pertained only to 10 patients who had a uric acid level in excess of 9.0 mg/dL. More relevant is the average annual incidence, which was 4.0% in the Framingham study and 4.7% in the Normative Aging study for patients with urate concentrations in the top 2%.

To determine the utility of prophylactic therapy, one needs to consider the costs and benefits of preventing an attack of acute gout. The cost of lifelong prophylactic therapy can reach thousands of dollars because the mean age at the time of detection is 35. The prevalence of adverse drug reactions has been reported to be as high as 10% for probenecid and 25% for allopurinol. These costs appear excessive when the safety, efficacy, and minimal expense of promptly treating a single acute attack of gout with a short course of an NSAID are considered (see Chapter 158). Only if gouty attacks become disabling and frequent does the cost–benefit equation shift in favor of prophylaxis. In most instances, the intervals between recurrences of acute gout are measured in years.

Prevention of Chronic Gouty Arthritis. The issue of prophylaxis for prevention of chronic gouty arthritis is of only minor importance because almost all patients with this condition go through a stage of acute gouty attacks before chronic joint changes develop. Thus, asymptomatic patients with no evidence of clinical gout are at little if any risk for silently falling victim to chronic gouty arthritis.

Prevention of Azotemia. Despite fears to the contrary and early studies that were confounded by high exposures to lead, chronic hyperuricemia does not appear to be a significant risk factor for the development of azotemia, nor does hyperuricemia *secondary to* renal failure pose an additional threat to the kidneys. In a prospective study from Kaiser-Permanente in which 113 patients with asymptomatic hyperuricemia and 193 controls were followed for 8 years, no difference was found in the incidence of azotemia between the two groups (1.8% vs. 2.1%). In the same study, no relation between uric acid level and risk for azotemia was found in 168 patients with clinical gout followed for 10 years. In the Normative Aging study, a creatinine level above 2.0 mg/dL developed in only 0.7% of the 94 patients with a uric acid level in excess of 9.0 mg/dL during the 15 years of follow-up. One set of investigators calculated that a significant risk for renal injury from chronic hyperuricemia required that a uric acid level of 13.0 mg/dL in men and 10.0 mg/dL in women be sustained for 40 years. A 3-year prospective study of hyperuricemic patients with and without renal failure showed no change in renal function when allopurinol was used to normalize the serum urate concentration.

One group of hyperuricemic patients at risk for renal failure are those with myeloproliferative or lymphoproliferative malignancy who are undergoing chemotherapy. With each cytotoxic treatment comes a huge uric acid load that may trigger injurious urate crystal formation in the renal tubular cells. Acute oliguric renal failure may ensue. Such patients require pretreatment with allopurinol and vigorous hydration.

Prevention of Nephrolithiasis. The risk for nephrolithiasis in patients with asymptomatic hyperuricemia is very small. In the Kaiser study, renal calculi occurred in 3 (2.6%) of 113 hyperuricemic patients and in 2 (1.1%) of 193 controls. In two of the hyperuricemic patients with stones, the stone was composed of calcium. The risk for development of a stone attributable to hyperuricemia was calculated to be less than 1% annually. Among patients with gout, the control of serum uric acid was the same for those in whom stones developed and for those in whom they did not.

This minimal risk for stone development conferred by hyperuricemia alone derives from the importance of other factors in stone formation (see Chapter 135). Family history, urinary pH, and level of hydration are particularly germane. Two of the three hyperuricemic patients with stones in the Kaiser study had a family history of nephrolithiasis. Urine acidity is a critical factor because the solubility of uric acid falls precipitously as the pH falls from 8.0 to 5.0. The amount of uric acid excreted in the urine per 24 hours has also been suggested as a factor, but careful studies have shown that the level of urinary uric acid is only a weak determinant of stone formation until extreme levels are encountered. However, dehydration is a well-established precipitant.

Urolithiasis is rarely life-threatening. In a study of 1,700 patients with gout, only one patient experienced serious obstructive uropathy.

Prevention of Atherosclerotic Disease. Although a statistical relationship exists between hyperuricemia and atherosclerotic disease, it does not appear to be an

etiologic one. Rather, the two conditions appear to share a common pathophysiologic link, namely thiazide therapy and hypertension. No evidence has been found that treating hyperuricemia lowers the risk for atherosclerotic disease.

THERAPEUTIC RECOMMENDATIONS

- Asymptomatic hyperuricemia is associated with an increased risk for acute gouty arthritis, but the cost of prophylactic therapy in patients who have never had an attack of gout greatly exceeds the cost of treating an acute attack symptomatically, should it occur.
- Only with the development of frequent acute gouty attacks is prophylactic therapy indicated (see Chapter 158).
- Treatment to prevent chronic tophaceous gout need not be started until clinical evidence of gout develops.
- The evidence to justify prophylaxis to prevent renal impairment is insufficient except in patients who have a myeloproliferative or lymphoproliferative disorder and are about to be treated for it. The degree of azotemia that can be attributed to hyperuricemia is mild and clinically insignificant in most other instances.
- The risk for urolithiasis is sufficiently low to justify waiting for the development of a stone before prophylactic therapy is initiated, unless the patient has a strong family history of nephrolithiasis. However, dehydration should be avoided.
- Although hyperuricemia is associated statistically with atherosclerotic disease, the relation is not etiologic, and no cardiovascular benefit is derived from lowering the serum uric acid level.

CHAPTER 156 MANAGEMENT OF RHEUMATOID ARTHRITIS

ALLAN H. GOROLL

INTRODUCTION

The management of rheumatoid arthritis (RA) is a challenge because the disease is chronic, relapsing, and potentially disabling, and no completely satisfactory methods of treatment are available. The problem is common. Population surveys indicate that 3% of women and 1% of men in the United States have definite or probable RA, based on the diagnostic criteria established by the American Rheumatism Association. Prevalence increases with age, and incidence peaks in the fourth decade. The estimated annual incidence of new cases ranges from 0.5/1,000 to 3/1,000. The functional objectives of therapy are to minimize pain and stiffness and preserve range of motion and muscle strength through the use of disease-modifying agents, antiinflammatory drugs, and physical therapy measures. The primary physician needs to implement an effective program of patient education, exercise, joint rest, and symptomatic medical therapy, and to decide when referral for consideration of disease-modifying treatment is required. A trend toward earlier use of disease-modifying agents is under way, encouraged by the advent of increasingly effective new drugs. Additional tasks are to monitor closely for disease progression and treatment side effects.

PATHOPHYSIOLOGY AND CLINICAL PRESENTATION

Pathogenesis

Rheumatoid arthritis is an immunologically mediated chronic inflammatory disease of unknown etiology, manifested by synovitis and destructive arthritis of the diarthrodial joints. In genetically predisposed hosts (genotype *HLA-DRB1*04/04*), a delayed hypersensitivity reaction to an as yet unidentified stimulus (e.g., infectious agent, constituent of synovium or cartilage) appears to be the initial event. Although the precise sequence of immunologic events leading to joint injury continues to be elucidated, important cellular components of the process include CD4 helper/inducer T-cell lymphocytes, CD4 memory T cells, plasma cells, activated macrophages, and neutrophils. Cytokines (e.g., *tumor necrosis factor*, *interleukins*, *granulocyte-macrophage colony-stimulating factor*) are released and serve as important immune mediators, stimulating B- and T-cell proliferation and differentiation and activating neutrophils and monocytes. Immunoglobulin G rheumatoid factor (RF) emanating from local plasma cells may form immune complexes with articular antigens and thereby activate complement. The net result is the elaboration of prostaglandins, vasoactive amines, oxygen-derived free radicals, activated platelets, collagenases, and other lysosomal enzymes into the joint cavity, which causes direct damage to articular cartilage and bone.

Pathologically, the synovium is the principal site of initial involvement. The earliest change is immunologically mediated damage to the endothelium of the microvasculature. Small-vessel lumina become obliterated by thrombi and inflammatory cells, after which new capillary formation, synovial lining cell proliferation, edema, and leukocyte infiltration take place. Neutrophils migrate into the joint space. As the inflammatory process progresses, the synovium becomes more hypertrophic, edematous, hypervascular, and further infiltrated by mononuclear cells. In severe cases, the formation of *pannus* represents an invasive synovitis with proliferation of lymphocytes, plasma cells, fibroblasts, and macrophages. Pannus is capable of eroding cartilage and bone; the process typically begins at the joint margin, then spreads over the entire cartilaginous surface. Lysosomal enzymes released from within the pannus and latent collagenases are believed to contribute to the direct erosive capacity. Often, osteopenia is seen in subchondral bone adjacent to the involved joint even before pannus has denuded the cartilage.

Clinical Presentation and Course

Initially, an effusion develops, distending the joint capsule. This is followed by damage to the articular surface and weakening of the capsule and periarticular ligaments. Secondary muscle atrophy results and leads to imbalance of opposing muscle groups. The net effect is an unstable, weak, swollen, subluxated joint. The synovium of tendon sheaths and bursae may also be affected by the inflammatory process, so that tenosynovitis and bursitis develop.

The clinical onset of RA is usually insidious, often beginning with vague *arthralgias*, *morning stiffness*, and *fatigue.* In some patients, the onset is more acute. Signs of *articular inflammation* (swelling, pain, and warmth) soon follow. The small joints of the hands and feet—the proximal interphalangeals (PIP), metacarpophalangeals (MCP), and metatarsophalangeals (MTP)—are typically among the first to be involved, but knees, ankles, wrists, or elbows may also be affected early on. *Tenosynovitis* is common. Initially, the arthritis may be asymmetric or may even present as a monoarticular process, but the characteristic symmetric distribution supervenes in most instances.

In an occasional patient, RA is preceded by *palindromic rheumatism*, a condition characterized by repeated episodes of transient joint pain, swelling, and redness extending beyond the joint. The condition lasts a few hours to a few days, then resolves completely without causing permanent joint injury. Fingers, wrists, shoulders, and knees are most commonly affected. Typical RA develops in about 50% of these patients.

Rheumatoid nodules appear in about 25% of patients with RA, usually as the disease progresses. These subcutaneous nodules are firm, nontender, and located principally along the extensor surface of the forearm and in the olecranon bursa. Their appearance is an unfavorable prognostic sign, as is the persistence of acute disease for more than 1 year, high serum titers of RF, and age under 20 at time of presentation.

Sustained joint inflammation lasting more than a year leads to permanent *erosion* and loss of joint function. At first, the changes are partially reversible, but as cartilage and bone erode, the injury becomes permanent.

Hands and Wrists. Characteristic hand deformities include ulnar deviation of the MCP joints, boutonnière deformities of the PIP joints, and swan neck contractures of the fingers. In the wrists, a permanent loss of extension often occurs. A boggy, tender, dorsal wrist mass may result from tenosynovitis, and the median nerve can be compressed. The subsequent *carpal tunnel syndrome* is usually reversible, but nerve damage is permanent by the time wasting of the thenar eminence becomes obvious.

Feet. Erosion of the metatarsal heads can lead to ventral subluxation. Increased weight bearing on the inflamed heads and the formation of painful calluses result. Erosive disease may be silent in the MTP joints.

Hips and Knees. Involvement of these joints can be a source of much disability when weight bearing causes severe pain. Loss of internal rotation is the first change noted in the hip, followed by flexion contracture. One hip may predominate, even though the process is bilateral. In the knee, distention of the suprapatellar pouch by synovial effusion is common. If pressure rises rapidly, herniation of the synovium with formation of a popliteal *Baker's cyst* can occur, and the cyst can cause severe pain if it ruptures into the calf. Loss of full knee extension is followed by flexion contractures and gait difficulties.

Other Joints. In the *elbow*, extension may be compromised, and olecranon bursitis is often present. *Shoulder* involvement presents as a subacromial or subdeltoid bursitis or as limitation of motion. Erosion of the rotator cuff leads to painful upward subluxation of the humeral head against the acromion. In the *cervical spine*, atlantoaxial subluxation is common, but usually asymptomatic. This development is potentially serious because it can lead to direct compression of the spinal cord or of the blood supply to the brainstem; fortunately, it is a rare event. When the *temporomandibular joint* is affected, pain is felt during chewing or biting, and it is difficult to open the mouth. *Avascular necrosis of the femoral head* and *vertebral osteoporosis* and collapse are usually a consequence of corticosteroid therapy.

Radiographic Manifestations. Radiographic manifestations of early disease are soft-tissue swelling around the joint and periarticular osteopenia. Relatively uniform narrowing of the joint space occurs as cartilage is destroyed, a finding often noted within the first 2 years of disease. Periarticular subchondral erosion is noted at the

joint margin where pannus has developed. Finally, joint architecture is lost as the joint space is obliterated and erosion of subchondral bone progresses.

Extraarticular Manifestations. Extraarticular manifestations are most prominent in patients with persistent symptoms and high titers of RF (so-called seropositive disease), although up to 50% of patients with RA may show some form of extraarticular disease. *Pulmonary* manifestations include interstitial changes, pulmonary nodules, and pleuritis. The latter is manifested by a pleural effusion, in which the levels of *glucose* (5 to 20 mg/dL) and complement are characteristically *low*, the *leukocyte count* (5,000/mm^3) is *low*, and the *lactate dehydrogenase* level is *high*. *Accompanying pleuritic pain may or may not be present. An asymptomatic pericardial effusion* also may occur. Keratoconjunctivitis sicca (*Sjögren's syndrome*) has a strong association with RA, being found in up to 15% of patients. *Splenomegaly* is present in 5% to 10% of patients with RA, and lymphadenopathy is not unusual. The combination of RA, splenomegaly, and neutropenia (*Felty's syndrome*) is noted in an occasional patient. Neutropenia may be severe, but the arthritis is often quiescent. Other features include chronic leg ulceration, lymphadenopathy, and cryoglobulinemia. The risk for sepsis is high.

Vasculitis is believed responsible for a number of systemic manifestations, including fever, mononeuritis multiplex, Raynaud's phenomenon, chronic leg ulcers, mucosal erosions of the gastrointestinal tract, focal ischemia of the digits, and necrotizing mesarteritis. The *anemia* of chronic disease is seen in a large percentage of patients with RA.

Clinical Stages. In stage I, no symptoms or signs are present, just the presentation of the relevant antigen to an immunologically susceptible host. Stage II, in which the immune response becomes organized in the perivascular areas of the synovium, is characterized by increasing numbers of T cells, proliferation and differentiation of B cells, antibody production, synovial cell increase, and new blood vessel formation. Morning stiffness develops because fluid about the joints is increased. They are warm but not erythematous because superficial vessels are uninvolved. In stage III, the pathophysiologic processes of stage II continue, and extraarticular manifestations become evident. In stage IV, proliferating synovial membrane becomes invasive, injuring cartilage, bone, and tendons.

Clinical Course and Prognosis. The clinical course is generally one of exacerbations and remissions. About 40% of patients become disabled after 10 years, but outcomes are highly variable. Some patients experience a relatively self-limited disease, and others suffer a chronic, progressive illness. Improvements in the detection of early joint injury have provided a previously unappreciated view of how common and important early joint damage is. Nonetheless, it remains difficult at the outset to predict the course of an individual case, although the *HLA-DRB1*04/04 genotype*, a *high serum titer of RF*, *extraarticular manifestations*, a *large number of involved joints*, *age below 30*, *female sex*, and *systemic symptoms* all correlate with an unfavorable prognosis. Insidious onset is also an unfavorable sign. Disease that remains persistently active for more than a year is likely to lead to joint deformities and disability. Cases in which periods of activity lasting only weeks or a few months are followed by spontaneous remission have a better prognosis. The absence of RF does not necessarily portend a good prognosis. Outcome is compromised when diagnosis and treatment are delayed. Other laboratory markers of a poor prognosis include early radiologic evidence of bony injury, persistent anemia of chronic disease, and elevated levels of the C1q component of complement.

The overall mortality for patients with RA is reported to be 2.5 times that of the general population. In those with severe articular and extraarticular disease, the mortality approaches that of patients with three-vessel coronary disease or stage IV Hodgkin's disease. Much of the excess mortality derives from infection, vasculitis, and poor nutrition. Mortality from cancer is unchanged.

Most data on rates of disability derive from specialty units caring for referred patients with severe disease. Little information is available on patients seen in primary care community settings. Estimates suggest that more than 50% of these patients remain fully employed, even after 10 to 15 years of disease, with one third having only intermittent low-grade disease and another third experiencing spontaneous remission.

DIAGNOSIS

Because subclinical but important joint destruction begins early in many cases (see below), early diagnosis becomes a particularly important task for the primary physician. Delay in diagnosis is common; in a study of the problem, the time to diagnosis averaged 36 months from onset of symptoms (see Chapter 146 for a discussion of diagnostic evaluation).

PRINCIPLES OF MANAGEMENT

Management Goals and Strategy

The effective management of RA requires the design and implementation of a comprehensive treatment program that is consistent with the patient's personality and fits well into the patient's life-style and home environment. The goals are to relieve stiffness and pain, preserve muscle strength and range of motion, and minimize progressive disability and deformity. There is no cure, but *disease-modifying therapy* can reduce morbidity and mortality by slowing disease progression, preserving joint function, and limiting complications. *Early initiation* of disease-modifying therapy is increasingly encouraged to counter the important but previously unappreciated early joint destruction that characterizes RA. The early initiation of disease-modifying therapy represents a strategic shift in the pharmacologic treatment of RA, which traditionally designated the antiinflammatory agents as first-line drugs and relegated the disease-modifying agents to a second-line role. Besides early initiation, another feature of the disease-modifying strategy is the use of *multiple drug regimens*, which provide synergistic benefit and make possible a reduction in dosing and therefore a reduction in the frequency and severity of adverse drug effects. Despite the major advances in drug therapy, *nonpharmacologic measures* continue to be critically important in the maintenance of daily function and prevention of disability.

A number of factors must be considered in the design of a management program; these include the age, social and occupational responsibilities, and emotional makeup of the patient, the activity and duration of disease, and the results of prior therapies. A balanced, multifaceted approach to therapy is most likely to provide optimal results because no single drug or treatment is by itself effective. The basic components of a program must include thorough patient education, adequate rest, proper exercise, and suppression of inflammation and immune-mediated articular and vascular injury.

Nonpharmacologic Measures

The importance of nonpharmacologic measures cannot be overemphasized. Controlled trials have demonstrated that programs including such measures along with detailed patient education (see below) can provide as much benefit in terms of functional improvement as many pharmacologic therapies and reduce the costs of care by reducing the number of physician visits necessary. Thus, nonpharmacologic measures deserve considerable attention and emphasis because their implementation can be quite cost-effective.

Exercise. Exercise helps to maintain range of motion and muscle strength. The goals are to strengthen supporting muscles and minimize the chances of postinflammatory contracture. Exercises that safely put involved joints through a full range of motion are taught to the patient. When pain is too severe for active exercises, isometrics can be performed, and passive exercises can be prescribed and carried out by a physical therapist. Joints with a tense effusion should be not be exercised because compression of the synovium may lead to ischemic injury. Prior application of *heat* or *cold* (either may work) will facilitate the exercise program. Hot baths, paraffin soaks, or ice packs are often efficacious in loosening stiff joints. Moist heat is also useful in relieving pain and shortening the duration of morning stiffness.

Exercises involving important muscle groups are prescribed to counteract the development of atrophy, strengthen periarticular tissues, and preserve joint stability. A judicious program of walking can play a similar role. The design and execution of an exercise program can be facilitated by the participation of a physical therapist. To protect the joint from damaging stress, the patient can be instructed in the use of implements that provide a mechanical advantage. Such "joint savers" are available commercially and are most helpful for tasks requiring use of the hands.

Rest and Splinting. Rest and splinting can be helpful, but in the patient with mild to moderate disease, complete bed rest is not only unnecessary but potentially harmful. Prolonged rest may lead to flexion contractures, osteoporosis, and muscle atrophy. Only the patient whose acute disease is severe enough to warrant hospitalization should be put to bed, in which case some benefit is derived. However, a period of rest during the day can be of considerable benefit to those patients with persistently active disease who are less ill, most of whom are usually bothered by fatigue. Selectively resting individual joints by splinting can help relieve pain and prevent contracture of severely inflamed joints, especially those too swollen to exercise. The principle is to maintain the joint in its physiologic position, especially during periods when the joint is stressed. Splinting of the wrist at night is the best example of this form of therapy. The pain of a patient with tenosynovitis of the wrist can be decreased, and flexion deformity, with its attendant loss of grip, can be prevented. A wrist splint applied at night places the joint in 10 to 15 degrees of extension. A cervical collar worn at night can provide similar relief when the cervical spine is involved. The patient with deformed feet requires specially constructed

shoes.

Dietary Measures and Supplements. Dietary measures and supplements are always appealing to patients because they offer a "natural" and presumably safe way to treat their illness. Surveys reveal that almost two thirds of patients with RA have tried dietary measures and megavitamin supplements, and about half of that group continue regular use. Although evidence of efficacy is lacking for most of these measures and supplements, an adequate *calcium* and *vitamin D* intake must be maintained because almost all patients with RA are at risk for osteoporosis, either from their disease or from its treatment. For patients taking low doses of glucocorticoids, an adequate intake of calcium and vitamin D has proved sufficient to prevent mineral loss. A total of 1.5 to 2.0 g of calcium daily and 400 IU of vitamin D daily is required and can be obtained by dietary measures and the use of low-cost supplements (see Chapter 164).

Claims for the efficacy of other dietary measures and supplements, usually put forward by commercial interests, continue to bombard patients; most are unproven. The results of well-designed, small-scale, prospective trials of high-dose g -*linolenic acid* (an essential fatty acid and close precursor of prostaglandin E $_1$ with demonstrated antiinflammatory and immunoregulatory activity) have been promising. Essential fatty acids may also have an immunomodulatory effect independent of prostaglandin activity. The dihydro metabolite of g-linolenic acid manifests such an effect, acting directly on T cells *in vitro* to suppress proliferation of interleukin-dependent T lymphocytes. The value of g-linoleic acid remains to be established by large-scale, prospective, randomized trials.

Based on studies of *fish oil supplements*, diets high in fish and plant fatty acids and low in animal fatty acids may confer a modest degree of subjective improvement. Such fatty acids are essential for the maintenance of cell membrane structure and function.

A popular diet free of additives, preservatives, fruit, red meat, herbs, and dairy products has been advocated as a treatment for RA. The only controlled, double-blinded, randomized study of this therapy failed to show any benefit in patients with long-standing, progressive, active RA.

Alternative and Complementary Measures. A wide range of alternative measures (e.g., chiropractic manipulation, special dietary supplements, biofeedback, herbal therapies, salves, magnets, acupuncture) are tried by patients. Surveys of arthritis patients being seen by rheumatologists find that up to half have tried at least one of them in the past and that nearly a fourth continue to make regular use of at least one of them. Predictors of regular use include severe pain and a college degree. Evidence of their efficacy remains nonexistent for most, but some should soon be tested in randomized, placebo-controlled trials now that the National Institutes of Health is funding formal study of these measures.

Pharmacologic Therapy: Antiinflammatory Agents

As noted earlier, the antiinflammatory agents have traditionally been the first line of therapy, providing both analgesic and antiinflammatory effects sufficient to achieve a reasonable degree of symptomatic relief. However, they do not prevent early joint destruction or alter the course of RA. Consequently, they are increasingly relegated to a secondary role in treatment of patients with active disease, although they retain an important place in most treatment programs as a means of providing quick symptomatic relief. Among agents in this category are *aspirin*, other salicylates, the nonselective *NSAIDs*, and the new *COX-2 inhibitors*.

Aspirin. Aspirin remains the cornerstone of antiinflammatory pharmacologic therapy for many patients and is the best proven and least expensive agent for the treatment of RA. Its mechanism of antiinflammatory action involves inhibition of prostaglandin synthesis. In adults under age 60, serum levels of 15 to 20 mg/dL are needed to suppress the inflammation of RA effectively. No standard dose predictably achieves this level, but usually at least 3.6 to 4.8 g/d are necessary. Because of the large dose needed and the short half-life (3 to 4 hours) of the drug, the patient must take a large number of tablets multiple times per day. The dose can be increased up to the amount at which tinnitus develops; tinnitus is a dependable and reversible sign of salicylate toxicity in adults. The most frequent adverse effect of aspirin is gastric mucosal injury, with many patients manifesting asymptomatic gastric erosions and some showing frank ulceration (see Chapter 68). Bleeding occasionally is caused by gastritis or ulceration and need not be preceded by symptoms of abdominal pain. Aspirin irreversibly inhibits platelet cyclooxygenase and impedes platelet function (see Chapter 81), causing easy bruising and a predisposition to bleeding. A single dose poisons the platelet for its entire 7-day life span.

Because regular aspirin is directly injurious to the gastric mucosa, additional aspirin preparations have been marketed as less "upsetting to the stomach." *Buffered* aspirin contains bicarbonate, but the amount is insufficient to overcome ambient acid and prevent aspirin-induced mucosal injury. Slightly better tolerated are preparations such as Ascriptin, in which aspirin is combined with a more potent antacid (magnesium hydroxide and aluminum hydroxide), but the cost is markedly increased. *Enteric coating* prevents aspirin from dissolving in the stomach and minimizes the risk for direct gastric mucosal injury; however, bioavailability is delayed, so that the onset of pain relief is slower, and again, cost is increased.

Nonacetylated Salicylates. Nonacetylated salicylates, such as *salsalate, choline magnesium salicylate*, and *sodium salicylate*, were developed to reduce the risks for gastric injury and platelet inhibition associated with aspirin yet preserve its analgesic and antiinflammatory effects. Lacking an acetyl moiety, these agents do not inhibit platelet cyclooxygenase and can be given to patients who are allergic to aspirin. However, they are still capable of causing gastric injury, and their effectiveness appears to be no better than, and in many instances less than, that of aspirin for patients with RA. The cost is much increased. *Diflunisal*, a derivative of salicylic acid, does not acetylate or break down to salicylate but does act like aspirin by virtue of its ability to inhibit prostaglandin synthesis. For patients with RA, it provides the analgesic and antiinflammatory effects of 2 to 4 g of aspirin daily, with a lower rate of gastrointestinal side effects. However, platelet inhibition does occur and can cause serious gastrointestinal bleeding. The cost of the drug is 15 times that of aspirin.

Nonsteroidal Antiinflammatory Drugs (NSAIDs). Although aspirin and its salicylate congeners are also technically NSAIDs, the term is usually reserved for the nonsalicylate NSAIDs. Because of their high cost and gastrointestinal side effects, the traditional NSAIDs should not be used until aspirin has been tried in a program sufficient to achieve therapeutic serum levels for at least 2 to 4 weeks. Only if aspirin proves inadequate or unacceptable should it be abandoned in favor of a traditional NSAID because of the high cost and associated gastrointestinal toxic effects of the latter (see below). The COX-2 NSAIDs, which are more selective and do not inhibit gastric prostaglandins, have fewer adverse gastrointestinal side effects, making possible earlier initiation of NSAID therapy, especially in persons with a history of past or active peptic ulcer disease or gastrointestinal bleeding.

Mechanism of Action. NSAIDs derive from a host of organic acids (propionic, indolacetic, phenylacetic, enolic, mefenamic) and share the ability to inhibit *cyclooxygenase (COX)*, a key enzyme in prostaglandin synthesis. The *COX-1* isoform is essential for renal, platelet, gastric mucosal, and vascular function; it is elaborated by the tissues it protects and is present in the serum in rather stable concentrations. The *COX-2* isoform participates principally in inflammation, elaborating prostaglandins in response to cytokines and the action of macrophages; however, it may also be involved in the healing of gastric mucosa and some modulation of renal function. All the older NSAIDs inhibit both isoforms of cyclooxygenase and have similar side effect profiles, including significant gastrointestinal toxicity. The promise of the COX-2–selective NSAIDs (e.g., celecoxib, rofecoxib) is antiinflammatory action without the adverse consequences of COX-1 inhibition (see below). These agents do not impair platelet aggregation, reducing risk of hemorrhage. However, the COX-2 inhibitors block formation of the prostaglandin vasodilator prostacyclin (PGI $_2$), raising concern about a potential prothrombotic effect (see below).

Updated: 10/19/01

Efficacy. On a milligram-per-milligram basis, NSAIDs are more potent than aspirin and longer-acting, so that a marked reduction in the number of tablets taken and the frequency of dosing becomes possible. The degree of pain relief and antiinflammatory effect achieved is equivalent to that of full-dose aspirin therapy. Although they are more convenient to use, NSAIDs, especially brand formulations can cost many times more than aspirin. See Table 156-1.

Table 156-1. Nonsteroidal Antiinflammatory Drugs

No particular NSAID (including the new Cox-2 agents) has consistently proved more effective clinically than any other when used at full doses. Nonetheless, some work better for individual patients than others. NSAIDs are sometimes compared according to their values for IC $_{50}$ (concentration that inhibits 50%), an *in vitro* measure of drug efficiency of inhibition, but the IC $_{50}$ has little to do with clinical efficacy. Efficacy is partially a function of dose. Persons not responding to one preparation after 2 to 4 weeks often report benefit when they try another from a different class (Table 156-1). This may be a consequence of individual variations in the serum level attained by taking a given dose, but most differences in efficacy are usually a function of compliance with the drug regimen. Patients on agents that must be taken three or four times daily often fare better when they switch to preparations that require dosing only once or twice daily. No synergy is gained when more than one NSAID is used at a time; mechanisms of action are similar for all, and all bind to the same serum proteins. Although they provide relief from inflammatory symptoms, NSAIDs do not appear to alter the course of RA. Their principal role is to relieve symptoms of inflammation.

Adverse Effects. Most adverse effects are related to COX-1 inhibition, but even the COX-2 agents have potential for adverse consequences. |**Updated: 10/19/01**

Gastric Ulceration and Bleeding. The integrity of the gastric mucosa depends on gastric prostaglandin activity and can be compromised by NSAIDs that inhibit COX-1. The consequences of such inhibition include dyspepsia, abdominal pain, peptic ulceration, upper gastrointestinal bleeding, and gastric perforation. The risk for clinically important ulceration is estimated to be 1% to 4% per patient-year of NSAID therapy with a nonselective agent. The risk is significantly reduced with the use of a COX-2–selective NSAID. Risk factors for gastrointestinal complications include previous NSAID-related gastrointestinal side effects (risk of 1.4% per year), concurrent use of prednisone (risk of 1.2% per year), advancing age (risk of 0.3% per year for every 5 years over the age of 50), and substantial disability (risk of 0.5% per year). The total annual risk for a given patient can be estimated by summing these figures. About 15% to 25% of long-term NSAID users demonstrate gastric ulceration at endoscopy; for users of a selective COX-2 inhibitor, the figure is in the range of 5% (just slightly above that for placebo).

Risk generally increases with dose and duration of therapy, but up to one fourth of complications have been observed within the first month of therapy. There may be no warning symptoms preceding severe bleeding or perforation. The risk for adverse gastrointestinal effects is similar for all nonselective NSAIDs because they all inhibit gastric prostaglandin synthesis to a significant degree. The use of a prodrug preparation (e.g., nabumetone) provides no advantage because superficial erosions are much less common than with plain aspirin. The use of NSAIDs in patients with a history of peptic ulcer disease, gastrointestinal bleeding, or abdominal pain requires careful monitoring.

Reducing Risk. Gastrointestinal risk can be reduced by the use of a selective COX-2 inhibitor, treatment of concurrent *Helicobacter pylori* infection, use of misoprostol (a gastric prostaglandin analogue), or use of a proton pump inhibitor (PPI), such as omeprazole or lansoprazole (see Chapter 68). It is not yet clear which choice is the most cost-effective, but use of a selective COX-2 inhibitor does significantly reduce the risk for gastric ulceration, gastritis, and gastrointestinal bleeding without any compromise in antiinflammatory efficacy. Although COX-2 agents and concurrent use of a nonselective NSAID with a PPI reduce gastrointestinal risk, they are not risk free, especially in high-risk persons, such as those with history of NSAID-induced bleeding. In a 6-month, randomized, controlled trial of celecoxib versus diclofenac plus omeprazole in patients requiring long-term NSAID therapy who recently had NSAID-induced ulcer bleeding, the rate of recurrent ulcer bleeding at 6 months was 4.9% for celecoxib and 6.4% with use of diclofenac (p>.05). No data exist on combination of a COX-2 agent with a PPI. Of note, little reduction is seen in the frequency of minor gastrointestinal side effects, such as dyspepsia, mild nausea, and diarrhea, with COX-2 drugs. |**Updated: 04/04/03**

Effects on Platelets and Blood Vessels. The nonselective NSAIDs reversibly inhibit platelet cyclooxygenase and impair platelet function. Gastrointestinal bleeding in the context of concurrent NSAID use can turn into life-threatening hemorrhage. However, unlike aspirin, NSAIDs prolong the bleeding time only while the drug is being taken; inhibition quickly ceases when drug use is stopped.

The clinical effects of the COX-2 agents on platelets and blood vessels remain to be more fully defined, but the absence of platelet thromboxane inhibition in conjunction with a reduction in vasodilator prostacyclin (PGI $_2$) may result in a relative increase in thrombus formation at a site of vascular injury. Of concern is the potential for these COX-2 effects to tip the balance between prothrombotic and antithrombotic NSAID actions and increase the risk for thrombotic cardiovascular events. Preliminary data suggest an increased relative risk for thrombotic cardiovascular events when comparing COX-2 users with COX-1 users, especially in persons at increased cardiovascular risk. These data have suggested a note of caution when considering continuous COX-2 use, especially in persons with known cardiovascular disease or multiple cardiovascular risk factors. |**Updated: 10/19/01**

Renal Injury. A normal, well-perfused kidney does not depend on renal prostaglandin activity to the extent that an injured, underperfused kidney does. Under situations of hemodynamic stress, prostaglandins serve as important regulators of renal blood flow. NSAID use may lead to fluid retention and diminished sodium excretion. Azotemia may worsen, and oliguria and renal shutdown have been reported in patients with preexisting renal disease. Control of hypertension may diminish with NSAID use. The risk for renal toxicity is greatest in the setting of inadequate renal perfusion (congestive heart failure, cirrhosis, dehydration, advanced age, use of potent diuretics). Renal injury may develop after only a few days of therapy but is reversible if NSAIDs are promptly stopped. Monitoring serum creatinine is advisable, especially in high-risk patients. Sulindac may be less nephrotoxic than other preparations because it has little effect on renal prostaglandin synthesis. NSAIDs may impair the action of antihypertensive agents. No nephrotoxicity has been reported with the prolonged use of high-dose aspirin.

No long-term data are yet available on the clinical effects of the COX-2 agents with regard to renal function and blood pressure control, but available data suggest that the degree of risk for renal impairment in elderly persons is approximately the same as for nonselective NSAIDs. In a randomized, 6-month trial comparing celecoxib with diclofenac, the risk of an adverse renal event (hypertension, peripheral edema, renal failure) was high in both groups (24.3% vs. 30.8%) and not significantly different. The literature should be followed for longer-term data on the renal effects of COX-2 agents. |**Updated: 04/04/03**

Mental Impairment. The elderly are particularly susceptible. Cognitive function, mood, or personality may be altered, especially with agents that cross the blood–brain barrier (e.g., indomethacin). Confusion, poor memory, irritability, depression, lassitude, difficulty sleeping, and even paranoid behavior are among the reactions noted. Minor neurologic side effects (e.g., headache, dizziness, light-headedness) are seen in patients of all ages.

Hepatotoxicity. Mild elevation in liver enzymes is sometimes noted, but severe hepatitis is rare. Cholestatic hepatitis has been reported. Occasional monitoring of the serum aminotransferase (transaminase) will suffice; the drug is halted if levels rise above the upper limits of normal.

Selection of Nonsteroidal Antiinflammatory Drug. Because side effects are relatively similar among the traditional NSAIDs, one can use cost, frequency of dose, and response to an empiric trial (2 to 4 weeks at maximum dosage) as the basis for selection (Table 156-1). Inquiry into past experience with NSAIDs can help save time. Aspirin remains the cheapest form of antiinflammatory therapy, but frequent dosing is required and a large number of pills must be taken each day. Generic ibuprofen is the most economical of the modern NSAIDs, but dosing three times daily is required. Generic naproxen is the least expensive of the twice-daily NSAID formulations. Generic indomethacin is also inexpensive, but its utility is limited by the frequency and severity of gastrointestinal and central nervous system side effects, especially in the elderly. Piroxicam offers once-daily dosing, but at a greatly increased cost.

A COX-2 agent is preferred in patients at increased risk for NSAID-induced peptic ulceration or its complications (e.g., prior history of peptic ulcer, bleeding, or perforation; general debility; concurrent steroid use; advanced age). The high cost of these agents is a marked disadvantage, but with declining long-term NSAID use (see below), the cost differential should be less of an issue. Moreover, some cost savings should result from the reduced frequency of stomach ulceration and its complications and from elimination of the need for concurrent proton pump or misoprostol therapy.

Until the question of a prothrombotic risk for COX-2 agents is more clearly answered, it is important to at least consider the potential thrombotic risk when prescribing use of these agents, especially in persons with known cardiovascular disease or multiple cardiovascular risk factors. |**Updated: 10/19/01**

Corticosteroids. The principal role for corticosteroids is to provide interim symptomatic control of inflammatory symptoms and extraarticular manifestations in patients with moderate to severe disease who are waiting for disease-modifying therapy to take effect. A limited course of relatively low-dose therapy (e.g., 5 to 15 mg of prednisone per day) can provide additional symptomatic relief in those who remain very uncomfortable despite NSAID use. If evidence of vasculitis or other serious systemic complications develops, then higher glucocorticoid doses are indicated (e.g., 40 to 60 mg of prednisone per day). Low-dose prednisone started in the early stages of symptomatic RA may have a modest joint-sparing effect, but more confirmatory and longer-term data are needed before steroids can be considered a valuable disease-modifying treatment. Steroids should be tapered to the lowest effective dose once symptoms are brought under control and discontinued as soon as

disease-modifying therapy takes hold.

Prolonged steroid therapy is to be avoided. Short courses of steroids that become long can produce severe *osteoporosis*, *muscle atrophy*, *ligamentous weakening*, and *aseptic necrosis* of the femoral head. Often, twice-daily administration is required to control symptoms adequately, which increases the risk for *hypothalamic–pituitary–adrenal suppression* (see Chapter 105). In extremely difficult situations, such as a disabling flare-up of joint disease, very low-dose therapy (5.0 to 7.5 mg of prednisone per day) may be restarted to tide the patient over until disease-modifying therapy takes hold. The only clear indication for parenteral high-dose steroid treatment is life-threatening extraarticular disease, such as vasculitis, pericarditis, or alveolitis. Intraarticular injection of a long-acting steroid preparation may improve functional status when one large, weight-bearing joint is disproportionately inflamed. However, repeated steroid injections into the same joint may hasten its degeneration and increase the risk for infection.

Pharmacologic Therapy: Disease-Modifying Agents

Efficacy and Approach to Use. Disease-modifying therapy has become the mainstay of treatment for RA, reducing disease morbidity and mortality by nearly 30% in randomized, controlled trials. The response rates to disease-modifying therapy average about 50%; complete remissions can occur in 20% to 40% of cases but are harder to come by in more severe disease. The use of multiple drug regimens often doubles or triples response and remission rates in patients with very active disease. Initial results of adding a tumor necrosis factor (TNF) inactivator suggest that a threefold to fivefold improvement in the response rate may be possible in refractory cases.

Unlike NSAIDS, disease-modifying therapy introduced early in the course of illness can halt or slow disease progression and limit permanent joint damage. No longer is disease-modifying therapy reserved for those who fail NSAID therapy. It is now appropriately considered for all patients at the outset of symptomatic disease. Careful radiographic studies show disproportionate joint destruction early in the course of active RA and poor outcomes in patients treated solely with NSAIDs during the first 6 months of illness.

Contributing to the success of disease-modifying therapy is the use of *multiple drug regimens*. As in cancer chemotherapy, outcomes are improved without an increase in adverse effects with the combined use of agents that act at different steps in the immunopathologic sequence. The latest additions to the therapeutic armamentarium are the TNF inactivators.

The onset of action is usually slow, with 6 weeks or more passing before any effect becomes evident, and 3 to 6 months before the maximum effect is obtained. Consequently, NSAIDs and, if necessary, low-dose prednisone are started along with these agents to control symptoms. Although drug-related toxicity can be substantial and close monitoring is required to maximize safe use, the documented efficacy of disease-modifying therapy strongly argues for its early application in the management of RA. Relative cost can be high (Table 156-2).

DRUG AND DOSAGE	RELATIVE COST PER MONTH
Antiinflammatory Agents	
enteric-coated aspirin, 3.6 g/d	1.0
ibuprofen 800 mg tid (generic)	1.2
naproxen 500 mg bid (generic)	1.8
celecoxib 200 mg bid	9.5
rofecoxib 25 mg/d	4.8
prednisone 10 mg/d	0.4
Disease-Modifying Agents	
methotrexate 17.5 mg/wk	4.2
sulfasalazine 2 g/d	2.3
hydroxychloroquine 400 mg/d	2.4
leflunomide 20 mg/d	15.5
gold salts 50 mg/mo	1.0
cyclosporine 175 mg/d	26.3
etanercept 25 mg SQ twice weekly	63.1

Adapted from Goldring SR. JAMA 2000;283:524, with permission.

Table 156-2. Relative Costs of Some Drugs for Rheumatoid Arthritis

At present, indefinite continuation of disease-modifying therapy appears to be necessary because disease activity returns when treatment is stopped. Nonetheless, certain data suggest some lasting benefit (e.g., better joint preservation) with even limited courses of treatment. More data are needed to determine the optimal duration of therapy.

Descriptions of a number of the disease-modifying agents and combinations follow:

Methotrexate. Methotrexate is a first-line disease-modifying agent that is commonly prescribed for persons with moderate to severe disease of new onset. It is among the fastest-acting of the disease-modifying drugs, often controlling symptoms within 6 weeks. It is also quite effective and well tolerated, so that it is among the most favored agents for treatment. Low-dose therapy (7.5 mg/wk) is given orally once weekly in three doses, 12 hours apart. The liquid preparation is the least expensive. Parenteral administration is less likely to cause *gastrointestinal upset* and *stomatitis*, common side effects. Aspirin and NSAIDs should not be used concurrently because they slow the rate of methotrexate excretion and increase gastrointestinal toxicity. Renal dysfunction is a contraindication to use. Short-term, low-dose therapy is well tolerated, but bone marrow suppression, hepatocellular injury, and idiosyncratic interstitial pneumonitis can occur. The latter may lead to *pulmonary fibrosis* and is important to recognize early. Mild, nonprogressive elevations in hepatocellular enzymes are common and not a contraindication to continued therapy, although careful monitoring is required. Alcohol use is contraindicated. Folic acid supplementation (1 mg/d) reduces the risk for drug toxicity without reducing efficacy. Longer-term therapy is often given and is well tolerated, but once the cumulative dose of methotrexate exceeds 1.5 g, the risk for *hepatic fibrosis* may begin to increase. The need for liver biopsy at this point remains unresolved.

Hydroxychloroquine. Antimalarial therapy is not as effective as methotrexate but is better tolerated and therefore a reasonable selection as initial disease-modifying therapy for patients with mild disease. At least 4 to 6 weeks of therapy is needed before results are detectable; full benefit may not be evident before 3 to 4 months. The most serious toxic effect is *visual impairment* (even blindness) caused by drug accumulation in the retina; this complication is extremely rare when doses are limited to 200 to 400 mg/d. Regular (every 6 months) ophthalmologic screening is indicated for patients who have been taking hydroxychloroquine for years or who have renal insufficiency; the yield is very low in those who take less than 6.5 mg/kg per day. Tinnitus and vertigo are sometimes noted.

Sulfasalazine. Sulfasalazine has a long-standing record of efficacy and safety in inflammatory bowel disease and as an alternative to hydroxychloroquine for patients with mild RA. It may be superior to hydroxychloroquine. Its safety profile makes it a popular first-line disease-modifying agent. Hypersensitivity to its sulfa moiety is common, so that its use is limited in patients allergic to sulfa. Because of occasional *hepatocellular injury* and minor degrees of *myelosuppression*, a periodic check of the complete blood cell count and aminotransferase levels is necessary. Gastrointestinal upset (anorexia, nausea, vomiting, diarrhea) is more common. Reversible oligospermia has been noted.

Combination Programs of First-line Drugs. Combining several *first-line disease-modifying agents* (e.g., methotrexate, hydroxychloroquine, and sulfasalazine) appears to provide synergistic effects, thereby improving response rates and potentially lowering the frequency of adverse effects by allowing smaller doses to be administered. Although it remains to be proved in long-term prospective studies, evidence is already accumulating that combination therapy produces significantly higher remission rates with no increase in overall risk for adverse effects. Whether combination therapy should be the initial program of choice remains a subject of debate; further study is needed. Combination programs are increasingly being instituted by rheumatologists if a patient's response to initial disease-modifying therapy with a single agent is inadequate. Combination therapy with first-line drugs may be better tolerated than therapy with a potentially more toxic second-line disease-modifying agent. Combination programs that include *second-line agents* and *anticytokine therapy* are used in more refractory disease (see below).

Leflunomide. Leflunomide is a new pyrimidine synthesis inhibitor that interferes with the cell cycle in rapidly proliferating cells such as activated lymphocytes. In placebo-controlled comparison studies with methotrexate, it demonstrates a similar degree of disease-modifying activity but not quite the same degree of tolerability; the frequency of diarrhea and allergic skin reactions is increased.

Gold. Gold was first of the disease-modifying agents. Because of the requirement for parenteral administration, the frequency and severity of adverse effects, and the

need for constant monitoring of blood and urine, gold has been relegated to a secondary role among disease-modifying agents. It is usually reserved for patients with moderate to severe disease who fail or cannot take methotrexate or combination therapy with other first-line drugs. Treatment may temporarily halt or even partially reverse articular erosion in up to 60% of cases, but fewer than 2% of patients treated have remissions that last longer than 3 years. The effects of gold are cumulative. Those who are going to respond do so by the time 1,000 mg has been given. Adverse effects are often idiosyncratic and range from *rashes* and buccal cavity *mucosal ulcers* to *bone marrow suppression*, *glomerulonephritis*, *interstitial pneumonitis*, and *exfoliative dermatitis*. Most side effects are reversible if the medication is stopped immediately.

Auranofin is an oral gold formulation usually taken twice daily. It causes fewer cases of mucocutaneous, renal, and bone marrow toxicity than parenteral gold does, but more cases of diarrhea (which is dose-related) and sometimes colitis. Often, the gastrointestinal side effects cease with continued therapy, although lowering the dose may be necessary. The efficacy is less than that of injectable gold but is still significant in placebo-controlled studies. Because of its relative safety, auranofin is worth considering to sustain remissions achieved with other agents. Monitoring is similar to that for parenteral therapy, although the frequency can be monthly rather than weekly. A low-dose regimen for 6 months is typical; if the response is inadequate, a 3-month trial at a higher dose may be considered before therapy is terminated.

Cyclosporine. Cyclosporine was developed to provide more selective inhibition of the immune mechanisms involved in autoimmune disease while leaving other immune pathways relatively unaffected. It is a selective T-cell immunosuppressor that is used as a second- or third-line agent in patients with active disease who fail combination therapy with first-line drugs. Combination with methotrexate has proved useful in refractory disease. Adverse effects include renal insufficiency, anemia, hypertension, and hirsutism, so that periodic checks of blood cell counts, renal function, and potassium levels are necessary.

Cyclophosphamide and Azathioprine. Cyclophosphamide and azathioprine are cytotoxic immunosuppressive agents that have been reserved for patients with otherwise refractory disease. Cyclophosphamide is used to treat systemic vasculitis. Both agents are contraindicated in pregnancy because they are *teratogenic*. The risk for malignancy is increased, especially with cyclophosphamide. Other adverse effects of cyclophosphamide include *hemorrhagic cystitis*, *marrow suppression*, and *sterility*. Azathioprine use is associated with gastrointestinal upset, hepatitis, and marrow depression, but the risk is low with the small doses given to patients with RA.

Penicillamine. Penicillamine is a chelating agent that can slow aggressive disease. Adverse effects are similar to those of parenteral gold and are best mitigated by giving low doses and increasing them slowly. Fewer than 50% of patients given the drug are able to continue it for prolonged treatment. Fatal *aplastic anemia*, *leukopenia*, *agranulocytosis*, and *thrombocytopenia* can occur. Proteinuria is seen in 10% to 15% of cases and may progress to the nephrotic syndrome. Rashes and autoimmune syndromes such as myasthenia gravis have been reported. The drug is contraindicated in pregnancy. It should be reserved for those who fail to respond to all other forms of therapy and should be prescribed only under the supervision of a rheumatologist skilled in its use.

Pharmacologic Therapy: Anticytokines and Other Agents

Anticytokine Therapy: Tumor Necrosis Factor Inactivators. The agents of this class represent the first direct attempts at the use of anticytokine therapy in RA. Anticytokines bind and inactivate circulating TNF, a key inflammatory cytokine in RA. Patients previously unresponsive to first-line disease-modifying therapy demonstrate marked reductions in disease activity when one of these agents is added to the treatment program. Whether they are truly disease-modifying remains to be determined; their long-term safety and cost-effectiveness are also still unknown. The direct cost of treatment is very high (Table 156-1).

Etanercept. Etanercept is a fusion protein made up of two soluble TNF receptors (p75) grafted onto the Fc portion of a human immunoglobulin G1 molecule by recombinant methods. When added to methotrexate therapy in randomized, double-blinded, placebo-controlled trials, it significantly improved control in patients with active disease not adequately controlled by methotrexate alone. Response rates improved twofold to fivefold, with more than 70% of patients having at least a 20% reduction in symptoms. To date, side effects are minimal other than local discomfort at the injection site, which ceases with continuation of therapy. Theoretical concerns about increased risks for cancer and infection (TNF is part of the surveillance system of the body) have not materialized, nor have increased levels of antibody to double-stranded DNA (an early observation) been noted. Twice-weekly SQ injections are required, which can be self-administered. Antibodies to the agent have not been observed, nor are they expected, as no foreign proteins are present.

Infliximab. Infliximab is a monoclonal antibody that binds TNF. It is composed of a murine TNF-binding site grafted onto human immunoglobulin G. It has been used with success in Crohn's disease and is now being applied in RA. Responses in RA are similar to those for etanercept, with nearly 80% of patients showing at least a 20% improvement in symptoms within 4 weeks of a single IV dose. Antibody formation to the murine portion of the monoclonal antibody occurs in 50% of patients but does not seem to limit efficacy. Combination use with methotrexate appears to reduce antibody production and enhance response.

Minocycline. Minocycline is a tetracycline derivative with prominent antiinflammatory and immunosuppressive effects, including inhibition of synovial collagenase, lymphocyte proliferation, and cell division. Randomized, placebo-controlled trials in patients requiring disease-modifying therapy have provided encouraging results, although the degree of clinical benefit appears modest at best. More study is required to define its efficacy and safety in comparison with other forms of disease-modifying therapy.

Analgesics. Analgesics without any antiinflammatory effect have a limited role in RA. Occasionally, a narcotic analgesic is prescribed for short-term pain control. The regular use of narcotic analgesics is to be avoided because of the risk for addiction in this chronic disease.

Additional Measures

Prevention and Treatment of Osteoporosis. The risk for the development of osteoporosis is markedly increased in RA by both inactivity and the use of glucocorticoids. Preventive measures are critical and effective. Adequate dietary calcium and vitamin D are essential components of any program for osteoporosis. Hormone replacement for menopausal women and bisphosphonates (e.g., alendronate) for those taking glucocorticoids have successfully prevented or halted osteoporosis in patients with RA. A modest degree of remineralization is sometimes noted with the use of estrogens and alendronate (see Chapter 164).

Surgery. Arthroplasty is an important component of therapy in patients with destroyed joints and marked disability. Hip and knee procedures are most successful; the outcome in hand, wrist, elbow, and ankle reconstructions is less certain, but rapid progress is being made. The risk for loosening of a hip prosthesis is significant (25%), even in the absence of active disease. Conventional synovectomy is generally ineffective and results in loss of joint motion; however, arthroscopic synovectomy may permit control of particularly severe monoarticular disease involving the knee.

Total Lymphoid Irradiation and Apheresis. Total lymphoid irradiation and apheresis represent desperate attempts to inhibit the immunopathology of RA. Controlled studies of irradiation suggest some benefit in extreme situations, but the risk for infection is markedly increased. The rationale behind apheresis is to remove immune complexes and other mediators of the inflammatory process. Placebo-controlled studies have failed to show significant benefit. Selective removal of lymphocytes from peripheral blood (leukopheresis) has yielded transient mild clinical improvement in refractory cases, but not of sufficient magnitude to justify the high cost. With the development of safer, more effective therapies, the demand for such measures should fade.

Monitoring

Disease activity and response to therapy are best monitored by reproducible measures, such as duration of *morning stiffness*, *sedimentation rate*, *number of tender swollen joints*, and *grip strength* (which can be measured with a blood pressure cuff). *Time required to walk 15 meters* and *ring size* are also helpful. The titer of RF does not correlate with disease activity but does decrease with gold and penicillamine therapy if the patient responds. Outcomes research has emphasized the utility of additional measures of function, such as the answers to questions regarding psychosocial functioning and the activities of daily living included in the *Health Assessment Questionnaire* and the *Arthritis Impact Measurement Scale*. The patient's self-assessment and the physician's global assessment also demonstrate validity.

Detecting early disease progression is more difficult but very important if disease-modifying therapy is to be instituted in a timely fashion. Joint space narrowing is a specific but late radiographic sign of cartilaginous erosion that may not develop until irreversible damage has already occurred. Magnetic resonance imaging has been used experimentally to detect synovial proliferation and early pannus formation, but the cost remains prohibitive for routine use. At present, one estimates the likelihood of disease progression by the duration of symptoms.

PATIENT EDUCATION AND COUNSELING

As shown in a randomized trial of the Arthritis Self-help Course (a model program of basic patient education), patient education and counseling are well worth the time invested because they help to reduce pain, disability, and frequency of physician visits. They represent a most cost-effective intervention.

Informing the Patient of the Diagnosis. With a potentially disabling disease such as RA, the act of informing the patient of the diagnosis takes on major importance. The goal is to satisfy the patient's informational needs regarding the diagnosis, prognosis, and treatment without going into an overwhelming and excessive amount of detail. Careful questioning and empathic listening are required to understand the patient's perspective, requests, and fears. Telling patients more than they are intellectually or psychologically prepared to deal with (a common practice) risks making the experience so intense as to trigger withdrawal. On the other hand, failing to address issues of importance to the patient compromises the development of trust. The patient needs to know that the primary physician understands the situation and will be available for support, advice, and therapy as the need arises. Encouraging the patient to ask questions helps to communicate interest and caring.

Discussing Prognosis and Treatment. Patients and family do best when they know what to expect and can view the illness realistically. Uncertainty contributes heavily to the "disease" of RA. Many fear crippling consequences and dependency. The most common disease manifestations should be described. Without building false hopes, the physician can point out that spontaneous remissions are frequent and that more than two thirds of patients live independently without major disability. In addition, it should be emphasized that much can be done to minimize discomfort and preserve function. A review of available therapies and their efficacy helps to overcome feelings of depression stemming from an erroneous expectation of inevitable disability. Even in patients with severe disease, guarded optimism is now appropriate, given the host of effective and well-tolerated disease-modifying treatments that are emerging. A major fear is abandonment. Patients are relieved to know that they will be followed closely by the primary physician and health care team, working in conjunction with a consulting rheumatologist and physical/occupational therapist, all of whom are committed to maximizing the patient's comfort and independence and preserving joint function.

Dealing with Misconceptions. Several common misconceptions deserve attention. A substantial proportion of patients and their families feel that they have done something to cause the illness. Explaining that there are no known controllable precipitants helps to eliminate much unnecessary guilt and self-recrimination. Dealing in an informative, evidence-based fashion with a patient who expresses interest in alternative and complementary forms of therapy can help limit expenditures on ineffective treatments. Another misconception is that a medication has to be expensive to be helpful. Aspirin, generic NSAIDs, low-dose prednisone, and the first-line disease-modifying agents are quite inexpensive (Table 156-1) yet remarkably effective, a point that bears emphasizing. The sense that one must be treated with a Cox-2 NSAID or the latest TNF inactivator can be addressed by a careful review of the overall treatment program and the proper role of such agents in the patient's plan of care. The active participation of the patient and family in the design and implementation of the therapeutic program helps to boost morale and ensure compliance, as does explaining the rationale for the therapies used.

Preserving a Sense of Self-Worth. A major goal is to preserve the patient's sense of worth and independence. However, when fatigue, morning stiffness, or specific joint disease interferes with a patient's capacity to carry out the usual responsibilities at work and at home, counseling will be necessary to recommend modification of work responsibilities and perhaps retraining. With the use of occupational therapy, the treatment effort is geared to helping the patient maintain a meaningful work role within the limitations of the illness. The family plays an important part in striking the proper balance between dependence and independence. Household members should avoid overprotecting the patient (e.g., refraining from intercourse out of fear of hurting the patient) and work to sustain the patient's pride and ability to contribute to the family. Allowing the patient with RA to struggle with a task is sometimes constructive.

Supporting the Patient with Debilitating Disease. Persons with long-standing severe disease who have already sustained much irreversible joint destruction benefit from an emphasis on comfort measures, supportive counseling, and attention to minimizing further debility. Such patients need help in grieving for their disfigurement and loss of function. An accepting, unhurried, empathic manner allows the patient to express feelings. The seemingly insignificant act of touching does much to restore a sense of self-acceptance. Attending to pain with increased social support, medication, and a refocusing of attention onto function are useful. A trusting and strong patient–doctor relationship can do much to sustain a patient through times of discomfort and disability.

INDICATIONS FOR REFERRAL AND ADMISSION

The increasingly early and more aggressive use of disease-modifying drugs and the expanding armamentarium of such agents argue for prompt referral to the rheumatologist at the time of initial diagnosis. It is no longer appropriate to wait until antiinflammatory therapy proves insufficient or overt signs of joint destruction appear. The benefits of early implementation of a disease-modifying program have been sufficiently established to warrant early referral for the design and implementation of such a regimen. Patients requiring regimens associated with a high risk for serious toxicity should be periodically seen by the rheumatologist; those on programs that are better tolerated can be managed almost exclusively by the primary care physician. In all cases, a close working relationship with the rheumatologist is essential.

Patients with evidence of persistent joint inflammation should be referred back to the rheumatologist for advancement of their disease-modifying therapy, especially those with characteristics that indicate a poor prognosis (e.g., genotype *HLA-DRB1*04/04*, high serum titer of RF, extraarticular manifestations, a large number of involved joints, age less than 30, female sex, systemic symptoms).

Referral to physical and occupational therapists is greatly appreciated by patients with active disease. The emphasis should be on teaching the patient things that can be done to improve function. Well-designed exercise and self-care programs can greatly facilitate carrying out the activities of daily living and reduce discomfort and disability.

The need for surgical referral is best determined by the rheumatologist, who is well trained to judge when medical therapy is insufficient. Examples of indications for surgery include carpal tunnel syndrome that persists despite corticosteroid injection, trigger finger deformity, tendon rupture with loss of manual dexterity, and refractory dorsal wrist effusions. The patient with disabling hip or knee destruction and severe impairment of weight-bearing capacity deserves a surgical assessment regarding possible prosthetic joint replacement. Arthroscopic synovectomy may be needed for a single, very refractory joint that cannot be replaced.

When fever or other manifestations of severe extraarticular disease appear (especially signs of vasculitis or diffuse serositis), then hospital admission for workup and IV administration of steroids should be promptly considered.

THERAPEUTIC RECOMMENDATIONS

- Provide a comprehensive patient and family education program that includes psychological support and strategies for maintaining the patient's activity, independence, and self-esteem. Utilize health care team members to enhance the educational and supportive efforts.
- Consider first-line disease-modifying therapy (e.g., methotrexate, hydroxychloroquine, sulfasalazine, or any combination) at the time of initial diagnosis for all patients, especially those with very active disease or indicators of a poor prognosis (e.g., genotype *HLA-DRB1*04/04*, high serum titer of RF, extraarticular manifestations, large number of involved joints, age below 30, female sex, systemic symptoms). Obtain early rheumatologic consultation for selection of the disease-modifying regimen. Coordinate care with the rheumatologist and closely monitor the patient for response to therapy and complications of the drug program (see below).
- While waiting for disease-modifying therapy to take effect (up to 6 months may be necessary), begin antiinflammatory treatment with a generic NSAID (e.g., 3.6 g of enteric-coated aspirin daily, 800 mg of ibuprofen three times a day, or 500 mg of naproxen twice daily).
- Consider use of a selective COX-2 inhibitor only if traditional nonselective NSAIDs are not well tolerated or if the patient is at high risk for peptic ulceration and its complications. Until more definitive data are available, weigh and review with the patient the potential thrombotic risk of using a COX-2 agent, especially when considering a program of daily long-term COX-2 use in persons with known cardiovascular disease or multiple thrombotic cardiovascular risk factors. | **Updated: 10/19/01**
- Use NSAIDs with care in patients with impaired renal perfusion; monitor blood urea nitrogen and creatinine. Also prescribe cautiously to patients with a prior history of peptic ulcer disease or gastrointestinal bleeding (see Chapter 68); monitor hematocrit and test for fecal occult blood.
- For patients with very active disease inadequately controlled by initial NSAID therapy, consider adding a small dose of corticosteroid therapy (e.g., 5 mg of prednisone per day, in split doses twice daily if necessary). Reserve daily use of systemic steroids for patients truly incapacitated by symptoms, and use only a short-term, low-dose program (e.g., 5.0 to 7.5 mg of prednisone daily until disease-modifying therapy takes hold). If steroids are to be utilized, begin a program of osteoporosis prevention that includes calcium (1.5 g/d) and vitamin D (400 to 800 IU/d) plus hormone replacement therapy, a bisphosphonate (e.g., 5 to 10 mg of alendronate per day), or both (see Chapter 144 and Chapter 164).

•Once disease-modifying therapy begins to take hold, taper and discontinue NSAIDs and corticosteroids. Continue disease-modifying program indefinitely.
•Prescribe a gentle exercise program to maintain range of motion and muscle strength, but avoid stressing a severely inflamed joint. Prior application of heat or cold (either may work) will facilitate the exercise program. Consult with a physical therapist to help design the program. Morning application of heat is particularly helpful before the patient engages in daily activity.
•Selectively rest severely inflamed individual joints that are too swollen to exercise. Maintain the joint in its physiologic position by splinting during periods when the joint is stressed (e.g., at night) to support weakened joints and prevent flexion contractures. Consult the rheumatologist if splinting appears indicated.
•Advise a daily rest period for patients bothered by generalized fatigue, but outpatients should avoid prolonged bed rest.
•Consult the rheumatologist again if the patient manifests persistently active disease. It may be necessary to advance the disease-modifying regimen or alter it. Increasingly, early rheumatologic consultation and aggressive treatment may be necessary if joint destruction is to be prevented, particularly in patients with findings suggestive of a poor prognosis.
•For patients incapacitated by one disproportionately inflamed large, weight-bearing joint, consider a single intraarticular injection of a long-acting corticosteroid (e.g., 2.5 to 10 mg of triamcinolone acetonide, depending on joint size, mixed with 1 mL of lidocaine). The knee is cleansed with iodine and alcohol and an intraarticular injection is performed under sterile conditions. Repeated injections into the same joint are to be avoided.
•Monitor disease activity and response to therapy by checking reproducible measures, such as duration of morning stiffness, sedimentation rate, number of tender swollen joints, and grip strength (have the patient squeeze a blood pressure cuff). Also monitor activities of daily living and psychosocial status.
•For patients on disease-modifying therapy, monitor for drug toxicity closely:

1. For those taking *hydroxychloroquine*, inquire regularly about visual acuity and arrange for an ophthalmologic examination every 6 months.
2. For patients taking *methotrexate*, follow the complete blood cell count, platelet count, and levels of aminotransferase, alkaline phosphatase, blood urea nitrogen, and creatinine. Inquire regularly about any pulmonary symptoms, which might be the first manifestation of interstitial pneumonitis and an indication for immediate cessation of therapy.
3. For patients taking *sulfasalazine*, monitor the complete blood cell count, inquire about gastrointestinal symptoms, and examine the skin for rashes and pruritus.

CHAPTER 157 MANAGEMENT OF OSTEOARTHRITIS

ALLAN H. GOROLL

INTRODUCTION

Osteoarthritis (OA), the most prevalent form of arthropathy, causes symptomatic discomfort in 10% to 20% of persons over the age of 65 and accounts for somewhat more than 30% of visits to primary care practitioners. OA remains the most common cause of disability in the elderly. Most patients have primary or idiopathic disease that is strongly associated with aging. Others present with posttraumatic and hereditary forms of the disease (e.g., chondrodystrophy, hemochromatosis, inflammatory OA, chondrocalcinosis). Although many changes are irreversible, much can be done to relieve discomfort, prevent further articular damage, and keep the patient functioning independently.

PATHOPHYSIOLOGY AND CLINICAL PRESENTATION

Pathogenesis

Osteoarthritis is characterized by (a) the degeneration of articular cartilage and (b) the reactive formation of new bone. What causes the demise of the articular cartilage remains incompletely understood. The simplistic "wear-and-tear" hypothesis has been superseded by an appreciation for the role of chondrocytes in actively remodeling cartilage. Articular damage appears to be the consequence of an interplay between cartilage metabolism and mechanical stress. The synovial inflammation that is characteristic of rheumatoid disease appears to play only a minor role, if any, in most cases of OA. The significance of genetic factors has not been fully defined, but their involvement is suggested by the strong hereditary pattern of OA hand changes in women and defective collagen synthesis in some familial forms. Obesity is a major risk factor for disease affecting the knee. Poor joint alignment and trauma are other causative factors. Running *per se* is neither protective nor destructive (unless the knee has been injured, in which case running does hasten degenerative change), but excessive stress from weight bearing can be harmful in the elderly.

Histologically and biochemically, the size and aggregation of *proteoglycan* monomers are reduced with age. Proteoglycan is a critical mucopolysaccharide component of the cartilage extracellular matrix, synthesized by cartilage chondrocytes and essential for elasticity. Contributing to this reduction is increased proteolytic enzyme activity by chondrocytes. The matrix is also composed of *collagen fibrils*, which provide resiliency; these fibrils are more susceptible to damage by trauma when matrix proteoglycan declines. Synovial collagenase can penetrate damaged cartilage and further degrade its collagen. With age, bone elasticity (which provides a cushioning effect during trauma) also declines, allowing increased stress to be transmitted directly to the cartilage. Conditions that alter the mechanical relationships of joints further increase the likelihood that degenerative changes will develop.

The earliest manifestations of OA are superficial erosions of the cartilage; the response is hypertrophy and hyperplasia of chondrocytes. Early cartilaginous injury can be repaired by chondrocytes, but fissured hyaline cartilage cannot be restored. Eventually, the cartilage frays, shreds, and cracks. Underlying bone responds by remodeling, which causes trabeculae to thicken. At the joint margins, the development of hypertrophic spurs (*osteophytes*) is followed by buttressing of adjacent cortical bone (*osteosclerosis*). The joint space narrows in an irregular fashion. Cyst formation is also seen. Little synovial reaction occurs unless the degenerative process is rapid, a piece of cartilage dislodges, or calcium pyrophosphate crystals form and incite an acute inflammatory response (pseudogout).

Clinical Presentation

Radiologic evidence of OA can be found in more than 80% of adults by age 65. The subset who are symptomatic complain of deep, aching joint pain that is aggravated by motion and weight bearing. In addition, stiffness may be present that is worsened by periods of inactivity. The involved joint can be enlarged by the formation of osteophytes, but swelling is usually inconsequential because soft-tissue involvement and effusions are, in most instances, minimal. In later stages, pain occurs on motion and at rest in conjunction with stiffness. Nocturnal pain after vigorous activity is common. Patients with advanced disease have pain on weight bearing and joint instability. Examination often reveals crepitus and discomfort on movement of the joint. Occasionally, slight warmth is noted in severely affected weight-bearing joints, but erythema and marked warmth are absent. Limitation of motion, malalignment, and bony protuberances from spurs are frequent findings. The joints most commonly affected include the knees, hips, distal interphalangeal (DIP) joints of the hands, carpometacarpal joint at the base of the thumb, and the joints of the cervical and lumbosacral spine.

Knees. Symptomatic knee involvement is estimated to affect as much as 10% of the population over the age of 65. Obesity is a major risk factor. OA of the knee produces pain that is localized to the medial and/or lateral joint line and worsened by prolonged weight bearing and stair climbing. In later stages, crepitus is often marked and range of motion reduced. A very small effusion may be noted. The joint appears enlarged and feels bony. Patellofemoral joint involvement produces anterior knee pain that is exacerbated by going down stairs. On occasion, very few physical findings may be noted, although pain and radiographic changes are prominent. A skyline view of the flexed knee can reveal patellofemoral disease.

Hips. Degenerative hip disease arises in young patients with congenital dislocations or slipped femoral capital epiphyses. In the elderly, it results from wear and tear. A unilateral or asymmetric distribution is typical. The patient may describe pain that is deep in the hip and radiates into the anterior medial thigh, groin, buttock, or medial knee. The site of radiation (e.g., groin or buttock) may be the only area of reported pain. At first, pain occurs only on prolonged standing or walking, but as OA progresses, discomfort may become continuous and especially unbearable at night. The ability to engage in sexual intercourse is sometimes compromised. Loss of internal rotation during flexion is the earliest change and is as reliable as radiographic findings for diagnosis. The result of Trendelenburg's test (see Chapter 151) is positive.

Hands. Characteristic sites include the DIP joints and base of the thumb (first carpometacarpal joint); sometimes, proximal interphalangeal (PIP) joint involvement is noted. Hand disease is most common in middle-aged and elderly women, many of whom have a strongly positive family history. In some, a low-grade inflammatory response may accompany early, rapid, mucinous degenerative changes, so that the joints take on a tender, cystic inflammatory appearance. Later, osteophytes form, giving rise to characteristic bony protuberances in the DIP joints (*Heberden's nodes*) and occasionally PIP deformities (*Bouchard's nodes*) that superficially resemble those of rheumatoid disease. Eventually, all inflammatory activity resolves, and the joints are left nontender with some limitation of motion.

The base of the thumb, a site of much physical stress, is vulnerable to degenerative change. Pain develops in the region of the thenar eminence and particularly over the carpometacarpal joint. Because the thumb is so important to manual dexterity, the development of arthritis at this site may be disabling. Grip becomes impaired, and fine movements of apposition are restricted. Osteophytes are palpable and, in rare instances, may encroach on the flexor tendon sheath, causing tenosynovitis.

Cervical Spine. Degenerative changes commonly involve the posterior diarthrodial joints of the lower cervical spine (see Chapter 148). Although radiographic changes are frequent, most persons are asymptomatic. Moreover, the correlation between symptoms and radiographic findings is often poor. The patient may have pain and stiffness in the neck, but sometimes pain is reported only in the occiput, shoulder, arm, or hand. In a few instances, scapular or upper anterior chest pain is produced. Osteophytes can protrude into the foramina and impinge on nerve roots (most often C-6 and C-7), causing *radicular pain* that radiates to the shoulder, upper arms, hands, or fingers (see Chapter 167). At night, the patient may awaken with paresthesias and numbness in the arms that can be alleviated by getting up and shaking the arms.

On examination, neck motion is restricted to some extent in all directions, especially lateral flexion and extension; movement reproduces or aggravates symptoms. Reactive muscle spasm and tenderness are often present, and decreased sensation, weakness, and diminished reflexes occur when root compression is marked.

However, even when symptoms of root compression are reported, neurologic findings may be scant, and their absence does not rule out the complication.

Lumbosacral Spine. Degenerative changes in the lumbosacral spine involve the intervertebral disks and the apophyseal joints. With aging, the disk nucleus becomes brittle and less elastic. Herniation posteriorly or laterally through a defect in the disk annulus may occur. Intervertebral spaces narrow and marginal osteophytes form. The apophyseal joints show typical secondary degenerative changes. Disk or osteophyte encroachment on the foramina can lead to nerve root compression. The L-4, L-5, and S-1 roots are most commonly affected. The patient reports pain across the lower back with radiation into the buttock and posterior thigh, or down into the lower leg if *root compression* has occurred. Forward flexion and extension are reduced, but lateral flexion is painless. Focal areas of tenderness are common and often caused by spasm of the paraspinous musculature. Disk or osteophyte encroachment into the spinal canal can lead to *spinal stenosis*, which affects the cauda equina and exiting nerve roots. Compression of nerve roots produces *pseudoclaudication* (pain in the buttocks or thighs during prolonged standing or walking that is relieved by sitting or bending). On examination, thigh symptoms may be brought on by 30 seconds of lumbar extension, then relieved by having the patient bend forward. In addition, the patient may have a wide-based gait and neurologic deficits in the lower extremities.

Other Sites. OA may involve the great toe at the metatarsophalangeal joint to cause bony enlargement and a valgus deformity. Crepitus and pain in the temporomandibular joint are sometimes seen secondary to bruxism (grinding of the teeth because of anxiety or anger). Pain is reproduced by opening the mouth widely. Because OA is not a systemic disease, no extraarticular manifestations and no serum abnormalities occur; the sedimentation rate is normal, as is the synovial fluid in early disease. Radiographic findings are limited to the joints and include irregular narrowing of the joint space, sclerosis of subchondral bone, bony cysts, marginal osteophytes, and buttressing of adjacent bone.

NATURAL HISTORY OF DISEASE

In large, weight-bearing joints, OA tends to be a progressive condition causing chronic joint pain, restricted joint motion, and resultant muscle weakness that compromises mobility. Through a period of 10 to 20 years, pain at rest develops in the majority of patients with untreated symptomatic OA of the knee, and they become unable to use public transportation; disability may ensue. Early onset of symptoms and varus deformity correlate with a poor prognosis. OA of the hip may follow a similar course. Obesity is a strong risk factor for progressive disease of the hips and knees (especially in women); heavy weight-bearing exercise is associated with an increased risk for knee disease in the elderly. Weight reduction reduces the risk. The progression of OA is typically limited to a few affected joints, and the disease does not become widespread. Clinical remissions do occur, especially in the hands, neck, and back.

PRINCIPLES OF MANAGEMENT

Osteoarthritis cannot be cured, and no medications (or supplements) have been shown capable of altering the course of the disease. Nonetheless, reduction in pain and restoration of activity can be achieved with a multifaceted program. The goals are to reduce abnormal stresses imposed on affected joints, restore joint alignment, strengthen muscles, and treat pain and muscle spasm. Pain relief is a first priority for most patients. Both pharmacologic and mechanical means are used. Those with severe pain are likely also to try alternative and complementary therapies. Surgical intervention should be restricted to patients who do not respond to conservative management and are so disabled that they cannot function satisfactorily.

Analgesics. In the absence of a major inflammatory component to the disease and until etiologically acting agents become available, analgesics remain the predominant pharmacologic approach to symptom relief in OA. Because an individual patient's response to analgesics is unpredictable, it may be necessary to try several different ones. Intermittent use of analgesics sometimes suffices, but continuous therapy is often needed.

Acetaminophen. Pure analgesics, such as acetaminophen, are at least as effective as NSAIDs, without the associated adverse gastrointestinal side effects and high costs (see below). The cost of acetaminophen is low, and its long-term safety is well established. The highly publicized risk for hepatic injury is rare with regular use of doses within the therapeutic range. Liver injury typically occurs only in cases of overdose or underlying alcoholic liver disease. Long-term therapy at high doses may increase the risk for renal tubular injury, but supporting data are sparse, and the risk appears no greater than that associated with prolonged NSAID use.

NSAIDs. (See also Chapter 156.) Although widely prescribed, NSAIDs are no more effective than acetaminophen in providing symptomatic relief. Their benefit seems to derive principally from their analgesic effects; they appear to have little net direct effect on the underlying disease process (despite occasional evidence pro and con). The absence of significant inflammation in OA helps explain why low, analgesic doses of NSAIDs are no better than high, antiinflammatory doses. NSAIDs can be very expensive (at up to 30 times the cost of acetaminophen), and the associated risk for gastrointestinal toxicity is high (see Chapter 68 and Chapter 156). Renal compromise may develop in persons with underlying renal insufficiency. Some elderly patients experience mental confusion while taking NSAIDs that penetrate the central nervous system (e.g., indomethacin).

The use of a *selective Cox (cyclooxygenase)-2 NSAID* preparation (e.g., *celecoxib, rofecoxib*) reduces the risk for peptic ulceration but greatly increases cost. Studies in patient with OA have found the Cox-2 drugs to be equivalent to the nonselective NSAIDs and about equal to acetaminophen in providing symptomatic relief.

Narcotic Analgesics, such as codeine and oxycodone, should be used sparingly, if at all, and only for acute disabling pain interfering with essential activity. *Propoxyphene* (Darvon), an opiate derivative, is taken by many patients with OA, but its potential for causing dependence is considerable—similar to that of codeine.

Exercise. Of the nonmedical therapies, exercise shows the most consistently beneficial results for patients with OA, especially those with disease of the knees. Restoration of favorable mechanics is essential to minimizing damage to injured joints. Strengthening the supporting muscles may help maintain proper joint alignment. *Quadriceps exercises* and a *walking program* for patients with knee involvement clearly improve exercise tolerance and decrease pain. Quadriceps exercises are among the simplest to perform; the patient extends the knee and holds the straightened leg in a horizontal position while sitting in a chair. A program of supervised graduated isometric and isotonic quadriceps exercises can decrease pain and make it possible to walk for longer distances. Isometric and active exercises for the neck improve muscle tone and may sometimes help in cases of painful cervical spine disease (see Chapter 148). Exercises for the abdominal and paraspinous musculature are useful for preventing back problems (see Chapter 147).

Aerobic exercise may provide some additional benefit over strengthening programs by enhancing overall conditioning. For patients with OA of weight-bearing joints, structured aerobic exercise programs with full or partial weight bearing can greatly enhance endurance, walking distance, and sense of well-being without aggravating the arthritis. A 2-month program of supervised fitness walking combined with patient education can improve functional status by close to 40% in patients with symptomatic knee disease. Gentle cycling and swimming also improve endurance, benefiting the muscle groups of the hips and knees. Participation in such conditioning programs also boosts morale considerably.

As beneficial as exercise may be, excessive exercise may only exacerbate pain and cause further disruption of the joint. Excessive joint strain, such as results from stair climbing, should be reduced as much as possible. Supervision and patient education are essential to a successful exercise program and far superior to simply telling the patient to get more exercise.

Rest and Assist Devices. Some relief can be obtained by partially resting a very painful joint. The objective is to reduce the mechanical stress imposed on the joint. However, joint rest should be alternated with exercise to prevent muscle atrophy and worsening joint alignment. Moreover, prolonged immobility greatly disturbs cartilage metabolism.

Assist devices can help rest or protect a diseased joint from excessive mechanical stress. The pressures on hip and knee joints generated by getting up from a toilet or low seat can be decreased by the use of hand rails, grips, and a raised toilet or chair seat. An often underutilized approach to joint rest is the use of a *cane* in the contralateral hand, which can reduce the mechanical stress on a weight-bearing joint by as much as 50%. Embarrassment and awkwardness often make patients reluctant to use a cane, but physician encouragement and a few sessions with an occupational therapist can greatly help.

A *cervical collar* can ease neck pain by supporting the spine and resting the paraspinous musculature. It may be necessary to continue use intermittently for many weeks before significant benefit is achieved. Cervical traction may also help (see Chapter 148). A *corset* or *brace* for the back may be similarly helpful, but its use should be combined with an exercise program to avoid muscle atrophy (see Chapter 147).

Orthotic devices help correct malalignment. Patients with hip disease resulting from or aggravated by differences in leg length may benefit from a heal lift that

equalizes leg lengths. If abnormal foot pronation is causing varus stress on the knee joint, a shoe orthotic device may reduce pain and ligamentous strain on the knee.

Weight Reduction. Excessive weight is one of the major risk factors for OA of the knees and hips. Weight bearing puts mechanical stresses on the hip and knee joints that can be as much as five times the patient's weight. Even modest degrees of weight loss may achieve substantial reductions in such mechanical stress. Epidemiologic studies show a strong correlation between obesity and risk for symptomatic knee arthritis, and a 50% reduction in such risk with weight loss in excess of 5 kg (11 lb) over 10 years. These results suggest that half-hearted, perfunctory advice to "lose weight" is insufficient and fails to provide the patient with an important opportunity to affect outcome. A comprehensive program of mechanically sensible, supervised aerobic activity combined with detailed dietary counseling should be constructed (see Chapter 233) and carried out. An assisted, supervised program is essential because obese persons with OA are otherwise likely to feel that weight loss and exercise are beyond their capacity.

Heat. Moist heat can give symptomatic relief from muscle spasm, although it has no effect on the disease itself. *Diathermy* and *ultrasound* units are expensive ways to deliver heat to deep tissues. Although many patients report improvement, controlled trials in which sham treatments were used showed no benefit. However, some patients derive considerable psychological benefit and a sense of well-being from undergoing such therapy.

Steroid Therapy. Injection of *intraarticular steroids* is a controversial treatment. Although widely used, no controlled studies have documented its efficacy. The experimental finding of steroid suppression of cartilage catabolism has renewed interest in this form of therapy. However, repeated steroid injections may accelerate joint degeneration and weaken supporting structures. Steroid injection should be considered only when a single disabling joint, refractory to other forms of therapy, is sufficiently inflamed that a trial of intraarticular steroids is justified. Facet joint injection for back pain is not effective. Epidural injections for spinal stenosis are commonly tried, but benefit is rarely long-lasting. Systemic steroids have no place in the treatment of OA.

Surgical Intervention. *Osteotomy* to correct the mechanical imbalances caused by single-compartment disease of the knee and early disease of the hip has been popular and does seem to provide at least short-term benefit. However, no data comparing such surgical therapy with conservative management (weight loss, orthotics, exercise) are available, and results of long-term follow-up are often disappointing. The role of such surgery may be viewed as a temporizing measure used to delay total joint replacement. *Arthroscopic surgery*, entailing debridement, smoothing of joint surfaces, and washing out of debris, appears to benefit the patients who undergo the procedure, although controlled trials suggest a strong placebo effect and no long-term benefit unless a foreign body or internal derangement is the cause of symptoms. *Total joint replacement* represents the most extreme form of treatment, to be undertaken only after all other therapeutic options have been exhausted. Indications include pain at rest that interferes with sleep, inability to bear weight without severe pain, unacceptable interference with daily activity, and a requirement for narcotics to control pain.

Replacement of hip and knee joints has been particularly successful. Referral for such surgery requires comprehensive consideration of the patient's medical condition, functional status, and psychosocial state. The ability to participate physically and psychologically in a demanding program of rehabilitation is an important precondition for an optimal outcome.

New intraarticular procedures currently under study and being applied selectively hold promise as potential alternatives to joint replacement, especially of the knee. Patients with focal articular defects, particularly young persons who have sustained trauma, are being treated with *autogenous cartilage implantation* and *osteochondral grafting*. In the former, chondrocytes are grown from the patient's own cartilage and implanted. Criteria for candidacy include normal knee alignment, absence of arthritis on the corresponding tibial surface, and preserved ligamentous joint stability. Outcomes data are promising in carefully selected patients. Persons with more advanced disease are being offered *intraarticular injection* of *hyaluronic acid*. The rationale is to improve the viscosity and elasticity of synovial fluid, thereby reducing discomfort and the need for medication. Response rates to a single injection range from 50% to 90%; patients with mild disease respond best. The duration of benefit may exceed 6 months. Local irritation occurs in about 7%, and pseudogout has been reported as a complication of this otherwise reasonably well-tolerated treatment.

Treatments of Possible, Unclear, or No Proven Benefit. As in the management of any common chronic condition that is difficult to treat definitively, claims of benefit have been made for a host of unproven therapies for OA. Some are widely promoted to the public as safe, "natural" means of treatment, so that they appear particularly attractive. Evidence of efficacy is often absent when such therapies can be marketed under the rubric of "dietary supplement" without Food and Drug Administration review of their safety and effectiveness. Studies of patients with arthritis reveal up to half trying alternative or complementary measures, especially if they are having severe pain. Only recently are some of these widely used measures finally being subjected to rigorously designed clinical trials.

Glucosamine. This "dietary supplement" is an intermediary in mucopolysaccharide synthesis. *In vitro*, it stimulates chondrocytes to produce proteoglycans. (*In vivo* basic science evidence of beneficial effect on articular cartilage remains to be demonstrated.) Nonetheless, use is widespread, despite the high cost of available preparations (reaching several dollars per day). The few double-blinded, controlled clinical trials of glucosamine that exist have been short (4 to 8 weeks) and limited to small numbers of patients. Although these studies suggest some modest symptomatic benefit (about the same as with ibuprofen), no long-term studies of safety or efficacy have been performed. A number of glucosamine salt preparations are sold in health food stores and pharmacies without being subject to any standards of purity or uniformity. U.S. Pharmacopia has started to issue labeling of preparations that meet its standards for purity and uniformity. Some are combined with *chondroitin sulfate*, a glycosaminoglycan touted to promote joint viscosity and cartilage repair. These supplements can be expensive, costing several dollars per day.

Evidence of efficacy for glucosamine use in patients with mild-to-moderate OA of the knee is starting to appear. Two nearly identical well-designed placebo-controlled trials involving a total of 400 patients followed for 3 years taking 1,500 mg/day showed significant slowing of joint space narrowing and improvement in functional status. These findings will need to be confirmed, and larger numbers of patients will need to be followed for longer periods of time before one can be assured of the safety and efficacy of long-term use. Nonetheless, the emerging evidence is encouraging. There are no similarly designed studies of chondroitin sulfate. **Updated: 11/12/02**

Diathermy, including Ultrasound. The rationale for delivering heat by these means before exertion is that they help to relax deep tendons and muscles. Such treatment is expensive and time-consuming. As noted above, in randomized, controlled trials that included sham treatment, diathermy provided no benefit over that derived from exercise alone.

Topical Analgesic Creams. Most nonprescription topical preparations contain methylsalicylate. When methylsalicylate is applied multiple times daily, measurable amounts of salicylate can be absorbed, which may account for any benefit obtained. No controlled trials of these preparations have been performed. One such trial, of capsaicin (an extract of chili peppers with topical analgesic properties), has revealed a modest benefit.

Spinal Manipulation. In careful, controlled study, a short course of chiropractic manipulation of the spine appears to provide relief of acute back pain caused by musculotendinous strain; however, such treatment has no demonstrably beneficial effect on the chronic pain and discomfort resulting from degenerative disease of the spine.

Acupuncture. Acupuncture has produced inconsistent results in double-blinded studies—sometimes working, sometimes not. Results have not been sufficiently beneficial to warrant its inclusion in a treatment program. Well-designed studies comparing acupuncture with sham needle placement reveal only a strong placebo effect, but the number of trials is very limited and more data are needed before firmer conclusions can be drawn.

Transcutaneous Electrical Nerve Stimulation (TENS). Most of the studies are poorly designed; superficially, they suggest benefit, but most appears to be derived from a placebo effect.

Antispasmodics. Antispasmodics are without effect except for their tranquilizing action.

INDICATIONS FOR REFERRAL

Treatment of the patient with OA requires a team approach. *Physical* and *occupational therapists* are essential to the design of a successful treatment program—teaching exercises, giving suggestions on how to perform the tasks of daily living, and providing psychological support. Referral should be made early in the course of disease for education in preventive measures, and also later, when OA begins to interfere with daily activity. Early referral to the *nutritionist* is critical to the care of the obese patient. A comprehensive program of diet and exercise is needed to effect a successful weight loss effort.

Surgical consultation should be considered for the significantly disabled patient who is failing conservative management. The consultation should be explained to the patient as an opportunity to weigh treatment options, rather than as an automatic capitulation to surgical intervention. The decision to refer for surgery must be made with an understanding of the risks involved and the need to undertake a vigorous postoperative exercise program. Surgery should be considered only in patients whose limitation of motion or pain has become so severe that it prevents them from living productively. They must be mentally and physically healthy enough to tolerate surgery and sufficiently motivated to carry out the exercise program needed to ensure full rehabilitation. Patients and their primary care physicians need to understand that standard arthroscopic intervention (washing and débridement), although appealing because it is less invasive, is in most instances no better than placebo. Only when internal derangement or a foreign body is documented to be the cause of disability should arthroscopic surgery become a consideration.

Updated: 7/31/02

PATIENT EDUCATION AND PSYCHOSOCIAL SUPPORT

Patients need to know that OA is not reversible, but also that much can be done to lessen pain, prevent further joint injury, and preserve, if not enhance, overall functioning. They appreciate knowing that degenerative disease is not a generalized, systemic illness. Moreover, those with cervical or lumbosacral disease can be given some hope for a spontaneous remission of their severe pain. The need to reduce weight and strengthen supporting muscles should be stressed, in addition to the importance of avoiding activity injurious to the joints and addictive analgesics. The teaching functions of the physical and occupational therapists and nutritionist are among the most critical components of the treatment program. It is important to avoid labeling the patient as "disabled" because active participation in the treatment program is essential to preservation of function. As noted above, surgical options should be discussed with patients who have incapacitating pain of the hips or knees.

Because a principal determinant of presenting for care is the *psychosocial state* of the OA patient, the importance of eliciting and attending to psychosocial stresses cannot be overemphasized. A careful history that includes attention to job, family, and any financial or interpersonal problems is likely to help in the design of an effective treatment program. If the patient reports being disabled yet manifests only modest mechanical dysfunction, then a search for depression and somatization disorder should be undertaken (see Chapter 227 and Chapter 230). The prognosis is heavily influenced by how well the patient is coping psychosocially. The physician's concern and support are essential. Return visits should be regularly scheduled, so that the patient can be made to feel that support and caring are being provided. A strong doctor–patient relationship helps many patients to tolerate the disease and remain active.

THERAPEUTIC RECOMMENDATIONS

- Begin a comprehensive, supervised program of exercise, weight loss, and education for patients with symptomatic disease of the hips or knees.
- Provide referrals to physical and occupational therapists for the design and implementation of exercise and activity programs that strengthen quadriceps and hip muscles, increase general conditioning, avoid excessive stress on the affected joints, and ensure the proper use of assist devices.
- Obtain the services of a nutritionist to help support the obese patient in a program of weight reduction.
- Inform the patient that regular aerobic exercise is beneficial and that gentle walking, swimming, and stationary cycling are permissible.
- Advise a short period (1 to 2 days) of joint rest if severe hip or knee pain flares up, but isometric and non–weight-bearing exercises should be continued and more prolonged inactivity avoided. Limit joint stresses (e.g., stair climbing) and prescribe use of a cane and other assist devices (e.g., railings, hand grips, elevated toilet seat).
- Consider use of a heel lift if leg lengths are unequal and use of a shoe orthotic device if marked foot pronation is noted. Check with an orthopedist or podiatrist if uncertain.
- Advise bed rest followed by exercises to strengthen supporting musculature for patients with back pain. A corset or brace may help, but not in the absence of an exercise program (see Chapter 147).
- Prescribe a soft cervical collar to those with cervical pain. It should be worn at all times, including the night. Four weeks or more of use may be necessary. Cervical traction is also helpful (see Chapter 148).
- Begin acetaminophen for control of pain; prescribe up to 4 g/d. Consider NSAIDs (including aspirin) only for patients who fail acetaminophen after trials at full doses. If NSAID therapy is used, prescribe only low, analgesic doses (e.g., 325 mg of enteric-coated aspirin three times daily or 200 mg of ibuprofen four times daily) unless the patient's arthritis has an inflammatory component. If NSAIDs are contraindicated because of a gastrointestinal condition, consider a selective Cox-2 agent (e.g., 12.5 to 25 mg of rofecoxib daily).
- Elicit and address sources of psychosocial distress.
- If the above measures prove insufficient in patients with OA of the knees, and functional impairment is limiting daily activity and quality of life, then consider a trial of glucosamine sulfate (1,500 mg qd; USP-certified preparation). Inform patient that evidence of efficacy and safety remains incomplete, and monitor closely for response and side effects. Do not continue without clear evidence of benefit. **Updated: 11/12/02**
- Avoid use of narcotics except in the setting of an acute disabling exacerbation that is not relieved by maximal doses of non-narcotic analgesics. Under such circumstances, consider no more than 1 to 2 days' worth of therapy with codeine sulfate or oxycodone.
- Refer for surgical consideration the patient with refractory, incapacitating disease of a major weight-bearing joint, provided the patient is well motivated and sufficiently healthy to tolerate surgery and engage in a rehabilitation program.

CHAPTER 158 MANAGEMENT OF GOUT

Gout is among the most common causes of acute monoarticular arthritis. Estimates of prevalence in the United States range from 0.3% to 2.8% of the population. Gout is predominantly a disease of adult men. Inborn errors of purine metabolism and abnormalities of uric acid excretion account for most cases of primary gout. The expanded use of agents that decrease uric acid excretion has markedly increased the incidence of secondary gout. In the Framingham study, almost half of new cases were associated with thiazide use.

The primary physician should be able to diagnose acute gout promptly, treat it, prevent recurrences, and minimize the chances for the development of chronic gouty arthritis. Patients who present with asymptomatic hyperuricemia also require attention (see Chapter 155).

PATHOPHYSIOLOGY AND CLINICAL PRESENTATION

The majority of patients with primary gout have a hereditary renal defect in uric acid excretion that leads to chronic hyperuricemia (see Chapter 155). Acute gout usually occurs after many years of sustained asymptomatic hyperuricemia. The higher the uric acid concentration, the greater the risk for an acute attack, although the risk remains relatively low until very high urate levels are reached (see Chapter 155). The mean duration of the asymptomatic period is about 30 years. During this time, urate may be deposited in synovial lining cells and possibly also in cartilage. Acute gout develops when uric acid crystals collect in the synovial fluid as a result of precipitation from a supersaturated state or release from the synovium. Trauma, a fall in temperature or pH, dehydration, starvation, excessive intake of alcohol, emotional or physical stress, and rapid changes in the serum uric acid concentration have all been implicated in the process. The risk is increased in renal transplantation patients undergoing cyclosporine therapy and in obese patients placed on very low-calorie diets.

The pathogenesis of the inflammatory response involves phagocytosis of crystals by leukocytes in the synovial fluid, disruption of lysosomes, release of enzymatic products, activation of the complement and kallikrein systems, and release of leukocyte chemotactic factor.

Acute Gouty Arthritis. In men, the first attack is usually during the fifth decade; in women, it tends to be after age 60. The episode is typically monoarticular and abrupt in onset, often occurring at night. Symptoms and signs of inflammation become maximal within a few hours of onset and last for a few days to a few weeks. Recovery is complete. The initial attack usually involves a joint of the lower extremity. In about half of patients, the *first metatarsophalangeal joint* is the site of inflammation (*podagra*). The tarsal joint (located at the instep), *ankle*, and *knee* are other common sites of initial attacks. Later episodes may involve a joint of the upper extremity, such as the wrist, elbow, or finger; shoulder or hip involvement is rare. More than 80% of attacks occur in a lower extremity; 85% of patients have at least one episode of podagra.

Polyarticular involvement is noted in about 5% of acute gouty attacks and may be confined to the upper extremities. Finger joint involvement is more common in women than in men and tends to present as a *Heberden's* or *Bouchard's node*. In elderly patients with gout and osteoarthritis, almost half have such nodal inflammation as the sole or initial manifestation of gout. In elderly women, the presentation of gout may be more insidious and polyarticular; multiple hand joints may be involved, with the condition resembling active rheumatoid disease.

The joint involved in an attack of acute gout appears swollen and erythematous; periarticular involvement is also common. Low-grade fever and leukocytosis may be present. A substantial fraction of patients may be *normouricemic* at the time of the acute attack. During resolution, the skin overlying the affected joint often desquamates. The clinical presentation may simulate joint infection (see Chapter 145) or even cellulitis (see Chapter 190).

Interval (Intercritical) Gout follows the initial attack. An asymptomatic period generally lasts for several years before a second episode of acute gout takes place. The original joint or another joint may be involved in subsequent attacks. Over time, the asymptomatic intervals between acute episodes shorten. In more advanced disease, polyarticular attacks are not uncommon, and resolution may be slower and less complete. Urate crystals may remain in the joint fluid.

Chronic Gouty Arthritis (Tophaceous Gout) takes years to develop. *Tophi* are typically noted an average of 10 years after the initial attack of acute gout. The risk for chronic gout is a function of the duration and severity of hyperuricemia. Tophi represent sodium urate collections surrounded by foreign body giant cell inflammatory reactions. They can occur in a variety of sites, including the synovium, subchondral bone, olecranon bursa, Achilles tendon, and subcutaneous tissue of the extensor surfaces of the arm. Eventually, cartilage erodes, joints becomedeformed, and chronic arthritis ensues. The joints of the lower extremities and hands are most commonly affected. In elderly women, the fingers may be the sole site of involvement by gouty disease; the condition may be mistaken for rheumatoid disease, with morning stiffness and tenderness and swelling of the metacarpophalangeal and proximal interphalangeal joints. The process is insidious; the patient notes progressive aching and stiffness. Tumescences may develop over joints of the foot and make wearing shoes difficult. Fortunately, the incidence of tophaceous gout has declined markedly with the introduction of effective antihyperuricemic agents. Chronic gouty arthritis develops in fewer than 15% of patients with acute gout.

Complications. The incidence of *nephrolithiasis* among patients with clinical gout is small; the risk for new stone formation in a patient with new onset of gout is less than 1% per year and is unrelated to the initial serum urate concentration or degree of uric acid control. Factors other than the serum urate concentration are important in stone formation and include a family history of stone formation, urine pH, hydration status, and possibly the amount of uric acid excreted by the kidneys (see Chapter 135). Stone formation is rarely dangerous; the risk for obstructive uropathy is less than 0.02%.

Concerns about the development of *chronic renal failure* as a complication of chronic hyperuricemia have been laid to rest by long-term studies (see Chapter 155). Lead intoxication is a cause in some populations; in others, it is concurrent hypertension, diabetes, cardiovascular disease, or underlying primary renal disease. *Acute renal failure* is a risk in patients undergoing treatment for lymphoproliferative or myeloproliferative disease. Immediately following chemotherapy, a massive uric acid load is present that may precipitate in renal tubules and elsewhere in the urinary tract and lead to acute oliguria.

DIAGNOSIS

Definitive diagnosis requires joint fluid examination and the finding of characteristic, negatively birefringent crystals (see Chapter 145). When classic podagra appears in a patient with a prior history of gout, a clinical diagnosis can be made with reasonable confidence, but when an acute monoarticular arthritis occurs in a less typical site, the full range of diagnostic possibilities must be considered (see Chapter 145). A chronic active polyarticular presentation in an older woman can be confusing because it may resemble rheumatoid disease, especially if confined to the fingers. A clue is the presence of Heberden's or Bouchard's nodes; the presence of tophi is another tip-off. Joint aspiration for crystal identification is needed to confirm the diagnosis. Similarly, in interval (intercritical) gout, joint aspiration and synovial fluid analysis can help establish the diagnosis, even in the absence of an acutely inflamed joint. Aspiration can be performed on a joint that is identified by history as having been previously inflamed. The serum uric acid level is not helpful diagnostically because it can be normal in the presence of active inflammatory disease.

PRINCIPLES OF THERAPY

Acute Gouty Arthritis

Acute symptoms can be relieved by the prompt institution of antiinflammatory therapy. Without treatment, an acute attack of gout usually resolves within 7 to 10 days, although severe episodes can last for weeks. Initiation of treatment at the very first sign of an acute attack produces a prompt and excellent therapeutic response. Delay of therapy is associated with less satisfactory results. Antiinflammatory therapy is usually continued until symptoms have resolved.

Nonsteroidal Antiinflammatory Drugs given in full doses are the treatment of choice. *Indomethacin*, *ibuprofen*, and *naproxen* are the best studied of the NSAIDs for use in acute gout, but almost any NSAID should suffice. Experience with the selective Cox (cyclooxygenase)-2 NSAIDs in gout is too limited at present for any

conclusions about their effectiveness to be drawn, but if they prove to have a role, they may be particularly useful in older patients who are at increased risk for the adverse gastrointestinal effects of traditional NSAIDs. Peptic ulcer disease and renal insufficiency are relative contraindications to the use of nonselective NSAIDs. Some elderly patients may experience mental confusion with indomethacin (see Chapter 156).

Colchicine is an alternative for patients unable to take NSAID therapy, but its tendency to cause *gastrointestinal upset* (nausea, vomiting, diarrhea) limits patient compliance. The doses needed to treat an acute attack effectively are the very ones associated with gastrointestinal side effects. *Bone marrow suppression* and an increased risk for *myopathy* and *neuropathy* have been reported in persons with concurrent *renal* or *hepatic insufficiency.*

Glucocorticoids are being used increasingly for acute gout; they can be very effective. The best candidates are persons who cannot take or do not respond to NSAIDs or colchicine. Intraarticular injection of an acutely involved joint can provide relief within 24 hours. Alternatively, one can prescribe a short course of high-dose oral prednisone, started at up to 60 mg/d and tapered rapidly to full cessation over 7 to 10 days.

Interval Gout

Although prophylactic therapy to prevent acute gouty arthritis is not necessary or cost-effective for a patient with asymptomatic hyperuricemia or a first attack of gout (see Chapter 155), it becomes cost-effective after a patient starts having two attacks per year, particularly if the episodes are disabling. Intervals between future recurrences are likely to shorten without prophylactic treatment. Of the risk factors for recurrent gouty attacks, hyperuricemia is among the most amenable to treatment. Other importance risk factors include use of thiazides and low-dose aspirin, obesity, and excessive intake of alcohol. Options include blocking urate production with allopurinol and enhancing renal excretion with *probenecid* or *sulfinpyrazone.* The goal is to lower the uric acid concentration below 6.5 mg/dL, the level at which extracellular fluid becomes saturated with uric acid.

Allopurinol is convenient to use (once-daily dosing) and relatively well tolerated, so it is widely prescribed. It inhibits the enzyme xanthine oxidase and blocks the formation of uric acid. The half-life of allopurinol is about 3 hours, but its metabolites are biologically active for up to 30 hours. As a result, the drug need be taken only once daily. Serum urate levels fall within a week of initiation of therapy, but the risk for gouty attacks does not decline until normouricemia has been sustained for 3 to 6 months.

Of the minor side effects, *rash* and gastrointestinal upset are among the more common; about 2% experience rash. If mild, the rash quickly resolves with cessation of therapy and may not recur if the drug is restarted at a low level. However, the development of a rash is associated with an increased risk for more serious adverse effects. The cumulative reported frequency of more serious adverse reactions is relatively high, at 3.5%. They include *fever, leukopenia, vasculitis,* and *hepatocellular injury.* A *fulminant hypersensitivity* syndrome characterized by *desquamative rash, fever, hepatitis, eosinophilia,* and *renal failure* is the most worrisome adverse effect. Although uncommon (prevalence <0.25%), it is associated with a 15% to 25% mortality rate and occurs mostly in patients with concurrent renal insufficiency or diuretic use. Allopurinol should always be used with caution and in reduced doses in patients with renal insufficiency. The white cell count and renal function should be monitored regularly for the first several months of treatment. Drug–drug interactions are also important. The risk for drug rash is increased 10-fold by the concurrent use of *ampicillin*, and the activity of drugs metabolized by hepatic microsomal enzymes (e.g., warfarin, azathioprine) can be potentiated.

Although allopurinol is often preferred by patients whose urate levels must be lowered because of its convenient dosing schedule and low frequency of side effects, it should not be prescribed casually. Carefully weighing the expected prophylactic benefit against the small but serious risk for a hypersensitivity reaction helps to ensure intelligent, safe use. The drug remains expensive. Patients with interval gout who are best suited for allopurinol treatment include those who are not candidates for uricosuric therapy because of hyperexcretion of uric acid (>1,000 mg/24 h), renal insufficiency, history of nephrolithiasis, or inability to tolerate or comply with a uricosuric program. Allopurinol has no beneficial effect in acute gouty arthritis; in fact, it may precipitate an attack during the early stages of therapy (see below).

Uricosuric Agents have an excellent safety record, so they are well suited for long-term prophylactic therapy. *Probenecid* and *sulfinpyrazone* are the principal uricosuric drugs; both act to inhibit renal tubular reabsorption of uric acid. About 80% of patients excreting less than 700 mg of uric acid daily can be effectively managed by uricosuric therapy. A uricosuric agent is often preferred to allopurinol therapy in persons with interval gout who are excreting less than 700 mg of uric acid per day and whose renal function is well preserved.

Their principal disadvantages are frequent dosing and an associated risk for precipitating nephrolithiasis. Because these agents are less convenient to use, compliance tends to be less than with allopurinol. Probenecid must be taken two to three times per day; sulfinpyrazone requires dosing three or four times daily. At the onset of therapy, uric acid excretion may reach extraordinary levels and trigger nephrolithiasis; therefore, initial doses must be modest. Generous fluid intake (2 to 3 L/d) and urinary alkalinization are also necessary. *Rash, autoimmune hemolytic anemia,* and *gastrointestinal upset* are the most common side effects. Sulfinpyrazone is associated with a very small risk for *marrow suppression.*

Drug–drug interactions are common. *Thiazides, loop diuretics,* and low doses of *salicylates* inhibit uricosuric action. *Probenecid* blocks the renal excretion of penicillins and the hepatic uptake of rifampin, prolonging the half-lives of both.

Losartan, an angiotensin II receptor antagonist, has been found to have uricosuric action and may be given to hypertensive patients, both to control blood pressure and prevent recurrent gouty attacks. Its cost is high, but the drug is well tolerated and requires only once-daily dosing. It may be combined with allopurinol.

Initiation of Antihyperuricemic Therapy. All drugs that reduce the serum uric acid level can trigger an attack of acute gout during the initial 3 to 6 months of therapy. This is believed to be a consequence of the mobilization of tissue deposits of uric acid. The risk is reduced when allopurinol is started at a low dose that is increased gradually during the course of a month. Only after the uric acid level has been normal for 3 to 6 months does the risk for a gouty attack begin to decline substantially. In the interim, low-dose antiinflammatory therapy is often prescribed for concurrent use with the urate-lowering agent. Both colchicine and NSAIDs are used.

Urate-lowering therapy is instituted only after all manifestations of an acute attack have fully resolved. No definitive data are available regarding the ideal duration of concurrent antiinflammatory therapy, but most authorities recommend that it be given for 3 to 6 months, or until all visible urate deposits have disappeared.

Diet. Only 10% of circulating purine is derived from dietary sources. Consequently, it is not necessary to restrict purine intake unless dietary habits or events appear to correlate strongly with attacks. Purine-rich foods include organ meats, other meats and seafood, yeast, beer and other alcoholic beverages, legumes, oatmeal, spinach, mushrooms, asparagus, and cauliflower. Most important is reduction of excess *weight* (without fasting) and abstinence from excessive *alcohol* intake and binge drinking. Obese patients with interval gout who are on a very low-calorie diet are at increased risk for an acute attack and may require prophylactic therapy.

Chronic Gouty Arthritis

Antihyperuricemic treatment is indicated in patients with tophaceous gout to prevent progressive articular damage. Prevention or relief of chronic gouty arthritis requires normalization of the serum urate level. Being the more effective and more convenient antihyperuricemic, *allopurinol* is usually prescribed for patients with tophaceous gout. Often, tophi begin to resolve after several weeks of therapy. A uricosuric agent is a reasonable alternative, provided that renal function is normal and no nephrolithiasis or excessive excretion of uric acid has been noted. Regardless of the agent selected, concurrent antiinflammatory therapy must be given until visible urate deposits have resolved.

Renal Complications

Although the risk for a renal complication is small, attention to renal issues is required in certain instances during the management of the gouty patient.

Nephrolithiasis. The gouty patient with an established uric acid stone should be treated with allopurinol and a high fluid intake; concurrent administration of a thiazide diuretic may be necessary (see Chapter 135). Allopurinol therapy to prevent stone formation is indicated for gouty patients with a prior history of nephrolithiasis and perhaps for those with a strong family history of kidney stones. All patients should be instructed to avoid dehydration, especially if they live in a warm, dry climate. Isolated hyperuricemia *per se* does not require treatment in the absence of other risk factors for nephrolithiasis (see Chapter 155).

Renal Failure. Patients undergoing chemotherapy for lymphoproliferative or myeloproliferative disease require pretreatment with allopurinol. Prolonged urate-lowering therapy has no role in the prevention of chronic renal failure in patients with gout, but avoidance of exposure to lead is important, as is the treatment of

common comorbidities such as hypertension, diabetes, and cardiovascular disease.

PATIENT EDUCATION

Patients who experience an acute gouty attack are highly motivated to undertake preventive measures and are very receptive to advice. If obese, they should be advised to avoid starvation or very low-calorie diets. Drinkers should be warned against binges. Maintenance of good hydration needs to be stressed to those at risk for nephrolithiasis. On the other hand, patients will find it comforting to know that severe dietary restrictions are unnecessary. Fasting should be avoided because it may precipitate an attack. The importance of treating an acute attack at the first sign of illness also needs to be stressed. For the patient with interval gout, a discussion of the risks and benefits of prophylactic therapy and the importance of compliance is indicated. Those taking allopurinol should be warned of the risk of a hypersensitivity reaction and advised to cease intake immediately and call the physician at the first sign of a rash, fever, or other manifestation.

THERAPEUTIC RECOMMENDATIONS

Acute Gout

- At the first sign of an attack of acute gouty arthritis, begin a nonsteroidal antiinflammatory agent (e.g., 500 mg of naproxen three times daily). Continue full-dose treatment until symptoms resolve, then taper to cessation over 72 hours. Advise the patient that delay in starting therapy may impair the response.
- For patients unable to take NSAID therapy (e.g., active peptic ulcer disease), consider colchicine (0.6 mg four times daily), but warn that diarrhea and some upper gastrointestinal upset are likely during the course of therapy; monitor blood cell count and hepatic and renal function. Avoid colchicine if underlying renal or hepatic insufficiency is present.
- For refractory cases of definite acute gout, consider a 7- to 10-day course of oral corticosteroids; start with prednisone at 20 to 40 mg/d and taper as clinically indicated. Intraarticular corticosteroid therapy is another option if oral therapy is not feasible and just one joint is involved.
- Provide an extra supply of antiinflammatory therapy so that it will be available for prompt use in a future episode.

Interval Gout

- Advise weight reduction (but not starvation diets) if the patient is obese and cessation of excess alcohol use; consider providing information on a reduced purine diet if attacks appear to be precipitated by dietary events.
- Avoid use of thiazides, loop diuretics, low-dose aspirin, and niacin to the extent possible.
- Determine with the patient if gouty attacks are sufficiently frequent and disabling to warrant prophylactic therapy. Once the patient has two attacks per year, long-term urate-lowering therapy becomes cost-effective.
- If the patient is willing to take long-term urate-lowering therapy, determine whether allopurinol or a uricosuric agent is preferred by (a) inquiring into any personal or family history of kidney stones or renal dysfunction, (b) measuring renal function (blood urea nitrogen, creatinine), and (c) determining 24-hour urinary uric acid excretion.
- For the patient who is excreting more than 1,000 mg of uric acid per day, has underlying azotemia, is at increased risk for nephrolithiasis, or is allergic to or fails uricosuric therapy, begin allopurinol (started at 100 mg/d and increased to 200 to 300 mg once daily over 4 weeks). Adjust the dose upward if the response is inadequate. Reduce the dose in the setting of renal insufficiency and use cautiously, especially when diuretics or ampicillin is being given concurrently. Stop at the earliest sign of a hypersensitivity reaction. Consider restarting at a low dose if the drug rash was mild, but monitor complete blood cell count and hepatic and renal function closely. Consider desensitization for patients who require allopurinol but who react to it with a mild drug rash.
- Begin probenecid or sulfinpyrazone if the patient has normal renal function, no risk for stone disease, and a urate excretion of less than 700 mg/d. Therapy should be initiated in small doses (e.g., 250 mg of probenecid twice daily or 50 mg of sulfinpyrazone twice daily), and at the same time fluid intake should be kept large (2 to 3 L/d) to prevent precipitation of uric acid in the urinary tract. Alkalinization of the urine to a pH of 6.6 is desirable during the first week of therapy but is difficult to achieve; gram doses of sodium bicarbonate are required, supplemented by acetazolamide (250 mg) before bed.
- Advance the uricosuric dose gradually to avoid triggering massive urate excretion. Continue high fluid intake during the early months of therapy. Maximum dose of sulfinpyrazone is 100 mg three to four times daily; for probenecid, it is 500 to 1,000 mg two to three times daily. Avoid the concurrent use of aspirin because it inhibits urate excretion.
- Monitor serum uric acid concentration and treat to achieve a level of less than 6.5 mg/dL, the point of supersaturation.
- To reduce the risk for an attack of gout during the first 3 to 6 months of urate-lowering treatment, prescribe concurrent antiinflammatory prophylactic therapy with either colchicine (0.6 mg daily or twice daily) or an intermediate-acting NSAID (e.g., 250 mg of naproxen daily or twice daily).
- Advise avoidance of precipitants such as binge drinking, fasting, and very low-calorie diets.

Chronic Gouty Arthritis

- Treat as for interval gout. Continue concurrent antiinflammatory therapy until all visible manifestations of uric acid deposits have resolved, which may take 6 to 12 months.

Renal Complications

- Pretreat cancer patients with allopurinol if a large uric acid load is likely to result from an application of chemotherapy.
- Advise a marked reduction in lead exposure (e.g., home-distilled alcohol, industrial contact).
- Treat patients with urate nephrolithiasis or a strong family history of kidney stones with allopurinol (300 mg once daily) and hydration. Long-term efforts to alkalinize the urine are impractical and need not be undertaken.
- Because the risk for chronic renal failure from chronic hyperuricemia is nil, long-term urate-lowering therapy to prevent it is unnecessary.

CHAPTER 159 APPROACH TO THE PATIENT WITH FIBROMYALGIA

Patients with diffuse, chronic musculoskeletal pain but no evidence of arthritis account for a large number of office visits. Some of them have mild rheumatoid disease; in other cases, their symptoms are caused by bony pathology, neuropathy, and myopathy. When no source stands out, clinicians start wondering about somatization despite protests from the patient that the problem is "not in my head."

In recent years, a syndrome of diffuse and chronic musculoskeletal pain, stiffness, focal tenderness, disordered sleep, and fatigue has become increasingly recognized as an important clinical entity. The terms *fibromyalgia, fibrositis,* and *fibromyositis* have been used to designate it, although the "-itis" terminology has been discouraged because no inflammatory pathophysiology has been detected. Although the cause of the syndrome is unknown, it appears to be common and is estimated to have a prevalence as high as 5% among adult women, who account for 80% to 90% of cases.

PATHOPHYSIOLOGY, CLINICAL PRESENTATION, AND COURSE

Pathogenesis. The cause of fibromyalgia remains unknown. Although the symptoms suggest somatization, careful psychological studies reveal no relationship between symptoms and psychological status. Only an increased frequency of life stress has been found. Most patients are not depressed, and any onset of depression does not correlate with the level of pain. One of the most consistent findings is an alteration in central nervous system neurotransmitter metabolism and function, with abnormal levels of serotonin, norepinephrine, and substance P found. This has suggested to some a pathophysiologic common denominator involving the neurochemistry of sleep and pain perception. Disturbances of stage 4 (non-rapid eye movement, non-REM) sleep are related to the symptoms. Neuroendocrine changes have also been observed but are not sufficient to be considered etiologic.

Muscle biopsy findings and electromyographic data demonstrate no consistent or unique changes. A subset of patients with fibromyalgia have abnormal antibodies, but they appear to have concurrent connective tissue disease. Because of the overlapping of symptoms of chronic fatigue syndrome and those of fibromyalgia, a common pathophysiology has been surmised, but the pathogenesis remains unknown for both conditions. Other patients have serology positive for Lyme disease, but treatment for Lyme disease usually does little to alleviate their symptoms. Some of these cases are believed to represent false-positive results that can be explained by the low specificity of Lyme serology and the high prevalence of fibromyalgia. A relation between recent infection and transient fibromyalgia syndrome has been observed in some cases of clinical Lyme disease and in some instances of acute mononucleosis, but no firm data are available to link infection with chronic symptoms.

Clinical Presentation. The typical patient is a woman in her midthirties to midfifties who describes chronic and diffuse musculoskeletal pain, stiffness, and fatigue. The pain tends to be constant, aching, and concentrated in axial regions (neck, shoulders, back, pelvis). Points of tenderness may also be found in the upper and lower extremities. "Stiffness" is the term often used to describe the discomfort, which is characteristically worse in the morning and exacerbated by changes in the weather, cold, humidity, sleeplessness, and stress and helped by warmth, rest, and mild exercise. Patients awake from sleep feeling tired and unrefreshed.

Physical examination findings are normal except for multiple, reproducible points of exaggerated tenderness to palpation. The tender points tend to be symmetric and located in the occiput, neck, shoulder, ribs, elbows, buttocks, and knees. Eighteen characteristic locations have been identified (Fig. 159.1).

FIG. 159.1. Tender points in fibromyalgia syndrome.

Clinical Course. Fibromyalgia is a chronic but nonprogressive disorder. Waxing and waning with changes in the weather, degree of situational stress, and amount of rest are characteristic. The number and location of tender points tend to be stable over time. In some patients, the condition may become disabling, at least temporarily, but the clinical course overall is one of steady but nonprogressive disease. A substantial minority of patients experience spontaneous remission, and many of those who continue to have symptoms report a general improvement with time. The degree of disability can be substantial; up to a fourth of patients receive disability payments at some time during their illness. Underlying psychosocial problems are the principal determinant of disability and health care utilization in patients with fibromyalgia.

DIFFERENTIAL DIAGNOSIS

The clinical diagnosis of fibromyalgia has been facilitated by a standardized case definition utilizing diagnostic criteria established by the American College of Rheumatology: (a) wide-spread pain including axial pain for at least 3 months, and (b) pain in at least 11 of 18 possible tender point sites (Table 159.1). Nonetheless, the diagnosis must not be considered established until a host of similarly presenting conditions have been ruled out, conditions that may be mistakenly labeled as fibromyalgia.

Table 159.1. The American College of Rheumatology 1990 Criteria for the Classification of Fibromyalgia [a]

Myofascial syndromes resulting from overuse may be confused with fibromyalgia, in that tender points are characteristic of both. Unlike those of fibromyalgia, the tender points of myofascial syndrome are clustered about just one area and trigger referred pain on compression (hence the term *trigger points*). Also, symptoms are focal rather than diffuse. A history of onset after excessive activity or muscle strain is typical. No fatigue or sleep disorder is associated with myofascial syndrome.

Rheumatoid disease in its early or mild forms may cause diffuse musculoskeletal discomfort, morning stiffness, fatigue,and focal tenderness on physical examination. However, the tenderness appears to be less exaggerated, and results of serologic studies are abnormal. *Polymyalgia rheumatica* superficially resembles fibromyalgia, but the onset is at a much later age, symptoms are confined to the hip and shoulder girdles, few tender points are present, and the sedimentation rate is markedly elevated. *Ankylosing spondylitis* produces axial discomfort, fatigue, and focal tenderness; however, most patients with axial symptoms are men, and sacroiliitis is a defining manifestation (see Chapter 146).

Spondyloarthropathy in women can easily be mistaken for fibromyalgia because the likely symptoms are diffuse and chronic axial discomfort, focal spinal pain in multiple sites, and disordered sleep. Because it is more common in men, spondyloarthropathy is not commonly considered in women, and neck pain may be more prominent than lower back pain, further confusing the picture. Clinical findings suggestive of spondyloarthropathy include a positive family history, psoriasis, inflammatory bowel disease, risk factors for Reiter's syndrome, relief of pain with exercise, sacroiliitis, and pain or tenderness at the site of insertion of a tendon or at the Achilles tendon or plantar fascia.

Chronic fatigue syndrome has been found to share many of the clinical features of fibromyalgia, including chronic, diffuse musculoskeletal pain and tender points, so that differentiation is difficult at times because both conditions are diagnosed clinically. Pain tends to be less prominent in chronic fatigue syndrome, and not all patients have tender points. Sometimes, distinguishing between chronic fatigue syndrome and fibromyalgia is impossible because of so much clinical overlap, which is not critical functionally because the approach to management is very similar for both.

Lyme disease also enters into the differential diagnosis but is readily recognized by a history of deer tick exposure, residence in an endemic area, rash, polyarthritis, and neurologic deficits (see Chapter 160). Some patients may have a transient syndrome that temporarily resembles fibromyalgia.

Hypothyroidism may be accompanied by diffuse myalgias and fatigue that simulate fibromyalgia. Differentiating features include cold intolerance, unexplained weight gain, characteristic skin changes, goiter, muscle weakness and soreness, and an elevated thyrotropin (TSH) level. Similarly, polymyositis may produce diffuse muscle achiness, but muscles are weak and diffusely sore, and the sedimentation rate and muscle enzyme levels are markedly elevated.

Depression and *somatization disorder* certainly can cause chronic musculoskeletal pain and fatigue, but no reproducible tender points are found, and these conditions are accompanied by definite manifestations of underlying psychopathology (see Chapter 227 and Chapter 230).

The pain of *hypertrophic osteoarthropathy* may be diffuse, but tender points are minimal and clubbing provides a unique hallmark.

WORKUP

The diagnosis depends entirely on the history and physical examination (Table 159.1). Laboratory studies are ordered to help rule out other conditions.

History. A careful delineation of the location of the pain is essential and helps differentiate fibromyalgia from conditions causing more localized or regional discomfort. Inquiry into associated features such as fatigue, nonrefreshing sleep, and exacerbations associated with changes in the weather facilitate differentiation. Pertinent negatives include other somatic and affective symptoms of depression (see Chapter 227), symptoms of hypothyroidism (see Chapter 104), frank arthritis, fever, rash, muscle weakness, and prior history of muscle injury.

Physical Examination. The skin, nails, mucous membranes, fundi, joints, spine, muscles, tendons, bones, and nervous system should be examined carefully for evidence of rheumatoid disease, spondyloarthropathy, myopathy, osteoarthropathy, thyroiddisease, and focal pathology (see Chapter 45 and Chapter 146, Chapter 147, Chapter 148, Chapter 149, Chapter 150 and Chapter 151). The mental status examination should be reviewed for signs of depression (see Chapter 227). If no abnormalities are found, then careful palpation of the 18 tender point sites is indicated (Fig. 159.1). Compression should be just strong enough to cause blanching of the examining fingertip. A positive response is the elicitation of exaggerated tenderness or outright pain. Tender points need to be differentiated from the trigger points of myofascial syndrome, which produce referred pain on compression. Mild discomfort during palpation is a nonspecific finding that may be elicited in a host of other musculoskeletal conditions.

Laboratory Studies. Because no diagnostic studies or characteristic laboratory findings exist, testing is conducted to rule out treatable conditions that may present in similar fashion. Among the more useful studies is an antinuclear antibody (ANA) determination; a negative result has a high negative predictive value, but a positive result has a high probability of being a false-positive if the pretest probability of lupus is low (see Chapter 146). Other parameters of use in ruling out important mimicking illness include the sedimentation rate and TSH and creatine phosphokinase levels. Obtaining Lyme titers is not indicated unless the patient has symptoms strongly suggestive of the disease (rash, arthritis, neurologic complaints, deer tick exposure, residence in an endemic area) because test specificity is very poor. When back pain is the predominant symptom, radiologic study of the spine or sacroiliac joints may have to be considered (see Chapter 147). When fatigue dominates the clinical picture, more extensive evaluation may be required (see Chapter 8).

PRINCIPLES OF MANAGEMENT AND PATIENT EDUCATION

As with any incurable and chronic pain condition of unknown cause, the principal goal is maintenance and enhancement of functional capacity (see Chapter 236). Although it may be difficult to "cure" the pain, much can be done to help the patient remain active and productive. The large number of patients with fibromyalgia who are disabled represents a challenge to improve the medical care of persons with this condition. Key components of an effective treatment program include establishing the diagnosis; forming a strong patient–doctor relationship; designing a medical regimen to control pain, promote sleep, and treat any concurrent depression; and initiating a program of nonmedical therapies to enhance functional capacity. In addition, it is critical to address any underlying psychosocial problems because they are a major determinant of prognosis and response to treatment.

Establishing the Diagnosis. The value of a careful workup that can confirm the diagnosis is ranked by fibromyalgia patients as one of the most valuable components of care. Knowing what the diagnosis is puts an end to the common fear that a more serious condition with a poor prognosis is responsible for symptoms. The patient feels she is being taken seriously. Repeated requests for further evaluation are fewer, and unnecessary or inappropriate treatments (e.g., antibiotics, steroids, NSAIDs) can be avoided.

Forming an Effective Patient–Doctor Relationship. The successful care of patients with fibromyalgia requires that a trusting, understanding relationship be formed early. At the time of the initial encounter, the physician starts by eliciting the essential details of the patient's illness experience and specific concerns. Careful history taking is essential for an accurate diagnosis, and it also provides the patient with a much-needed sense of "being heard." A directed physical examination pertinent to the differential diagnosis and the patient's concerns helps to reinforce the patient's confidence and feeling of "being taken seriously." Taking time at the end of the visit for a focused but unhurried review of findings and their meaning is critical to consolidating the initial efforts to build a good working relationship.

Addressing Pain, Fatigue, and Any Concurrent Depression. Therapies that affect neurotransmitter metabolism, such as the *tricyclic antidepressants*, are among the most consistently effective in fibromyalgia. They are thought to act on the serotoninergic and adrenergic biochemistry of central pain perception, sleep, and depression. Controlled trials of tricyclic antidepressants at low doses (e.g., 25 to 50 mg of amitriptyline daily at bedtime) have repeatedly shown them to be beneficial to a significant degree, although their effect on pain seems to be the least durable. Selective serotonin reuptake inhibitors (SSRIs) have also been studied and found most helpful in the treatment of sleep disturbances and depression; their effects on pain are less demonstrable. Small doses of tricyclic antidepressants may suffice and are usually well tolerated, but larger onesare sometimes necessary and can be problematic (see Chapter 227). Improvements in all disease manifestations have been noted, but relapse commonly occurs with cessation of therapy.

Various additional therapies have been tried to reduce discomfort. Some pain control has been observed with use of the analgesic *tramadol* (see Chapter 236). The few studies examining *benzodiazepines* are of inadequate quality, but results suggest short-term improvement; however, the prolonged use that would be necessary for treatment of fibromyalgia would be inappropriate, given the risks for benzodiazepine dependency and withdrawal (see Chapter 227). *NSAIDs* and systemic

corticosteroids have little effect on pain. *Opioids* have not been studied. Injection of tender points with topical *lidocaine* has been tried, but the large number of sites that are tender, the modest responses, and the considerable amount of pain after injection make this treatment of little consequence. *S*-adenosyl-L-methionine (*SAMe*) is a popular nonprescription derivative of methionine with purported antidepressant, analgesic, and antiinflammatory actions. Small-scale, short studies suggest modest reductions in pain, depression, and number of tender points. *Acupuncture* may be helpful, but available studies are flawed and results are equivocal. *Biofeedback* and *hypnotherapy* have their advocates, but data are too limited to judge efficacy.

Empiric parenteral antibiotic treatment for Lyme disease has no place in the treatment of patients with fibromyalgia and positive Lyme serology. Positive serology in the absence of clinical evidence for Lyme disease is likely to represent a false-positive result. Only patients with clinical manifestations strongly suggestive of Lyme disease (rash, arthritis, heart block, or neurologic deficits) should be considered candidates for such therapy (see Chapter 160).

Enhancing Functional Capacity. As noted earlier, the goal of management is not so much the elimination of pain as the preservation and enhancement of function. Toward this end, a number of additional measures are worth considering. *Cognitive–behavioral therapy* has proved very helpful in redirecting the patient's focus away from pain and disability and toward the restoration of function and full participation in daily life. Most programs studied have been multidimensional, combining cognitive restructuring, pacing of activity, and patient and family education with aerobic exercise, relaxation training, and meditation. Results are best for those with symptoms of recent onset. Programs run from 1 to 6 months. Long-term results can be demonstrated many months after completion. *Cardiovascular fitness training* (aerobic exercise three times weekly) raises pain thresholds and global assessment scores, but sleep and fatigue levels may not improve much when training is undertaken without the implementation of other treatment modalities, and effects do not last after exercise has been stopped. No improvement has been noted with flexibility exercises only.

Refractory Complaints: Addressing Underlying Psychosocial Factors. Patients who make repeated visits and appear refractory to treatment efforts should undergo a full psychosocial assessment and be carefully evaluated for psychiatric, family, occupational, and social difficulties. Problems in these areas are the most important determinants of health care utilization and disability in patients with fibromyalgia. They have little effect on the severity of symptoms, but they do determine illness behavior. Similarly, patients who perceive their symptoms to be the consequence of an injury suffered at work or in an accident also have a poor prognosis, with disability and a poor response to treatment persisting until litigation and related issues have been settled. The first step in the management of persons with refractory disease must be a thoughtful approach that directly addresses these underlying psychosocial difficulties.

CHAPTER 160 APPROACH TO THE PATIENT WITH LYME DISEASE

ALLAN H. GOROLL

INTRODUCTION

Lyme disease is a treatable multisystem illness caused by infection with the tick-borne spirochete *Borrelia burgdorferi*. The condition has become the most common vector-borne disease in the United States, with more than 40,000 cases reported to the Centers for Disease Control and Prevention in the past 10 years. In most instances, the acute infection can be readily diagnosed and effectively treated. The neurologic and musculoskeletal manifestations of later stages may be more subtle and resemble those of chronic fatigue syndrome, fibromyalgia, or depression. The nonspecificity of symptoms and shortcomings of available serologic tests lead to both underdiagnosis and overdiagnosis.

The primary physician needs to be skilled in the clinical recognition of early disseminated and late disease; clinically capable of differentiating it from other acute, subacute, and chronic neurologic and musculoskeletal conditions; cognizant of the limitations of diagnostic methods; and capable of prescribing an effective antibiotic program.

EPIDEMIOLOGY, PATHOPHYSIOLOGY, AND CLINICAL PRESENTATION

Epidemiology

The spirochete causing Lyme disease is transmitted to humans by *Ixodes* ticks. Nymph-stage ticks feed on humans from May through July, transmitting the spirochete in the process. Endemic areas for species of the responsible tick include the northeastern coastal states, Wisconsin and Minnesota in the Midwest, and the coast of Oregon and northern California. Outbreaks in Europe and Asia have also been reported. In the U.S. eastern coastal regions and in the Midwest, the deer tick *I. dammini* is the principal vector. More than a third of deer ticks carry the spirochete, which accounts for outbreaks of epidemic proportion. In the western United States, the *I. pacificus* species is responsible, but the carrier rate is only 1% to 3% and human infection is much more sporadic. The condition has also been reported in Europe and Asia.

The rising frequency of Lyme disease and its geographic spread have been linked to enlarging deer populations and concurrent suburbanization. The spirochete is transmitted horizontally to field mice, which are critical to sustaining its life cycle (deer are not, but the ticks prefer them). Human infection is a biologic dead end for the spirochete.

Human babesiosis, caused by the intracellular rickettsial parasite *Babesia microti*, is endemic to many of the same areas as Lyme disease. Transmission to humans is by the same deer tick, and the same field mice serve as the animal reservoir. The shared tick vector and animal reservoir increase the risk for concurrent infection. Approximately 10% of patients with active Lyme disease are concurrently infected with *B. microti*.

Human granulocytic ehrlichiosis is yet another recently appreciated rickettsial disease that is zoonotic in the same geographic sites as babesiosis and Lyme disease. So far, no evidence of concurrent infection has been found.

Pathophysiology

The spirochete enters the bloodstream at the time of tick feeding. After a short bloodstream phase, the organism moves out of the blood and, in seemingly trophic fashion, into the skin, synovial membranes, heart, and nervous system. The means by which the spirochete damages tissue remains unclear; hypotheses range from direct injury to the production of antispirochetal antibodies that cross-react with tissue antigens. Patients with symptoms that persist after appropriate antibiotic therapy are suspected of having an exaggerated, sustained immune response. Such a response may account for the overlap in clinical manifestations with those of fibromyalgia and chronic fatigue syndrome, in which an immunologic pathophysiology is also suspected (see Chapter 8 and Chapter 159). The fact that patients who are positive for HLA-DR4 appear to be at increased risk for such chronic illness suggests that the severity and chronicity of disease may be related, in part, to cell surface antigens and genetic susceptibility.

Unlike *B. burgdorferi*, the *Babesia* organism resides predominantly in the red cells and causes mostly systemic symptoms with little localization. Infection can impair host defenses and may enhance injury caused by *B. burgdorferi*.

Clinical Presentation and Course

The biting tick is usually no larger than the size of a pencil mark and often inapparent. Shortly after the bite, the first symptoms develop. The clinical course can be divided into three stages: (a) acute, localized disease; (b) subacute, disseminated disease; and (c) chronic disease.

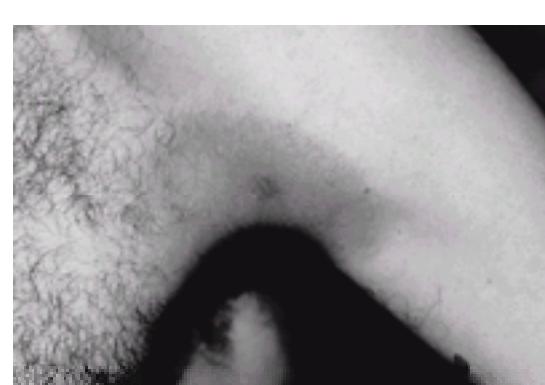
Stage 1: Acute Infection. In most patients, the first clinical manifestation of *B. burgdorferi* infection is a skin reaction to the organism. In about 80%, a characteristic expanding erythematous rash, *erythema migrans*, develops (Fig. 160-1). It usually begins as a red macule at the site of the tick bite and spreads out to form a large annular lesion with red secondary outer rings, an intense red outer border, and some clearing toward the center, although induration may be noted at the site of the bite. The lesion is large, averaging 15 cm. Minor constitutional *flulike symptoms* (a "summer flu") and regional *lymphadenopathy* may accompany the rash. The remaining 20% of patients have flulike symptoms without a rash or no acute-stage symptoms at all. The rash starts to fade by 3 to 4 weeks. During stage 1, the immune response is minimal.


Figure 160-1. Erythema migrans of the axilla.

Stage 2: Disseminated Infection. Hematogenous dissemination follows the acute phase within several days to a few weeks of the tick bite and leads to a host of

symptoms, mostly dermatologic, musculoskeletal, and neurologic. Constitutional symptoms may be prominent, with patients complaining of generalized *malaise* and debilitating *fatigue*. Often, bouts of severe *headache* lasting a few hours may develop, accompanied by mild neck stiffness, as may *migratory arthralgias* and musculoskeletal pain.

Dermatologic Manifestations. Dermatologic manifestations include new *annular skin lesions*, smaller and less migratory than the initial one. Malar rash, diffuse erythema, and urticaria have also been noted.

Cardiac Involvement. Cardiac involvement is noted in about 5% to 10% of patients, beginning several weeks into the infection. *Transient heart block* may be a consequence, ranging from asymptomatic first-degree atrioventricular block to complete heart block with fainting. The cardiac phase lasts 3 to 6 weeks, with the most severe forms of heart block persisting for about 1 week and not requiring pacemaker placement.

Neurologic Sequestration. Neurologic sequestration ensues weeks to months after the initial infection, affecting 15% to 20% of untreated patients. It consists of a *lymphocytic meningitis* and cranial or peripheral neuropathy. The cerebrospinal fluid (CSF) shows a pleocytosis with about 100 lymphocytes per cubic millimeter, elevated protein and normal glucose levels, and antibodies to the spirochete. A mild *encephalopathy* may ensue and produce mood changes, somnolence, and memory disturbances. A unilateral or bilateral *Bell's palsy* is the most common cranial nerve deficit. The *peripheral neuritis* presents as motor and sensory changes of the trunk or limbs in a dermatomal distribution. These neurologic manifestations can last for weeks to months.

Musculoskeletal Symptoms. Musculoskeletal symptoms evolve into frank arthritis in up to 60% of untreated patients. The onset of arthritis is variable but averages 6 months from the time of initial infection. Characteristically, self-limited attacks of acute asymmetric *monoarticular* or *oligoarticular arthritis* develop. Pain and swelling are noted in one or a few large joints. The knee is the most common site. A joint effusion may form, composed of increased numbers of neutrophils (10,000 to 25,000/mm^3). No more than three joints are usually involved in the course of the illness. Symptoms and signs last several days to a few weeks. After an attack, the joint returns to normal.

Stage 3: Chronic Infection. Following a latent period of several months and beginning a year after the time of the original infection, symptoms of chronic infection begin to appear. Bouts of arthritis may become more prolonged, and chronic neurologic deficits may ensue.

Skin Changes. Most patients in the United States do not manifest skin changes in the late phases of Lyme disease, but in Europe, a chronic atrophic form of *acrodermatitis* unique to Lyme disease has been observed.

Arthritis. The transient form of arthritis characteristic of disseminated disease is supplanted by a more persistent one that lasts months instead of weeks. The knee remains the most common site, and the pattern continues to be oligoarticular. Joint erosion is reported but uncommon and rarely leads to permanent loss of function. In a small percentage of patients, the arthritis persists even after a full course of antibiotic therapy. An immunologic mechanism is postulated. Over the years, the frequency of arthritic episodes declines.

Neurologic Impairment. Distal paresthesias, radicular pain, and memory loss comprise the principal neurologic manifestations of late disease, representing polyneuropathy and encephalopathy. Often, they occur concurrently. Tiredness may also be reported. In rare instances, a leukoencephalopathy with spastic paraparesis may develop. Two thirds of patients with neurologic symptoms have elevated levels of protein in the CSF, and half have Lyme antibodies in the CSF. In most patients, electrophysiologic study findings are abnormal, demonstrating evidence of axonal degeneration.

Natural History of Disease. Without treatment, disseminated disease develops in about 80% of patients. Attacks of oligoarthritis are common (60% to 80%) but resolve within 1 to 3 years, even without treatment. Chronic neurologic and persistent joint symptoms affect about 5% to 10% of patients. Susceptibility to late chronic disease may be genetically determined. A "*post-Lyme syndrome*" may be seen in up to a third of treated cases; it is characterized by persistence of fatigue, myalgias, and arthralgias for several more months after objective disease manifestations have resolved.

Concurrent Infection with *B. microti*. The symptoms of human *babesiosis* include fever, chills, sweats, arthralgias, headache, and lassitude. Patients with concurrent Lyme disease and babesiosis typically manifest what appears to be a more severe and prolonged case of Lyme disease. Marked fatigue, headache, sweats, chills, nausea, conjunctivitis, emotional lability, and splenomegaly occur more frequently than in patients with Lyme disease alone. Moreover, almost half remain symptomatic for more than 3 months, whereas fewer than 5% of those with Lyme disease alone remain symptomatic for that long. Similarly, patients with concurrent babesiosis and Lyme disease appear to have a more severe case of *Babesia* infection than would be typical.

DIFFERENTIAL DIAGNOSIS

Acute and Early Disseminated Stages. Lyme disease patients with acute-phase flulike symptoms, rash, and a history of tick bite may be confused with persons having *Rocky Mountain spotted fever*, which also is tick-borne and produces an acute febrile illness with rash, musculoskeletal pain, headache, and gastrointestinal upset. However, the rash of Rocky Mountain spotted fever is different; it starts within a few days of the tick bite as an outbreak of small, blanching macules on the wrists and ankles, spreads centripetally and also to the palms and soles, and then becomes generalized and petechial. As noted previously, *human babesiosis* may mimic or exacerbate the early phases of Lyme disease and should be considered when a patient with a recent tick bite in an endemic area appears to have a particularly severe set of systemic Lyme symptoms that persist beyond 3 months. *Summertime viral illnesses* enter into the differential diagnosis in patients who present with flulike symptoms but without erythema migrans or a history of tick bite.

Patients with symptoms and signs of meningeal irritation require careful evaluation. *Viral encephalitis* is among the summer viral illnesses that may present with headache, stiff neck, and mental changes. *Bacterial meningitis* must also be considered. The erythema migrans and concurrent Bell's palsy or radiculoneuritis of Lyme disease should help differentiate *B. burgdorferi* infection from other causes of meningeal irritation.

Late Disseminated and Chronic Stages. The presence of acute episodes of oligoarthritis raises the question of *gout*, *pseudogout*, and a *seronegative spondyloarthropathy* (e.g., Reiter's syndrome, psoriatic arthritis, ankylosing spondylitis). At the time of the initial presentation, *infectious arthritis* also enters into the differential diagnosis. Even early *rheumatoid arthritis* may present as a monoarticular or oligoarticular disease involving a large joint. The correct diagnosis can usually be made based on the associated clinical findings and the results of serologic testing and joint fluid analysis (see Chapter 145 and Chapter 146).

The subtle neurologic and joint manifestations of late Lyme disease can cause considerable diagnostic confusion. *Depression*, *fibromyalgia*, and *chronic fatigue syndrome* have manifestations that overlap with those of Lyme disease. Clinicians encountering patients with these difficult conditions may overdiagnose Lyme disease, especially if too much emphasis is placed on serologic testing and too little on symptoms and signs (see below and Chapter 8, Chapter 159, and Chapter 227). Adding to the confusion is the possibility that, in some instances, Lyme disease may be followed by a post-Lyme syndrome or may trigger fibromyalgia.

WORKUP

In general, the diagnosis of Lyme disease is made clinically, by recognizing the characteristic symptoms and signs within the epidemiologic context of the illness. Serologic testing for antibody against *B. burgdorferi* can supplement the clinical evaluation, particularly in persons with an intermediate pretest probability of Lyme disease, but overdiagnosis leading to overtreatment is common (see below).

Early Disease. A careful history and physical examination remain the best approach to the early diagnosis of Lyme disease. Antibody will not appear for several weeks, so that a clinical diagnosis is necessary at this stage of the illness. One asks the patient about having recently been in a wooded, brushy, or grassy area of an endemic region; tick bite; rash; and any flulike illness occurring in the spring or summer. A history of tick bite is not necessary for diagnosis. (The nymph tick is very small, and its bite is easily missed.) The presence of the characteristic annular lesion of *erythema migrans* is pathognomonic. It appears in 50% to 80% of patients. Most other clinical findings are nonspecific.

In endemic areas, patients presenting with early, nonspecific symptoms are often tested at the onset of symptoms or after a tick bite, a practice that is probably a response to patient concerns and a demand for early testing and treatment. However, it is too early to detect antibody, and the pretest probability of Lyme disease in patients with early, nonspecific symptoms is very low. Testing them at this stage maximizes the risk for false-positive and false-negative results and should be

discouraged (see below). Those in an endemic area with especially severe systemic symptoms should be evaluated for concurrent babesiosis (see below).

Disseminated Disease. In disseminated disease, the principal clues to the diagnosis continue to be clinical. In addition to epidemiologic inquiry, a review of key historical features is necessary, including new erythematous lesions, palpitations, near-syncope, stiff neck, facial weakness (which may be bilateral), radicular pain, migratory musculoskeletal complaints, and later, frank oligoarticular arthritis, particularly of the knee. Physical findings of importance include the multiple annular erythematous skin lesions of *secondary erythema migrans*, irregular pulse, nuchal rigidity, facial nerve palsy, and joint swelling with effusion. Suspicion of early disseminated Lyme disease is particularly high if the lesions of secondary erythema migrans are present. Again, when patients have particularly severe and persistent systemic symptoms, concurrent babesiosis should be suspected, and they should be tested accordingly.

The diagnosis can be facilitated by obtaining serum for *antibody testing*, but only in patients with sufficient clinical evidence of Lyme disease to have an intermediate (20% to 80%) pretest probability of Lyme disease (see Table 160-1 and below). For patients with meningeal signs, lumbar puncture should be considered. The CSF is sent for antibody testing in addition to cell count, differential, and chemistries. Most patients with central nervous system involvement have detectable antibody in the CSF, a pleocytosis, and an elevated protein concentration. If a joint effusion is present, *arthrocentesis* is indicated. *Polymerase chain reaction* methods (see below) may become useful for linking *Borrelia* infection to the arthritis.

CLINICAL PRESENTATION	COMMUNITY INCIDENCE: 0.1%	COMMUNITY INCIDENCE: 1.0%	COMMUNITY INCIDENCE: 3.0%

Table 160-1. Pretest Probability of Lyme Disease Based on Epidemiology and Clinical Presentation

Late Disease. The diagnosis of late disease requires careful attention to the patient's musculoskeletal and neurologic symptoms. One checks for chronic oligoarticular arthritis (particularly of the knee), memory loss, spinal radicular pain, and distal paresthesias. Patients with findings suggestive of encephalopathy should undergo a *lumbar puncture* for antibody testing of the CSF, cell count, and chemistries. Peripheral polyneuropathy can be confirmed by *electrophysiologic study*, if necessary.

Differentiating Late Lyme Disease from Other Conditions. As noted earlier, *chronic fatigue syndrome* and *fibromyalgia* may be mistaken for Lyme disease. Tiredness and chronic neurologic and musculoskeletal symptoms are common to all three. Clinical features that help to differentiate Lyme disease from the other two include (a) oligoarticular musculoskeletal complaints that include signs of joint inflammation; (b) limited and specific neurologic deficits (memory loss, distal paresthesias, radicular pain); (c) abnormalities on CSF examination and electromyography; and (d) absence of disturbed sleep, chronic headache, depression, and tender points. Complicating differentiation are (a) the ability of Lyme disease to trigger chronic fatigue syndrome and fibromyalgia; and (b) the inadequate specificity of available diagnostic tests. Depression can also mimic some of the nonspecific manifestations of these conditions and should be considered in patients who present with fatigue and multiple nonspecific bodily complaints (see Chapter 8 and Chapter 228).

Diagnostic Studies. Laboratory confirmation of *B. burgdorferi* infection remains problematic. Antibody testing can contribute to the diagnosis, but only under carefully selected conditions and at the risk of generating false-positive results. Isolation of the spirochete is not practical, and DNA detection by polymerase chain reaction technology remains experimental. The diagnosis of Lyme disease remains predominantly a clinical one. Laboratory testing should be used only as a supplement to the clinical findings and not as the basis for the diagnosis.

Antibody Testing. Clinicians often turn to serologic testing for Lyme disease when the clinical picture is unclear or patient concerns are high. Serologic testing aims to detect immunoglobulin M and immunoglobulin G antibodies expressed against *B. burgdorferi* antigens in response to spirochete infection. Most so-called *first-step tests* utilize ELISA (enzyme-linked immunosorbent assay) technology for antibody detection. First-step antibody testing is sensitive; when performed more than 12 weeks after the onset of symptoms, its sensitivity ranges from 90% to 100%. However, the specificity is more modest (70% to 90%) because some *Borrelia* antigens are shared with other microorganisms and cross-reacting antibodies are found in persons with conditions that may resemble Lyme disease (e.g., viral illnesses, other tick-borne infections, connective tissue diseases, encephalitis). Specificity can be improved by subjecting a serum sample with positive or indeterminate results by first-step assay to *Western blot testing*. This so-called *second-step test* provides enhanced specificity but is more supplementary than truly confirmatory because it detects antibodies to the same antigens as does first-step testing. Currently, 3 million serologic tests for Lyme disease are ordered annually in the United States at a cost of nearly $100 million. In untreated persons, antibody titers become detectable several weeks into *Borrelia* infection and remain positive for years. ELISA can also detect antibody in CSF. Hyperconcentration of antibody in the CSF is strong evidence for central nervous system infection.

Pitfalls. Improper use and interpretation of Lyme serology are common, often resulting in overdiagnosis, overtreatment, and the associated adverse consequences (e.g., inappropriate health care utilization, treatment-related adverse effects, disability, and depression). The Food and Drug Administration issued a public health advisory regarding the potential for the misdiagnosis of Lyme disease when commercially available antibody assays are used. The advisory and subsequent study by the Centers for Disease Control called attention to numerous shortcomings, such as lack of reproducibility of results, poor sensitivity when used in the early stages of illness, and unacceptably high false-positive rates when used in persons with a low pretest probability of disease. Moreover, Lyme antibodies usually persist for years after infection has cleared, so that the differentiation between active and previous infection is difficult. The proper use of antibody testing for Lyme disease needs to be understood by clinicians to avoid errors in diagnosis and resultant adverse outcomes.

Timing. Because it takes several weeks for immunoglobulin M and especially immunoglobulin G antibodies to be expressed in response to infection, antibody testing should not be ordered during the acute phase of illness. Such early testing maximizes the chances of a false-negative result, which can exceed 50% in the first 2 weeks after onset of symptoms. A testing strategy that utilizes acute-phase and later-phase sera does not appear to be cost-effective. False-negative test results can also occur when patients are treated during early stages of the disease.

Patient Selection. Antibody testing contributes best to clinical decision making when applied to persons with an *intermediate pretest probability* (20% to 80%) of having Lyme disease (Table 160-1 and Chapter 2). Testing persons with a high (>80%) pretest probability contributes little to diagnosis; a negative test result does not rule out the condition and a positive test result does not substantially increase the probability of disease. Patients with a low (<20%) pretest probability (Table 160-1) also do not benefit because the combination of low pretest probability together with high test sensitivity and insufficient specificity produces more false-positives than true-positives (see Chapter 2). Despite such reasons for not testing patients with a low probability of disease, many clinicians still do, often because they want to provide reassurance that the patient does not have Lyme disease. Although it is true that a negative antibody test result obtained after the acute phase of illness has passed does effectively rule out the condition, the chances of a false-positive are substantial and may only aggravate the patient's concerns and disability.

Test Selection. The Centers for Disease Control recommends a two-step testing strategy, which begins with selection of a first-step test for initial assessment followed by Western blot testing of all "indeterminate" and "positive" sera. Theoretically, this approach has the capacity to reduce false-positive results, but its cost-effectiveness remains to be proved. With more than 40 commercially available testing kits available for Lyme antibody detection, much variability in kit performance, often poor interlaboratory and intralaboratory reproducibility, and little standardization, it is essential that one use a laboratory with skill and experience in Lyme antibody testing.

DNA Detection. Better diagnostic studies are needed to differentiate active from past infection in antibody-positive patients, and to distinguish a true-positive ELISA result from a false-positive one. Short of isolating the organism (which is difficult), one can attempt to detect its DNA. Under development is use of *polymerase chain*

reaction technology to detect *Borrelia* DNA sequences in bodily fluids. Preliminary studies suggest it can be used to determine active infection in arthritic joints. Further testing is needed, but if the technique proves effective, it may overcome the limitations of antibody testing.

Testing for Concurrent Babesiosis. The diagnosis can be made by identifying the parasite in red cells on *Giemsa-stained thin blood smear*, but because the parasites frequently cannot be seen, test sensitivity is greatly decreased. *Indirect immunofluorescence* is the principal antibody study available; a positive test result consists of a fourfold rise in titer and immunofluorescence persisting at a 1:32 dilution. *Polymerase chain reaction* assays are very sensitive and highly specific but not widely available.

PRINCIPLES OF MANAGEMENT

Antibiotics are effective against *B. burgdorferi*. Treatment is determined by the stage of disease and type of clinical manifestation. *Doxycycline* and *amoxicillin* are preferred for oral treatment programs, and *ceftriaxone* or *high-dose penicillin* when IV therapy is required. Optimal dose and duration of therapy continue to be the subject of study. Current recommendations are presented in Table 160-2. Response rates are excellent, but noninfectious sequelae may still develop in fully treated persons. Additional antibiotic therapy is without benefit in such persons. Patients with severe or prolonged systemic symptoms should be tested for concurrent babesiosis and treated specifically with clindamycin and quinine if the results are positive.

Table 160-2. Recommendations for Antibiotic Treatment[a]

Stage 1: Acute Infection

The earlier antibiotic treatment is instituted, the better the outcome and the lower the risks for dissemination and chronic disease. Patients residing in or visiting an endemic area who develop symptoms and signs indicative of a high probability of Lyme disease (see Table 160-1) are reasonable candidates for prompt initiation of a full course of antibiotic therapy without serologic testing. Most others, including those with tick bites, should be evaluated for the development of symptoms and signs of Lyme disease (see above). If clinical evidence suggests an intermediate pretest probability of the disease (see Table 160-1), then serologic testing should be undertaken, allowing sufficient time after onset of symptoms for an antibody response to develop. Those who test positive under such circumstances are also candidates for a full course of antibiotics. | **Updated: 9/12/01**

Antibiotic Regimens

Doxycycline (100 mg twice daily) and amoxicillin (500 mg three times daily) are the agents of choice. Although the trend in recent years has been to extend treatment of acute infection to 21 to 28 days to prevent relapse of symptoms, this duration of therapy in randomized controlled study was no better than 10 days of treatment in regards to long-term outcomes with doxycycline use. Adding a single intravenous dose of ceftriaxone at the outset of therapy for the purpose of terminating any early occult CNS spread provides no increase in cure rate. Cefuroxime (500 mg twice daily) approaches the efficacy of doxycycline. Macrolide antibiotics are less effective, and newer generation macrolides offer no advantage over doxycycline and amoxicillin. In a carefully conducted multicenter study, 7 days of azithromycin was associated with an unacceptably high relapse rate in comparison with 20 days of amoxicillin (16% vs. 4%). | **Updated: 5/16/03**

Prophylactic Therapy

Some clinicians "prophylactically" prescribe a standard course of antibiotic therapy to those who present with a tick bite contracted in an endemic area. | **Updated: 9/12/01**

This practice is to be discouraged, because only those with a high clinical probability of acute Lyme disease (e.g., typical erythema migrans rash, residing in or visiting an endemic area; see Table 160-1) benefit from a full course of empiric antibiotic therapy. For the majority of patients in nonhyperendemic regions who present with a tick bite, the most practical approach is simply to be sure the tick is removed promptly and thoroughly and the patient monitored for development of erythema migrans and other symptoms and signs of acute Lyme disease. Patients should be reassured that the risk of developing Lyme disease is low (especially if the tick was removed within 24 to 36 hours) and that treatment is effective, should symptoms and signs develop. However, in hyperendemic regions, it is reasonable to treat tick-bite patients prophylactically with a single dose of doxycycline (200 mg), especially in cases where follow-up is uncertain or patient anxiety about chronic effects cannot be allayed. Patients should be aware that antibiotic prophylaxis is not a substitute for primary prevention through proper clothing, insect repellent, and avoidance of tick-infested areas. | **Updated: 9/12/01**

Stage 2: Disseminated Disease

In disseminated disease, it is common for a host of organ systems to be involved, although treatment recommendations are by organ system and clinical presentation. If more than one is involved, then the most potent antibiotic program takes precedence.

Cardiac Involvement. Cardiac involvement is a potentially worrisome form of disseminated disease. Although heart block is usually self-limited, patients with a severe PR–interval in prolongation of (>0.4 seconds) are commonly treated with IV antibiotics (ceftriaxone or high-dose penicillin) to prevent significant myocardial invasion. For those with less severe PR interval prolongation oral doxycycline or amoxicillin prescribed for 21 to 28 days suffices.

Neurologic Involvement. Although most neurologic manifestations of disseminated disease eventually clear without treatment, antibiotic therapy is strongly recommended, both to shorten the duration of symptoms and to prevent sequelae.

Facial Nerve Palsy. In the absence of evidence for meningitis, treatment can be oral with doxycycline or amoxicillin for 3 to 4 weeks.

Meningitis. Antibiotic therapy produces a prompt clinical response and shortens the clinical course substantially. Both IV ceftriaxone and high-dose penicillin G are curative. Ceftriaxone is much more expensive, but its once-daily schedule makes home administration possible and obviates a prolonged hospitalization. Lumbar puncture with CSF analysis is needed to confirm the diagnosis but not to assess response to treatment. Duration of therapy is best determined by the clinical response. Most authorities recommend 2 to 4 weeks.

Polyneuropathy. Peripheral neuropathy and radiculopathy tend to occur in conjunction with meningitis and respond well to treatment of the meningitis. When no clinical or CSF evidence of meningitis is found, an oral program of either doxycycline or amoxicillin for 3 to 4 weeks is a reasonable alternative.

Arthritis. The migratory musculoskeletal pains and brief attacks of oligoarticular arthritis are typically self-limited, but antibiotic therapy is given to halt symptoms and prevent progression to chronic arthritis. The optimal antibiotic program has not been established. Because of the development of chronic arthritis that persists despite

prolonged courses of antibiotics, antibiotic regimens have been made longer. Thirty days of oral doxycycline or amoxicillin (with probenecid to delay urinary excretion) is often recommended, with IV therapy reserved for more refractory chronic arthritis (see below). Intraarticular steroids are to be avoided because they increase the risk for antibiotic failure.

Stage 3: Chronic Disease

Late disease tends to be more difficult to treat, with responsiveness to antibiotics often less impressive than in disseminated disease. This has led to the use of prolonged and repeated courses of antibiotics. The inability to distinguish infectious from noninfectious sequelae has hindered the design of treatment programs. With the advent of DNA detection techniques, it should be possible to make more pathophysiologically correct treatment recommendations. It is hoped that etiologic therapy will become available to persons with noninfectious sequelae.

Arthritis. Treatment is 30 days of oral doxycycline or amoxicillin (plus probenecid) or 2 to 3 weeks of IV ceftriaxone or penicillin G. Retreatment may be necessary, but only in cases with objective evidence of persistent infection (e.g., results of polymerase chain reaction testing of synovial fluid remain positive).

Encephalopathy. Patients with Lyme disease in whom documentable memory or cognitive deficits develop in conjunction with elevations in CSF protein and antibody are candidates for antibiotic therapy. The program is identical to that for meningitis. Resolution is sometimes incomplete, and retreatment is carried out. It is unclear whether the cause in such cases is infectious or not. Polymerase chain reaction testing of the CSF may prove useful in making this distinction, but such testing remains to be evaluated.

Patients with the neuropsychiatric symptoms of chronic fatigue syndrome or fibromyalgia often request treatment for Lyme disease, especially if they test positive for antibody. Those who have no clinical evidence for Lyme disease do not respond meaningfully to antibiotic therapy, and it should not be prescribed for them, even if they are antibody-positive. Whether the occasional patient with fibromyalgia or chronic fatigue syndrome whose illness appears to have been directly precipitated by Lyme disease will respond is unclear, but it is unlikely if the mechanism is noninfectious.

Prevention

Vaccination. First-generation Lyme vaccines containing recombinant outer-surface lipoprotein A with adjuvant have been developed and approved by the Food and Drug Administration for use in high-risk settings. Administration of a three-injection program over 2 years is required to achieve maximum efficacy. At 1 year and after two injections, the reported efficacy in the prevention of symptomatic infection is 49%, and it is 76% after 2 years; for the prevention of asymptomatic infection, the rates are 83% and 100%, respectively. Vaccination interferes with current ELISA serologic testing by stimulating antibodies to outer-surface protein, which are measured by most ELISA tests. Long-term safety and required frequency of booster injections remain to be determined. Use in children has not been studied. Soreness at the injection site occurs in about 7%, and 2% have a febrile response. Because the vaccine is not fully protective, precautions still need to be taken outdoors in high-risk areas.

Avoidance Measures, Protective Clothing, Tick Removal, and Use of Repellants. Standard preventive measures begin with avoiding brushy, wooded, or grassy habitats; these include grassy dunes, but not open sandy beaches. Tucking one's pants into one's socks is also commonly suggested. Because it takes more than 24 hours of tick contact before spirochete transmission occurs, it is recommended that daily checks for ticks be performed and removal attempted if a tick is found. Proper *tick removal* is best accomplished by using a tweezers to grip the mouth parts of the tick, which is pulled straight outward with steady gentle pressure. The fingers can be used instead of a tweezers, but gloves should be worn and the hands washed afterward. Other methods (e.g., hot match tip, alcohol, petroleum jelly, nail polish) are not effective.

Diethyltoluamide (*DEET*)-*containing repellants* and acaricides such as permethrin that can be applied to clothing provide added protection to persons who cannot avoid high-risk settings. DEET-containing repellants should be used with care, especially in young children, who are quite susceptible to DEET neurotoxicity. Maximum DEET concentration in the repellant should be 15% for children and 35% for adults; use on the skin of infants, on the hands and face of young children, and on cuts, abrasions, and sunburned skin should be avoided. One should apply the repellant just once daily and wash it off with soap and water after returning indoors.

Other Management Issues

Pregnant Patients. Maternal–fetal transmission of infection with subsequent injury to the fetus has been reported. Antibiotic treatment should be instituted promptly in symptomatic patients. For localized early disease in which erythema migrans is the only symptom, the recommended treatment is oral amoxicillin for 3 weeks. For more disseminated disease, IV high-dose penicillin G is required for 2 to 3 weeks. No increased risk for fetal malformation has been found in asymptomatic women who are antibody-positive. Screening asymptomatic pregnant women for Lyme antibody and treating those who test positive is not warranted.

Patients with Concurrent Babesiosis. The program of choice is a combination of *clindamycin* and *quinine*. Treatment for concurrent disease should be carried out in consultation with an infectious disease specialist familiar with the management of tick-borne disease.

Prophylactic Therapy after a Tick Bite. The common practice of administering prophylactic antibiotics to persons in an endemic area who have been bitten by a tick should be discouraged because the risk for infection is less than the risk for an adverse drug reaction. After the tick comes in contact with the skin, it takes 24 hours for the spirochete to be transmitted. Persons who discover a tick usually do so before that much time has elapsed and remove it before transmission can occur. Under such circumstances, the risk for infection is about the same as that for an adverse or hypersensitivity drug reaction. A better approach is to follow patients for the appearance of symptoms (e.g., erythema migrans) and then treat promptly those in whom characteristic manifestations of the disease develop.

PATIENT EDUCATION AND INDICATIONS FOR REFERRAL

Patients who suspect but do not have Lyme disease require as much education about the condition as those who do. The person with depression, chronic fatigue syndrome, or fibromyalgia who insists on treatment for Lyme disease needs to know how the diagnosis is made. Those who are antibody-positive will benefit from a discussion of the minimal significance of a positive antibody test result in the absence of other defining clinical manifestations. The physician, while explaining that the probability of active Lyme disease is very low, must take care not to deny the reality and severity of the patient's symptoms. Attention should be directed to treatment of the underlying condition (see Chapter 8, Chapter 159, and Chapter 227).

Persons living in or visiting an area endemic for Lyme disease should be instructed to venture into tick-infested areas only after proper application of insect repellent (see above) and to cover skin surfaces with protective clothing. In addition, they should be taught to recognize the rash and other manifestations of early Lyme disease and the importance of early treatment. Parents of children should be taught the proper technique of tick removal (see above).

Patients with Lyme disease benefit from being informed about the excellent response of their condition to antibiotic therapy and its very favorable prognosis. However, those with protracted symptoms that do not respond to antibiotic therapy and with no evidence of persistent infection should be informed about the possibility of a noninfectious pathogenesis that is usually self-limited but slow to resolve. It is hoped that more etiologic therapy will be available for such persons in the future.

Referral is indicated when the patient with strong clinical evidence of Lyme disease fails to respond to a course of appropriate antibiotic therapy. Consultation is particularly important for those with refractory neurologic deficits, debilitating arthritis, or signs of severe cardiac involvement.

RECOMMENDATIONS

Diagnosis

- Make the diagnosis of Lyme disease predominantly according to the clinical presentation (e.g., erythema migrans, relapsing oligoarthritis, heart block, facial nerve palsy) and epidemiology (e.g., community incidence).
- Use serologic testing only as a supplement to the clinical diagnosis.
- Limit serologic testing to persons with an intermediate pretest probability of Lyme disease (based on clinical presentation).
- Avoid serologic testing early in the course of the illness because of the increased risk for false-negative results.

- Consider a two-step approach to serologic testing to reduce the false-positive rate: ELISA, followed by Western blot for sera with indeterminate or positive results by ELISA.
- Use only a high-quality laboratory that has persons skilled and experienced in performing Lyme serology.

Treatment

- Treat empirically without testing only those persons with a high clinical probability of Lyme disease (e.g., typical erythema migrans rash, endemic area).
- Treat after testing those who present with an intermediate pretest probability of Lyme disease and have a positive result on serologic testing.
- Do not treat empirically persons with nonspecific symptoms (e.g., flulike syndrome, chronic fatigue), even if they have a history of a tick bite in an endemic area, but who report no characteristic rash and no other symptoms or signs of Lyme disease. **Updated: 9/12/01**
- Do not treat prophylactically any asymptomatic person who reports a tick bite while in an endemic area. Instead, follow such persons for development of symptoms and signs of Lyme disease and serologically test and treat as appropriate. **Updated: 9/12/01**
- Consider prophylactic therapy (doxycycline, single 200 mg dose) only for asymptomatic patients who contract a tick bite in a hyperendemic area, especially when follow-up is uncertain or patient anxiety about chronic effects cannot be allayed. **Updated: 9/12/01**
- For persons with uncomplicated stage 1 disease (acute localized illness—erythema migrans), prescribe amoxicillin (500 mg three times daily) or doxycycline (100 mg twice daily) for 10 days; consider extending treatment for a total of 3 or 4 weeks in those with more severe early disease symptoms; cefuroxime (500 mg twice daily) is an effective alternative; do not use the 1-week azithromycin program because of an increased risk for relapse. **Updated: 5/16/03**
- For persons with stage 2 disease (acute disseminated disease), treat according to the organ(s) involved: for meningitis or severe cardiac manifestations, prescribe ceftriaxone (2 g IV once daily for 2 to 4 weeks); for peripheral neuropathy and arthritis, treat with amoxicillin (500 mg three times daily) or doxycycline (100 mg twice daily) for 3 to 4 weeks.
- For persons with stage 3 disease (chronic disease), treat the arthritis initially with the same program of amoxicillin or doxycycline as for stage 2 joint disease, but consider IV ceftriaxone if the initial program fails; treat encephalitis with ceftriaxone (2 g IV once daily for 2 to 4 weeks, the same treatment as for meningitis in stage 2 disease).

Prevention

- Teach patients the basics of avoiding tick habitats, dressing properly, using repellants safely, and removing ticks effectively.
- Consider vaccination for persons with a very high risk for infection, but only with the understanding that the vaccine is not fully protective, that it can compromise results of current serologic testing, and that long-term safety has not been established.

CHAPTER 161 APPROACH TO THE PATIENT WITH POLYMYALGIA RHEUMATICA OR TEMPORAL ARTERITIS

Polymyalgia rheumatica (PMR) is a common nonarticular rheumatoid disease characterized by neck, shoulder-girdle, and hip-girdle complaints and an elevated erythrocyte sedimentation rate (ESR). It affects mostly Caucasian patients over the age of 50, with a 2:1 female predominance. The annual incidence in persons over age 50 is 5/10,000; the prevalence is 50/10,000. The condition is usually self-limited, but the risk for temporal arteritis (TA) is increased. Up to 40% of patients with TA have a prior history of PMR. TA (also referred to as "cranial," "giant cell," or "granulomatous" arteritis) is a vasculitic disorder of unknown origin that can cause sudden blindness and aortic aneurysm and dissection. It too is limited to persons over the age of 50. The incidence and prevalence are about one-fifth that of PMR. Women are more often affected than men.

The primary physician needs to be alert to these diseases, which can be subtle in presentation and easily dismissed as vague functional complaints or confused with other conditions. The associated risks for blindness and aortic injury make the prompt recognition and treatment of TA especially critical. Because treatment requires long-term glucocorticoid therapy, it is just as important to avoid a false-positive diagnosis.

PATHOPHYSIOLOGY, CLINICAL PRESENTATION, AND COURSE

Polymyalgia Rheumatica

The pathogenesis of PMR is unknown, but a genetic susceptibility has been suggested by an association with the HLA-DR4 allele. The onset is gradual, with the condition developing over weeks or months. Bilateral pain and stiffness of periarticular structures in the *neck* and *shoulders* is the presentation in two thirds of cases, with *hip* and *thigh* involvement accounting for the other third. Many patients have both shoulder and thigh involvement. Diffuse swelling of the *hands* occurs in some patients. *Morning stiffness* and pain with movement are highly characteristic. Synovitis have been documented histologically, and rotator cuff bursitis and synovitis can be demonstrated by magnetic resonance imaging. Muscle biopsy specimens are usually normal or show minor inflammatory infiltrates; muscle strength is unimpaired. Low-grade *fever, weight loss*, and *fatigue* may accompany the musculoskeletal symptoms. The *ESR* is characteristically above 40 mm/h, but an occasional patient with characteristic clinical features of PMR may have an ESR below 40 mm/h and a milder form of the disease. The ESR correlates with disease activity, as do levels of *interleukin-6* and *C-reactive protein*.

Polymyalgia rheumatica tends to be a self-limited illness with a duration of 1 to 2 years. Three subsets of patients have been described: One responds promptly to initial steroid therapy and has no flares after taper; the required course of steroids is relatively short. A second also responds satisfactorily but has repeated flares and requires a longer course of steroids. A third does not respond to the initial doses of steroids, so that higher initial amounts are necessary; also, more flares occur and a prolonged course of steroids is required. The risk for progression to TA appears low in the first group and possibly increased in the latter two. The pretreatment ESR and the response of the interleukin-6 level to treatment help to identify these subsets.

Polymyalgia rheumatica shares many of the immunologic features of TA, so that some postulate that PRM may be a *forme fruste* of arteritis. Estimates of the risk for the development of clinical TA average 10% to 15%. However, when headache, jaw claudication, cranial artery tenderness, or visual complaints develop in a patient with PMR, the probability of TA is markedly increased (see below).

Temporal Arteritis

Temporal arteritis is a vasculitic condition of unknown origin. It is characterized pathologically by histiocytic, lymphocytic, and giant cell infiltrations of the walls of medium or large arteries originating from the aortic arch. Any one of these vessels can be involved, as can the aorta, but those of the head are most often affected. The internal elastic lamina is fragmented in conjunction with proliferation. The inflammatory process tends to be segmental. Many characteristics of an autoimmune process are present, but the precise pathophysiology remains to be elucidated. The fact that TA, like PMR, is associated with HLA-DR4 suggests a genetic predisposition. Direct inflammation of the arterial wall and the resultant ischemia secondary to vasculitic narrowing account for most symptoms.

The onset is gradual. Early symptoms include headache, low-grade temperature, and the aching and stiffness of PMR. *Headache* is reported in about 70% of cases and is the initial symptom in about 35%. The pain can be piercing or throbbing, often localized to the arteries of the scalp and unlike that of any previous headache. *Polymyalgia* symptoms may be the presenting manifestation in more than 50%. *Constitutional symptoms* of fatigue, malaise, anorexia, and weight loss occur in the majority of patients. In about a fifth of patients, the presentation may be atypical, with *fever of unknown origin* (FUO) being a classic atypical presentation of TA (accounting for about 15% of cases of FUO in patients over the age of 65).

As the condition progresses, *cranial artery tenderness* and enlargement may be noted. The temporal artery is most commonly affected, but any cranial artery may become involved. Ischemic symptoms such as *masseter claudication* (jaw pain with chewing) occur in one third to one half of patients.

Visual manifestations are the consequence of vasculitis of the ophthalmic or posterior ciliary arteries. *Blindness*, the most dreaded manifestation, has an abrupt onset and irreversible course unless it is treated very aggressively and very early (see below). Vision loss is sometimes preceded by transient visual symptoms, such as amaurosis fugax, flashing lights, or field defects. In untreated patients, visual loss occurs in up to 50% of cases. Acute *hearing loss* and *vertigo* have also been reported. An *aortic arch syndrome* may occur if the arch or a major branch vessel is involved. The risk for *aortic aneurysm* and *dissection* is increased nearly 20-fold; most often, the thoracic aorta is involved, but occasionally just the abdominal portion is affected. Granulomatous inflammation of the aortic wall is found. *Carotid* involvement may present as localized tenderness in the neck accompanied by *neurologic deficits. Subclavian* disease may cause *ischemic symptoms* in the arms (e.g., Raynaud's phenomenon, claudication); pulses are diminished, and a subclavian bruit may be heard.

A *markedly increased ESR* is characteristic of the disease; a normal sedimentation rate in the absence of strongly suggestive symptoms makes the diagnosis unlikely. A low-grade *anemia of chronic disease* and mild elevations of *serum liver enzymes* are also often present. On occasion, the anemia can be severe.

Temporal arteritis is a chronic illness that may last for years. Although it tends to be self-limited, the clinical course is highly variable. Complications of late disease are rare, but attempts to discontinue therapy often cause relapses.

DIAGNOSIS

Polymyalgia Rheumatica

The diagnosis is a clinical one. Criteria include (a) bilateral pain for at least 1 month in any two of the following: neck, shoulder girdle, hip girdle, in association with morning stiffness; (b) ESR above 40 mm/h by the Westergren method; (c) age over 50 years; (d) exclusion of other diagnoses except for TA; (e) marked clinical improvement in response to 1 week of treatment with less than 15 mg of prednisone per day. Patients meeting all criteria except an elevated ESR are usually considered to have PMR also.

Temporal Arteritis

The current American College of Rheumatology criteria for the diagnosis of giant cell (temporal) arteritis include (a) age at onset of symptoms *over 50 years*; (b) new onset or new type of localized *headache*; (c) temporal *artery tenderness* or diminished pulse; (d) *ESR above 50 mm/h* by the Westergren method; and (e) *temporal*

artery biopsy specimen showing mononuclear infiltration or granulomatous infiltration with giant cells. The presence of any three criteria constitutes evidence for the diagnosis of TA (sensitivity, 93.5%; specificity, 91.2%). Some characteristic symptoms and signs have been omitted from the criteria list because of their lack of sensitivity or specificity.

Temporal Artery Biopsy is the most invasive of the diagnostic determinations and sometimes a source of concern to patients. It is performed under local anesthesia as an ambulatory procedure, and morbidity is very low. The best results are obtained when an accessible cranial artery is selected that feels tender or has a diminished pulse (not caused by atherosclerotic disease). The temporal artery is usually selected. A 2- to 4-cm specimen is optimal because the inflammatory process may be focal and may demonstrate skip areas. A single biopsy has a sensitivity of about 90%. A negative first biopsy result does not rule out the diagnosis.

Treatment with corticosteroids before biopsy may lower the test sensitivity slightly, but not by so much as to preclude immediate therapy followed by biopsy within the first 1 to 2weeks after therapy is started. Some authorities suggest that biopsy can be omitted altogether when the clinical evidence for TA is compelling. However, most argue that histologic confirmation should be obtained before a patient is committed to such potentially morbid therapy as long-term daily corticosteroids. Biopsy is unnecessary when it will have no effect on clinical decision making. Patients with negative biopsy results and without strong clinical evidence for the diagnosis of TA have an excellent prognosis; signs of arteritis develop in fewer than 10% at a later time.

Color Duplex Ultrasonography of the temporal arteries appears promising as an alternative or complement to temporal artery biopsy. Its sensitivity for TA is 73% and its specificity is 100% when the finding of a dark halo about the vessel (believed to represent vessel wall edema) is used as the key diagnostic feature. Prospective study is necessary to validate the utility of the test, but possible applications include screening of asymptomatic patients with PMR to identify those who might need further evaluation, and confirming the diagnosis of TA without performing a biopsy in persons with clinically evident disease.

Arteriography is sensitive but nonspecific and unreliable diagnostically; however, it is helpful when an area must be chosen to sample after a first biopsy result has been negative.

PRINCIPLES OF MANAGEMENT

Polymyalgia Rheumatica

Polymyalgia rheumatica in the absence of TA characteristically responds quickly and well to modest doses of *prednisone* (e.g., 10 to 15 mg/d). Patients with severe symptoms and a very high ESR at the time of presentation may require a higher initial dose of prednisone (e.g., 20 to 30 mg/d). As the sedimentation rate falls and symptoms clear, one can begin tapering prednisone in small decrements (1 to 2.5 mg/d every 2 weeks). Therapy is titrated against symptoms and ESR. Some have suggested that following the interleukin-6 response to treatment can help predict the dose and duration of prednisone therapy. Symptomatic flares may require restarting or increasing prednisone, after which tapering is resumed. Between months and 1 to 2 years of daily low-dose steroid therapy may be required. The most prolonged therapy and the highest doses are likely to be needed by persons who manifest a markedly elevated ESR and prominent symptoms at onset and whose serum levels of interleukin-6 fail to normalize after initial steroid treatment. To minimize the adverse effects of daily steroids, the lowest possible dose of prednisone should be prescribed and taken in the morning (see Chapter 105). Osteoporosis prophylaxis is necessary if prolonged steroid therapy is required (see Chapter 146). The steroid doses required to prevent the development of TA in patients with PMR are not known, nor are the determinants of risk, but it appears that the likelihood of TA is low when disease activity is well suppressed. There is no evidence that alternate-day therapy is effective.

Temporal Arteritis

Initiation of Therapy. The first priority is to establish control of the disease quickly to limit the risk for irreversible blindness. When the patient's pretest probability of TA is high (e.g., age over 70 years, new headache, palpably enlarged and tender cranial artery, jaw claudication, high ESR), it is best to begin empiric *high-dose glucocorticoid* therapy (e.g., 40 to 60 mg of prednisone per day) immediately. Biopsy confirmation of the diagnosis is necessary, but empiric therapy before biopsy is appropriate in patients manifesting characteristic clinical features. A biopsy specimen obtained within 1 to 2 weeks after onset of prednisone therapy is not likely to be altered significantly.

In most instances, the clinical response starts within 24 hours of initiation of treatment. *Daily therapy* is needed; alternate-day schedules do not control the arteritis. To minimize adrenal suppression, prednisone should be taken once daily in the morning (see Chapter 105). The initial doses can be given parenterally when visual compromise is a concern, but to be effective, parenteral treatment must be started within the first several hours of visual impairment. Ophthalmologists recommend 5 days of high-dose parenteral *methylprednisolone* (1,000 mg IV every 12 hours) under such circumstances.

Tapering. The steroid dose is titrated against symptoms and sedimentation rate. To minimize the adverse effects of prolonged daily steroid therapy (see Chapter 105), the daily prednisone dose should be tapered. Tapering can be started after clinical and laboratory manifestations have normalized; it can be steady but should not be precipitous. Rapid tapering of prednisone to less than 20 mg/d over the first 1 to 2 months is associated with a 30% relapse rate. More reasonable is tapering to a daily dose of 20 to 30 mg within the first 2 months and more slowly thereafter. The goal is a maintenance dose of less than 10 mg/d, but it may take more than a year to achieve it.

Monitoring and Termination of Therapy. As the dose is reduced, the patient must be monitored for recurrence of *symptoms* and elevation of the *sedimentation rate*. Most patients require treatment for 2 to 3 years. Relapses occur in up to 50% of patients who attempt termination of therapy before that time. Nonetheless, the risk for blindness and other serious disease-related complications is minimal late in the course of disease, and a trial of discontinuing therapy can be attempted every 6 to 12 months after the first year. The trial should be halted at the first sign of recurring symptoms or a marked rise in the ESR. Close monitoring for relapse is essential during the first 12 months that the patient is off therapy. Despite tapering efforts, many patients experience steroid-related side effects because of the prolonged duration of daily steroid therapy. Efforts to limit osteoporosis should be undertaken (see Chapter 164).

Because the risk for potentially life-threatening aortic disease is increased in TA, some have suggested that monitoring for aortic aneurysm be part of the routine follow-up. Suggestions for monitoring range from palpating the abdominal aorta for signs of enlargement (see Chapter 58) and obtaining yearly posteroanterior and lateral chest films to consideration of ultrasonographic screening. The most cost-effective approach remains to be determined.

PATIENT EDUCATION

Patients with PMR in the absence of TA can be reassured. They benefit from knowing that the risk for the development of TA is small, that the disease does not progress to disabling arthritis, and that their condition is self-limited, although it may take a few years to clear. They should be instructed to watch for symptoms of TA and report them promptly. The adverse effectsof corticosteroid therapy need to be reviewed so that patients will use prednisone carefully and as directed.

Patients with TA and their families must understand the rationale for daily prednisone therapy in addition to its adverse side effects, both to ensure compliance and to provide an informed basis for long-term steroid use. Instruction in the means of minimizing steroid side effects is appreciated (see Chapter 105). Patients can be reassured that the serious complications of TA can be avoided by proper therapy.

INDICATIONS FOR REFERRAL AND ADMISSION

Prompt consultation with a rheumatologist is helpful when initiation of high-dose steroid therapy for presumed TA is being considered before a temporal artery biopsy can be performed, but therapy should not be delayed if consultation is not available immediately. Urgent ophthalmologic evaluation is needed if visual impairment is reported. If it is not available, one can proceed directly to hospitalization for immediate institution of high-dose parenteral corticosteroid therapy. Rheumatologic consultation is also indicated to consider the need for steroid therapy when cranial artery biopsy results are negative but the clinical presentation strongly suggests TA. The occasional patient with PMR or TA who does not respond adequately to steroid therapy requires a referral for reconsideration of the diagnosis and for other forms of immunosuppressive therapy (e.g., azathioprine, cyclophosphamide, dapsone).

THERAPEUTIC RECOMMENDATIONS

Polymyalgia Rheumatica

- Begin with low-dose prednisone (10 to 15 mg/d), provided no evidence of TA is found. For patients with a very high ESR and severe symptoms, consider starting prednisone at a higher dose (e.g., 20 to 30 mg/d).
- Taper in decrements of 1.0 to 2.5 mg/d every 2 weeks, titrating the dose against symptoms and ESR.
- Prescribe the lowest dose possible, to be taken in the morning.
- Continue steady tapering to full cessation of therapy if possible, monitoring symptoms and ESR for 2 years for evidence of relapse.
- Restart or increase prednisone by 5 to 10 mg/d if a flare of disease occurs; adjust the dose as needed and resume tapering as soon as remission has been achieved.
- Instruct the patient to report promptly any symptoms suggestive of TA (e.g., visual disturbances, tender cranial artery, headache, fever, jaw claudication).

Temporal Arteritis

- Begin therapy with daily high-dose glucocorticoids (e.g., 40 to 60 mg of prednisone every morning). Consider prescribing IV methylprednisolone (100 mg every 12 hours for 5 days) for patients who present with visual disturbances.
- Begin reducing the initial dose once the sedimentation rate has been normalized (<40 mm/h) and symptoms have cleared; aim for a daily prednisone dose of 20 to 30 mg after 1 to 2 months.
- Continue daily prednisone therapy, tapering slowly as tolerated over 12 to 18 months to the minimum dose sufficient to keep the sedimentation rate normal and the patient free of symptoms; a prednisone dose of less than 10 mg/d is often sufficient.
- Monitor symptoms and the sedimentation rate to determine the rate and extent of tapering permissible. Halt tapering if the ESR rises or symptoms return.
- Continue daily steroids for 18 to 24 months; consider a trial of phasing out therapy at that time and then every 6 to 12 months.
- After cessation of therapy, continue to monitor for recurrence of symptoms and a rise in the sedimentation rate over the next 12 months.
- Watch for the development of aortic aneurysm.

CHAPTER 162 MANAGEMENT OF PAGET'S DISEASE

SAMUEL R. NUSSBAUM

Paget's disease of bone, or osteitis deformans, is a focal disorder of unknown cause. It is characterized by deformity of the external contour and internal structure of bones that results from excessive resorption and rapid, disorganized formation of new bone. The incidence of Paget's disease is 3.3% in autopsy series and 0.1% to 4.0% in radiologic studies. The clinical presentation is variable. In the majority of cases, the diagnosis is made in an asymptomatic patient by the incidental discovery of an elevated alkaline phosphatase level during multiphasic screening or of the hallmark radiolucent (osteolytic) areas with compensatory new bone formation on radiographic films of the pelvis, vertebrae, or skull. Symptomatic patients report pain in the back or lower extremities, disturbances of gait, increasing head size, hearing loss, and occasionally symptoms related to high-output cardiac failure. The primary physician needs to be able to recognize the condition and know how and when to use agents that suppress osteoclastic activity.

PATHOPHYSIOLOGY AND CLINICAL PRESENTATION

The pathophysiologic hallmarks of Paget's disease are *excessive osteoclastic destruction* and resorption of bone, followed by the *unregulated osteoblastic formation of new bone*. The initial stimulus for bone resorption remains unknown, but the process culminates in an abnormal pattern of lamellar bone. Excessive local vascularity and an increase in fibrous tissue, which extends into the marrow, are characteristic. Both cortical and cancellous bone may be involved, each with several foci at different stages. The nature of the resultant bone, which is mechanically defective, distorted, and enlarged, leads to the cardinal manifestations of Paget's disease—bone pain and pathologic fractures.

Clinical Presentation. Although any bone may become involved, the common sites are *spine, pelvis, skull, femur,* and *tibia*. Most patients are asymptomatic, with Paget's disease presenting as an incidental finding on x-ray films or an isolated elevation in alkaline phosphatase. Those who are symptomatic present with bone pain, bony deformity, fracture, or a complication of increased marrow vascularity or bony encroachment on neural structures. About 15% of patients have very localized (so-called "monostotic") disease.

Bone pain may result from fracture or be independent of it. In the latter instance, it is usually located over lytic areas of bone where active osteoclastic resorption is taking place. The severity of pain does not always parallel the extent of radiographic involvement. Exacerbating factors include weight bearing, muscular activity, and cold weather.

Fractures may affect the long bones or vertebrae. The *lesser trochanter* of the femur and the upper third of the *tibia* are characteristic sites for fractures in long bones. A history of trauma can usually be elicited, but some of these fractures may occur spontaneously. Pain may result, but not always. Most vertebral fractures occur in the lumbar and sacral regions. They are usually painless but can lead to loss of height, kyphoscoliosis, and, in rare instances, spinal cord compression.

Bony deformity and *encroachment* are most notable in the *skull*, which may become visibly enlarged in the frontal and occipital regions. The overlying superficial blood vessels often become prominently dilated and visibly pulsatile. *Hearing loss* can ensue from involvement of the ossicles in the middle ear, which impinge on the eighth cranial nerve in the temporal bone. *Cerebellar* and *long-tract* signs are complications of posterior fossa encroachment. Vertebral encroachment on the *spinal cord* or *nerve roots* is rare but can cause a compression syndrome, including paraplegia. Deformity of the *long bones* is manifested as anterolateral bowing; it contributes to susceptibility to *fracture*.

Degenerative joint disease can result from hypertrophy of subchondral bone, which damages the overlying cartilage and causes joint dysfunction. Joint injury accounts for about 50% of the discomfort experienced by patients. Hip pain is a major problem in patients with long-standing subchondral bone involvement in the acetabulum and femoral head; it can lead to protrusio acetabuli. Degenerative disease of the knee joint may occur in similar fashion if the distal femur or patella becomes pagetic. Extensive and severe skeletal involvement increases the risk for *osteogenic sarcoma*, an uncommon but uniformly fatal cancer that affects fewer than 1% of pagetic patients. It is heralded by localized pain and bony enlargement and occurs more frequently in the upper extremities and skull of patients over the age of 50.

Hyperuricemia leading to gouty arthritis and *hypercalciuria* resulting in renal calculi are among the biochemical consequences of disrupted bony metabolism. *Hypercalcemia* can be precipitated by immobilization. *High-output heart failure* may occur in patients with extensive Paget's disease because of the marked increase in the vascular bed.

Laboratory and Radiographic Features. Serum *alkaline phosphatase*, produced by osteoblasts, is usually increased and correlates with the degree of new bone formation. *Urinary hydroxyproline*, a measure of bone matrix resorption, is also increased. In most patients, these parameters are complementary markers of disease activity and parallel radionuclide uptake on bone scan, the most sensitive measure of disease activity. In patients with disease localized to a single bone, results of standard serum and urine tests may be normal. The *bone-specific alkaline phosphatase* level provides a more sensitive determination of new bone formation, and the urinary level of *pyridinoline* (a specific component of bone matrix) is a better measure of bone resorption. Although these values are 50 to 100 times more expensive to obtain than the unfractionated alkaline phosphatase, they are useful indicators of disease activity in persons with involvement limited to a single bone.

Technetium *bone scan* demonstrates areas of increased uptake before diagnostic changes are visible on *standard radiography*. The first radiologic bony changes occur in the lytic phase and are well-demarcated areas of decalcification (seen best in the skull). With onset of new bone formation, areas of increased density become evident, as does expansion of bone and coarse trabeculation. In later phases, sclerosis, enlargement, and increased bone density are observed. The localized enlargement of bone that results is unique to Paget's disease and helps to distinguish it from other causes of bony sclerosis, such as prostatic cancer. Radiologic changes are most commonly evident in the pelvis, femur, and skull.

Clinical Course. Although many patients manifest slow radiologic progression, symptoms never develop in most. Others are noted to have radiologic changes that remain stable; a few have rapidly progressive disease. Although clinical remission after treatment is the rule, new complications can occur in those who do not achieve full biochemical remission (see below).

PRINCIPLES OF THERAPY

Patients with Paget's disease who are asymptomatic require no specific therapy unless the location of their disease places them at risk for a potentially serious complication (see below). Localized mild bone pain can be controlled with *analgesics* such as acetaminophen. Painful joints usually respond acutely to *acetaminophen* or an NSAID (e.g., 400 mg of *ibuprofen* three times daily or 500 mg of *naproxen* twice daily), agents commonly used for the symptomatic relief of osteoarthritis (see Chapter 157). More definitive therapy can halt the disease process by inhibiting bone resorption. The efficacy and safety of modern antipagetic therapy and the potentially disabling consequences of the disease have lowered the threshold for treatment.

The management of Paget's disease has been greatly enhanced in recent years by the development of *second-generation bisphosphonates* (e.g., *alendronate, risedronate*), which are well tolerated, orally effective, and capable of inhibiting osteoclast-mediated bone resorption without compromising bone mineralization. They effect radiographic, biochemical, and clinical improvement.

Indications for Disease-specific Therapy. At present, most patients are considered reasonable candidates for treatment unless they are asymptomatic and the disease is confined to areas where it is unlikely to cause complications (e.g., ribs, iliac crest, sacrum, upper limbs, scapula). Indications for immediate treatment include the following: (a) severe pain in pagetic areas; (b) compression of medulla, cauda equina, or auditory nerve with neurologic deficit; (c) high-output cardiac failure; (d) hypercalcemia secondary to immobilization; (e) marked radiographic lytic lesions in long bones and skull representing a risk for fracture or brain trauma; (f) multiple fractures; (g) prevention of disfigurement when the skull is extensively involved; (h) recurrent renal calculi secondary to hypercalciuria; and (i) severe

hyperuricemia and gout. Prophylactic therapy is indicated when orthopedic surgery is planned in an involved area, and when disease is located in an area (e.g., base of skull, spine, long bones of lower extremity, hip, or knee) where progress is likely to cause a complication. Standard courses of therapy are specified, but any sign of clinical or biochemical relapse (e.g., pain, neurologic deficit, or biochemical marker >20% to 30% above normal) is an indication for repeated treatment.

Bisphosphonates, which include alendronate, risedronate, pamidronate, and etidronate, are the treatment of choice for the vast majority of patients with Paget's disease. The second-generation drugs (e.g., alendronate, risedronate) are particularly effective. After absorption, they bind primarily to bone and may persist there for months to years, which perhaps accounts for their prolonged effects long after therapy is discontinued. They markedly decrease bone turnover by inhibiting osteoclastic bone resorption. First-generation biphosphonates (e.g.,etidronate) also impair bone mineralization, a distinct disadvantage. All decrease the number of osteoclasts and induce osteoclast apoptosis. The deposition of new bone proceeds in lamellar fashion rather than in the woven pattern characteristic of Paget's disease. Patients with moderate disease respond almost completely. Bone pain decreases and neurologic deficits lessen. The alkaline phosphatase level returns toward normal, and radionuclide uptake on bone scan decreases markedly. Hearing loss may not improve, but it ceases to worsen. Bony films may show some repair of lytic lesions. By turning off bone resorption, the most potent bisphosphonates may lower serum calcium, so that calcium and vitamin D supplementation becomes necessary to prevent secondary hyperparathyroidism from developing.

Alendronate is among the most effective of the available orally active bisphosphonates approved by the Food and Drug Administration. When given in full doses (40 mg/d), this second-generation bisphosphonate normalizes the alkaline phosphatase level in about half of cases and produces an overall mean reduction in the alkaline phosphatase level that approaches 75%, so that this agent is superior to etidronate and calcitonin and equal to IV pamidronate in effectiveness. Its main drawback is that is causes gastroesophageal mucosal injury that can result in ulcer; this adverse effect can be minimized by taking alendronate with a full 8-oz glass of water and remaining upright for at least 30 minutes. Because food nullifies absorption, alendronate must be taken on an empty stomach. A standard recommended course of treatment is 6 months; treatment is restarted if a relapse occurs. The remissions achieved can last from 6 months to several years. Many patients either experience a prolonged remission after a single course of therapy or respond well to repeated treatment. The remainder, who manifest more severe disease, may relapse more quickly.

Risedronate is among the latest of the second-generation bisphosphonates approved by the Food and Drug Administration. Its efficacy is similar to that reported for alendronate (73% of patients manifest biochemical remission at 6 months, and 53% at 18 months), although no direct comparison studies have been performed. The risk for gastrointestinal mucosal injury is similar to that for alendronate, so that similar precautions with use must be taken. About 10% experience flulike symptoms. The recommended duration of therapy is only 2 months; in comparison with alendronate, the cost of a course of treatment is about 10% less (i.e., the cost per tablet is much higher, but the total cost for a standard course of therapy is reduced).

Pamidronate is too injurious to the gastroesophageal mucosa for oral use to be possible, but the efficacy of IV therapy is similar to that of oral alendronate. Flulike symptoms are a common accompaniment. Pamidronate is used mostly in hospital settings when Paget's disease is complicated by important neurologic deficits, but it may also be a reasonable option when compliance with long-term oral therapy is a concern. The standard dose is 30 mg/d for 3 days. The mean duration of remission achieved is about 14 months. The inhibition of bone resorption can be sufficiently marked to lower serum calcium. Calcium and vitamin D supplementation is required to limit the risk for hypocalcemia, which can trigger the reactive secretion of parathyroid hormone. Bone mineralization is not impaired unless the cumulative dose exceeds 180 mg.

Etidronate was the first of the orally effective bisphosphonates, providing therapy that was relatively well tolerated except for some mild diarrhea. Although still available, it is less effective than alendronate or risedronate and less desirable because it can impair bone mineralization. Consequently, it is not the bisphosphonate of first choice. Patients who relapse rapidly after etidronate tend to become resistant to repeated treatment. Prolonged continuous therapy or higher doses (10 to 20 mg/kg per day) induce a mineralization defect that may lead to increased fracture rates in areas of lytic bone and a worsening bone pain. Thus, etidronate should not be used for more than 6 months consecutively, nor at a dose greater than 5 mg/kg per day. The newer bisphosphonates are more effective and do not produce mineralization defects.

Calcitonin. Before the advent of the bisphosphonates, calcitonin was the only available treatment capable of inhibiting osteoclastic activity. Biochemical and clinical remissions are achieved in one third of patients, improvement is noted in another third, and the response is minimal or unsustained in the balance of cases. Urinary hydroxyproline starts to decline within a few days of onset of therapy; after a few weeks, a reduction in alkaline phosphatase and then clinical improvement are noted. Calcitonin is used primarily in settings in which second-generation bisphosphonates are not available or cannot be used. For example, it can be given in conjunction with a slower-acting first-generation bisphosphonate, such as etidronate, to control bone pain until the effects of the latter take hold.

Synthetic salmon and human calcitonin preparations are commercially available. The salmon calcitonin preparation is the less expensive, and it differs by just one amino acid from human calcitonin. Although up to 50% of patients manifest neutralizing antibodies to synthetic salmon calcitonin, the risk for clinically important inactivation is small. Control can be reestablished by switching to human calcitonin.

The major disadvantages of calcitonin are nausea (in some patients), flushing, cost (two to three times that of bisphosphonate therapy), and the need for parenteral administration. A nasally absorbed preparation is available but is less effective and not approved by the Food and Drug Administration for use in Paget's disease. Not only is therapy expensive; it also requires patient education and the ability to learn self-injection techniques. The calcitonin dosage may be reduced when the disease is in remission. Current data suggest that a low dose needs to be continued indefinitely to prevent relapse.

Cytotoxic Agents. *Plicamycin* (formerly *mithramycin*) and *dactinomycin* are cytotoxic agents that potently suppress bone resorption. They are administered IV to patients with serious complications of Paget's disease, such as severe high-output heart failure or hypercalcemic crisis. Hospitalization and consultation are required for proper use because of the risks for acute (although reversible) renal, hepatic, and hematologic toxicities. Thrombocytopenia can be particularly severe. These agents are rarely used at present because of the availability of less toxic agents.

Surgery. Neurosurgical intervention is necessary in patients with spinal cord or nerve root compression syndromes. Orthopedic procedures such as total hip replacement and tibial or femoral osteotomy may help to restore mobility.

Monitoring Therapy. Factors found to predict the duration of remission include initial values for biochemical markers, the lowest posttreatment levels attained, and the speed of the biochemical response to the first course of therapy. These findings argue for regular monitoring of the serum *alkaline phosphatase* level, supplemented only if necessary by monitoring of the urinary *hydroxyproline* (which costs about 100 times more to perform). Two baseline alkaline phosphatase measurements should be obtained before therapy is started, followed by monthly determinations during treatment until remission is achieved. Skeletal *radiographic films* are also helpful to have at the commencement of therapy. They are not repeated routinely except when the base of the skull or a long bone of the lower extremity is involved, where disease progression can be dangerous. The technetium *bone scan* provides an alternative baseline measure. Once remission is achieved, follow-up measurement of the alkaline phosphatase level is indicated every 6 months. Patients with bone or joint pain or minor neurologic deficits benefit from an office check every 3 months while they remain symptomatic.

PATIENT EDUCATION AND INDICATIONS FOR REFERRAL

Patients should be instructed to drink at least 2 L of liquid daily, especially if they are unable to keep active, because immobilization and dehydration can precipitate hypercalcemia and renal stone formation. Patients who are candidates for calcitonin therapy require detailed teaching by a nurse in the techniques of SQ injection. Confirmation of the proper technique should be obtained before self-administration is prescribed unless another household member is going to be administering the medication.

Hospital admission and prompt neurosurgical consultation are warranted in patients who have evidence of nerve or cord compression. Admission is also indicated for severe hypercalcemia. Orthopedic surgical consultation is indicated for the person severely limited by pagetic degenerative joint disease of the hip or knee. Consultation with an endocrinologist or rheumatologist is required when initiation of specific therapy is being considered for an asymptomatic patient with radiologic or biochemical evidence of advancing disease. Referral is beneficial when standard courses of etidronate and calcitonin fail to achieve remission and when relapse occurs.

TREATMENT RECOMMENDATIONS

- Follow asymptomatic patients yearly and expectantly and as long as they have no involvement of the base of the skull, spine, hip, knee, or long bones of the

lower extremity; at annual visits, assess clinically and obtain an alkaline phosphatase determination.

- For those with mild to moderate pain caused by localized bony involvement or secondary degenerative joint disease, prescribe acetaminophen (e.g., 300 mg four times daily), aspirin (325 mg three times daily), or another NSAID (e.g., 400 mg of ibuprofen up to three times daily as needed or 500 mg of naproxen up to twice daily as needed) for the short-term relief of symptoms.
- For all symptomatic patients and for those with asymptomatic disease who have bony involvement in a potentially critical area (base of the skull, spine, hip, knee, or long bone of the lower extremity), obtain baseline plain x-ray films and measurements of alkaline phosphatase and urinary hydroxyproline; then begin oral bisphosphonate therapy with a second-generation preparation (e.g., 40 mg of alendronate per day or 30 mg of risedronate per day). Specify that each dose be taken half an hour before breakfast on an empty stomach with at least 8 oz of water and without lying down.
- Continue bisphosphonate therapy for the specified standard course of treatment (e.g., 6 months for alendronate, 2 months for risedronate) or until clinical and biochemical remissions are achieved. Monitor the alkaline phosphatase monthly until remission is achieved, then every 6 months. Consider reinstituting therapy if symptoms recur or if the alkaline phosphatase level rises to 20% to 30% above the upper limit of normal.
- Consider IV pamidronate (30 mg/d) for patients with severe disease, especially those ill enough to require hospitalization.
- Consider parenteral calcitonin (100 MRC units given SQ daily) as a means of providing short-term relief for very symptomatic patients while they are waiting for bisphosphonate therapy to take effect, especially if etidronate is being used. Once clinical and biochemical remissions have been achieved, reduce the dose to 50 MRC units and continue therapy three times a week.
- Obtain two baseline measurements of the alkaline phosphatase level and a baseline skeletal roentgenogram or bone scan before therapy is started. Follow the serum alkaline phosphatase level at monthly intervals during therapy. Also monitor the serum calcium level at the outset. Routine repetition of radiologic procedures is unwarranted, but repeating radiography periodically may be helpful if the patient has a high-risk lesion (e.g., base of skull, long bone of lower extremity). If fracture is suspected, another film is essential.
- Advise the patient to avoid immobilization and dehydration. Prescribe at least 2 L of liquid per day, especially if the patient is inactive. Prescribe a total daily calcium intake of 1.5 to 2.0 g and 800 IU of vitamin D daily if the patient is on parenteral or second-generation bisphosphonate therapy. Monitor the serum calcium level if the adequacy of calcium intake is a concern.

CHAPTER 163 APPROACH TO THE PATIENT WITH RAYNAUD'S PHENOMENON

Raynaud's phenomenon is strongly suggested when patients report bilateral blanching and discomfort in the fingers in response to cold or stress, followed by purplish discoloration and reactive erythema. For some, it is an isolated problem; for others, it may represent the first manifestation of connective tissue disease, arterial occlusion, or a hematologic problem. The primary physician needs to be able to determine what the chances are of underlying disease being present or developing, how to perform the initial workup, and how to provide symptomatic relief.

PATHOPHYSIOLOGY AND CLINICAL PRESENTATION

Alteration in dermal blood flow is a basic mechanism of thermoregulation and is also a common response to stress-induced catecholamine release. In patients with Raynaud's phenomenon, this vascular reactivity is exaggerated. It may be functional (secondary to *vasospasm*), anatomic (secondary to *arterial occlusive disease*), or rheologic (secondary to *alterations in blood viscosity or red cell deformability*). *Platelet activation* appears to play a role in patients with abnormal vascular anatomy. In many instances, the pathophysiology is multifactorial. The characteristic clinical sequence begins with a rapid onset of digital blanching (vasospastic phase), which is followed by cyanosis (venospastic phase). It ends with the restoration of flow and redness (reactive hyperemia).

Clinically, Raynaud's phenomenon is classified as "primary" or idiopathic (Raynaud's disease) if no evidence of an associated condition can be found and "secondary" if an associated condition is present. Some have objected to this designation because secondary causes (e.g., connective tissue disease) may not become clinically evident for years.

Primary Raynaud's Phenomenon: Raynaud's Disease. Patients with truly idiopathic disease appear to experience excessive vasospasm, with mild symptoms often precipitated by emotional stress. Peripheral adrenergic tone is especially high. The condition is most common in women, with onset often at menarche. Attacks may be frequent (several times daily), mild, and precipitated by emotional stress, and they may affect persons with other vasomotor problems (migraine, livedo reticularis). The fingers show no edema, nail bed erythema, or ischemic changes. The prognosis is excellent in terms of ischemic injury.

A pathophysiologic relative of primary disease is is drug-induced disease. *Vasoactive drugs* used to treat migraine (b-blockers, ergotamine, methysergide) have all been implicated, as has *migraine* itself. Whether drugs can cause the problem in the absence of an underlying vasomotor disorder remains unclear.

Secondary Raynaud's Phenomenon: Underlying Disease. In many patients with seemingly isolated Raynaud's phenomenon at the time of their initial presentation, characteristic manifestations of *connective tissue disease* (especially *scleroderma* and *systemic sclerosis*) eventually develop, although sometimes not for several years. In some patients, subtle manifestations of connective tissue disease are already evident, including mild sclerodactyly, early calcinosis, telangiectasia, and presence of antinuclear antibodies. In others, they are not, but an abnormal nail fold capillary pattern is especially predictive. In comparison with primary disease, secondary Raynaud's phenomenon affects men as well as women and tends to appear later (patients in their midtwenties or older). The episodes are more severe and less likely to be precipitated by emotional stress. Loss of finger pulp and skin ulcers as a consequence of ischemia may be evident.

The chances of eventual manifestation of frank connective tissue disease (almost always systemic sclerosis) are small and likely to be much less than the reported 12.6% or 3.2/100 patient-years derived from metaanalysis of referral-based studies. The mean onset is almost 3 years from the time of diagnosis and more than 10 years after the onset of symptoms. At the time of initial presentation, the best predictors for the development of systemic sclerosis include abnormal nail bed capillary pattern, presence of antinuclear antibodies, presence of skin lesions, abnormal pulmonary function, and esophageal dysmotility. Although predictive, none of these factors has a positive predictive value in excess of 50%.

Raynaud's phenomenon is especially prevalent in patients with systemic sclerosis, occurring in more than 90% of cases. In such patients, structural narrowing of digital vessels iscaused by intimal fibrosis. Abnormal vascular reactivity and platelet activation have been demonstrated. Symptoms may be especially severe, and the risk for digital ischemic injury is substantial. The compromise to digital blood flow is considerably less in patients with scleroderma.

A host of other conditions can cause vasoocclusive Raynaud's phenomenon, including *atherosclerotic disease*, occupational *vibratory injury* (jackhammer operators, welders, sheet-metal workers), and *neurovascular compression* syndromes (thoracic outlet, carpal tunnel). The clinical course is a function of the underlying disease, a number of which are reversible.

DIFFERENTIAL DIAGNOSIS

The causes of Raynaud's phenomenon can be grouped according to the predominant pathophysiologic mechanism (Table 163.1), although, as noted above, multiple mechanisms may be operative. About 20% of patients presenting initially with idiopathic or primary Raynaud's phenomenon prove after 2 to 3 years to have underlying connective tissue disease.

Vasospastic Disease
  Primary
  Drug-induced (β-blockers, ergot, methysergide)
  Migraine
Arterial Occlusive Disease (+/− platelet activation)
  Scleroderma
  Systemic sclerosis
  Systemic lupus erythematosus
  Occupational trauma (jackhammer operator)
  Atherosclerotic disease
  Compression (thoracic outlet, carpal tunnel)
Hemorrheologic Disease
  Paraproteinemia
  Polycythemia
  Cryoproteinemia

Table 163.1. Important Causes of Raynaud's Phenomenon

WORKUP

History and Physical Examination

Confirming the Diagnosis. The diagnosis of Raynaud's phenomenon is a clinical one, based on a history or direct observation of the characteristic changes in skin color in response to cold or stress. If the diagnosis is uncertain, one can test the patient's response to cold by immersing the hands in ice water and observing for blanching, cyanosis, and reactive hyperemia. At least two of the three characteristic skin changes must be present for the diagnosis to be confirmed.

Differentiating Primary from Secondary Disease. Because Raynaud's phenomenon is often the presenting manifestation of an underlying disease, it is important to consider such conditions in the early phase of the evaluation. Screening by history and physical examination can facilitate the selection of patients who require more detailed testing. The differentiation is facilitated by attention to age at onset, gender, frequency and severity of attacks, distribution of skin changes, ischemic skin

changes, manifestations of connective tissue disease, precipitating factors, associated digital swelling, and other vasomotor phenomena, such as migraine and livedo reticularis.

Primary disease is suggested by onset in the teens, female sex, occurrence of multiple mild attacks every day, symmetric involvement, precipitation of attacks by stress, normal skin except for livedo reticularis, and migraine headaches. Secondary disease should be suspected in a male patient or in a female patient with onset in the midtwenties or later. Other clues include moderate to severe attacks not necessarily occurring every day, asymmetric presentation triggered predominantly by cold, and associated finger swelling, ischemic skin ulcers, or loss of fingertip pulp.

Further Evaluation of Suspected Secondary Disease. Patients with a presentation suggestive of secondary disease should be checked carefully for additional symptoms of connective tissue disease, such as skin rash, morning stiffness, arthralgias, joint swelling, fatigue, and fever (see Chapter 146), and of peripheral vascular disease, such as claudication, angina, and leg ulceration (see Chapter 23). Although less common, symptoms of thoracic outlet and carpal tunnel syndromes (see Chapter 167) and polycythemia (see Chapter 80) should also be sought if the diagnosis of underlying disease remains unclear. The occupational history is noted for any vibratory injury. Medications should be reviewed, and any effects of b-blockers, ergotamine, methysergide, or calcium channel blockers on symptoms noted.

The physical examination should include a thorough check for manifestations of connective tissue disease (e.g., malar flush, sclerodactyly, petechial rash, telangiectasia, calcinosis, joint redness, swelling, and effusion). The hand and arm pulses are carefully palpated, and capillary filling is noted in the digits. The fingertips are felt for loss of pulp, which is indicative of ischemia, and the skin is observed for ischemic changes. The *nail fold capillary pattern* should be examined carefully because an abnormal pattern is a prime predictor of systemic sclerosis. If available, a wide-field microscope provides excellent views of the capillary bed, but the magnification afforded by the more readily accessible hand-held ophthalmoscope may suffice. One looks at the pattern of capillary loops; asymmetry indicates dropout of capillary loops, which is characteristic and predictive of systemic sclerosis.

Laboratory Testing

Patients judged to have definite primary disease on the basis of the careful history and physical examination noted above require no additional evaluation. An antinuclear antibody test can be ordered to rule out further the risk for underlying connective tissue disease (negative predictive value of 93%), but a positive test result in the absence of other suggestive findings has a very low positive predictive value and may raise concern inappropriately. Consequently, only those with clinical evidence suggestive of connective tissue disease should be subjected to *antinuclear antibody* testing. For patients who test positive for antinuclear antibodies, an *anticentromere antibody* determination can help predict the risk for development of limited systemic sclerosis (i.e., scleroderma), but the test is expensive, and its contribution to overall clinical decision making needs to be considered before it is ordered.

Noninvasive studies of arterial flow (*plethysmography, Doppler ultrasonography*) can confirm anatomic vascular compromise; however, similar information can often be obtained bya careful history and physical examination, and test data usually do not help differentiate among anatomic causes of the disease.

A *complete blood cell count* and *serum globulin* determination should suffice to screen for common hematologic problems; *immunoelectrophoresis* is reserved for patients in whom myeloma is suspected (elderly, markedly elevated globulin, anemia; see Chapter 79). A *cryoprotein* determination is indicated if other manifestations suggestive of cryoglobulinemia (arthralgias, purpura, proteinuria) are present. A cold agglutinin test is worth considering for patients with anemia and splenomegaly.

MANAGEMENT

Prevention. Regardless of the underlying cause, keeping the trunk and the extremities warm on cold days is essential. Of particular importance is *truncal warmth* because any threat to the maintenance of core body temperature is a potent stimulus to reflex peripheral vasoconstriction. *Smoking cessation* and elimination of passive smoking are essential. Any drugs found to trigger episodes should be stopped or cut back.

Occupational precipitants, such as repetitive activity that leads to carpal tunnel syndrome or vibratory injury, should be reduced or eliminated. Although *pneumatic tool* operation (e.g., jackhammer) is the classic occupational association, smaller and less inertial tools that produce *high-frequency vibrations* have been found to be even more likely to cause vascular injury. Working on a vibrating or rotating tool (such as those used by welders, sheet-metal workers, carpenters, and painters) for as little as 1 to 2 hours per day can inflict vascular damage. Prevention, by limiting the number of hours such equipment is used, is the best approach but is often not feasible. Alternatively, at the first sign of symptoms, use should be markedly reduced or eliminated. Antivibration gloves and coated tool handles have not proved sufficient.

Symptomatic Relief. Because Raynaud's phenomenon has a strong vasoconstrictive component, it follows that vasodilators should provide symptomatic relief. *Calcium channel blockers* have proved symptomatically useful for patients with primary disease and for many with secondary disease. Their mechanism of action includes vasodilation plus some platelet inhibition. The resultant improvement in perfusion sometimes helps speed the healing of skin ulcers. *Nifedipine* and its congeners (*nicardipine, isradipine*, and *felodipine*) are the most potent vasodilators. However, they can produce reflex tachycardia and peripheral edema secondary to their venodilator effects; their use in persons with concurrent coronary disease or heart failure can be problematic (see Chapter 30 and Chapter 32). Occasionally, headache and flushing may be troublesome, and esophageal function may worsen in patients with scleroderma. Sustained-release preparations are convenient to use and reasonably well tolerated. There is no evidence to suggest that vasodilator therapy alters the natural history of the underlying disease.

a-*Blocker therapy* is also capable of providing symptomatic relief. The newer preparations such as *doxazocin* are longer-acting and appear less likely to cause first-dose syncope than older preparations such as prasozon. Postural light-headedness is still a problem, especially as the dosage is increased to above 2 to 3 mg/d.

Patients with vasospastic disease accompanied by substantial endothelial injury and platelet activation (e.g., those with systemic sclerosis) may not obtain adequate symptomatic relief with the sole use of vasodilator drugs. Painful episodes may persist, and ischemic skin ulcers may fail to heal. The addition of *aspirin* or *dipyridamole* to the treatment program has helped to heal some ulcers but has not reduced vasospastic symptoms. *Fish oil supplements* rich in omega-3 fatty acids can impair platelet activation and stimulate vasodilation through prostacyclin synthesis. Paradoxically, the best responses have been noted in patients with primary disease. IV *prostacyclin* and *iloprost* (a prostacylin analogue) are being studied; they are both vasodilators and inhibitors of platelet activation. Early results are encouraging, with effects lasting up to 3 months after a single 5-day course of therapy.

Sympathectomy has been used as a measure of last resort. Patients who respond to temporary ganglionic blockade with an injected anesthetic are the best candidates for sympathectomy.

PATIENT EDUCATION AND INDICATIONS FOR REFERRAL

The major elements of patient education are preventive (see above). For patients with occupationally induced disease, a change of job or job activities must be weighed against the risk for worsening of vascular compromise. Patients with strong features of primary disease can be reassured that the risk for underlying illness is low and that their prognosis is excellent. Those with features of secondary disease associated with a risk for development of connective tissue disease need to understand their risk, but also that it may be many years before other disease manifestations appear, if they develop at all.

Referral is indicated for those with refractory symptoms, especially if accompanied by signs of ischemia.

CHAPTER 164 PREVENTION AND MANAGEMENT OF OSTEOPOROSIS

INTRODUCTION

Osteoporotic fractures, particularly in aging women, represent a major health problem in industrialized nations. In the United States, more than 150,000 hip fractures occur annually in women over the age of 65, with 15% to 25% of these women experiencing excess mortality or needing long-term nursing home care. Current expenditures for hip fractures approach $10 billion yearly. Osteoporotic vertebral crush fractures, manifested by back pain, loss of height, and decreased ambulation, are present in 5% to 10% of women by age 60 and in 40% by age 80. The pathophysiologic mechanisms for postmenopausal osteoporosis are imperfectly understood, but the means to ensure maximal skeletal growth and strength, prevent loss of bone mass, and noninvasively evaluate bone mass are now available.

The primary care physician should educate women about the prevention of osteoporosis and the development of personalized strategies for maximal skeletal accretion and preservation. These tasks are facilitated by knowing how to identify high-risk patients and screen them (see Chapter 144).

Although less well appreciated, osteoporosis also affects older men, with about 30 percent of all osteoporotic fractures occurring in men. Concern about osteoporosis and attention to its detection and treatment should extend beyond menopausal women.	**Updated: 10/06/03**

PATHOPHYSIOLOGY AND CLINICAL PRESENTATION

Osteoporosis is a reduction in the mass of bone per unit volume. The World Health Organization diagnostic criterion for osteoporosis is a bone mineral density (BMD) that is 2.5 or more standard deviations below the mean for a healthy young person of the same sex (*T-score of -2.5 or less*). Because the strength of a bone is proportional to its density, the mechanical support of the skeleton is affected as bone mass declines. In contrast to osteoporosis, osteomalacia is characterized by a defect in the mineralization of the organic phase of bone.

Increased Osteoclastic Bone Resorption and Reduced New Bone Formation. The resorption and formation of bone is a continuous process throughout life. Under steady-state physiologic circumstances, the rates of these processes are equal and coupled. The explanations for the uncoupling of bone resorption and formation and the development of osteoporosis remain speculative. Estrogen receptors are present on osteoblasts, the cells that synthesize bone matrix proteins. Communication between osteoblasts and osteoclasts (which resorb bone) occurs, but the precise mediators have not been fully identified. Cytokines in bone (e.g., interleukin-1, tumor growth factor) and skeletal growth factors may act synergistically and serve as mediators of bone formation and resorption.

With the onset of estrogen deficiency, osteoclastic bone resorption increases. Later in life, new bone formation is impaired. Fractional intestinal *absorption of calcium* in elderly persons is *decreased*. This decline in intestinal calcium absorption appears to be caused by a *decrease in the formation of 1,25-dihydroxyvitamin D*, the active form of vitamin D.

Risk Factors. Attention to risk factors is essential in estimating the probability of osteoporosis and risk for fracture, but the predictive value of most risk factors is not great. Those that seem to confer the greatest risk include *advanced age, low body mass index (<22 kg/m²)*, *maternal fracture*, and *current smoking*, but the strength of these associations is only moderate. Physical *inactivity* can lead to decreased bone mass, as can intense exercise that results in *amenorrhea*. A poor *lifetime intake of calcium* is a weak risk factor. Fair skin and excess alcohol consumption have been suspected but not confirmed. For osteoporotic *hip* fracture, additional risk factors are related to falling (e.g., *physical inactivity*, use of long-acting *benzodiazepines, impaired vision*).

Conversely, increased bone mass correlates with *increased weight, grip strength*, and *estrogen use for longer than 2 years*. Height and increased age at onset of menopause are also moderate predictors of increased bone mass. Increase in current calcium intake has only a minor effect on bone mass. Maintaining body weight, walking for exercise, minimizing caffeine use, and correcting impaired vision reduce the risk for hip fracture.

Medical conditions enhancing osteoporotic risk include *Cushing's syndrome*, exogenous *glucocorticoid* administration, prolonged *heparin* therapy, *thyrotoxicosis, hypogonadism, hyperprolactinemia, anorexia nervosa*, and *hyperparathyroidism*. However, these diseases account for a small percentage of cases of osteoporosis.

The strongest measurable determinant of risk is the *BMD*; it is necessary to measure it directly (see below and Chapter 144). The risk for osteoporotic fracture increases twofold to fourfold for every standard deviation of reduction in BMD. However, the BMD is not the only determinant of bone fragility and is an imperfect predictor of fracture risk in an individual person. A prior *history of fracture* is probably the strongest indicator of bone fragility and future fracture risk.

Clinical Presentation. Skeletal mass is usually maximal by age 35 and declines in women after age 40 and in men after age 50 when the rate of new bone formation does not equal the rate of bone resorption. The rate of decline in skeletal mass is most rapid in women *within 2 years of menopause*. The greatest loss occurs in trabecular bone in the *femoral neck* and *lumbar vertebrae*, sites where future fracture is likely.

The progressive decline in skeletal mass (which may approach 50%) becomes clinically manifest when fractures are sustained spontaneously or after minimal trauma. A *loss of height* and developing *kyphosis* generally indicate vertebral compression fracture. Fractures most commonly occur in the sacral and lumbar vertebrae, hip, humerus, and wrist. The clinical course and frequency of fractures in individual patients cannot be predicted.

Osteopenia is a radiologic term that indicates a reduced amount of bone and encompasses both osteomalacia and osteoporosis. The characteristic radiographic finding in osteoporosis is the loss of horizontal vertebral trabeculae, which accentuates the end plates and results in biconcave "codfish" vertebrae. Pseudofractures, generally occurring in weight-bearing long bones, are pathognomonic for osteomalacia.

The laboratory features of postmenopausal osteoporosis include normal serum levels of calcium, phosphate, vitamin D, parathyroid hormone (PTH), and alkaline phosphatase, although the alkaline phosphatase may be elevated in the context of a healing fracture.	**Updated: 10/07/03**

WORKUP

Measurement of Bone Mineral Density. Because bone density is the principal determinant of fracture risk, its measurement is essential in diagnosis and decision making. *Dual-energy x-ray absorptiometry (DEXA)* is considered by most to be the technique of choice, representing the best combination of sensitivity, technical simplicity, reproducibility, cost, and minimization of radiation exposure. Measurement of forearm BMD provides an inexpensive approach suitable for mass screening, but separate BMD determinations in the hip and spine provide the best assessments of risk for the individual patient. The degree of osteoporotic change may be different in the hip and spine, so that separate BMD determinations are necessary. These tests are safe and acceptable to patients, and they have predictive value for the development of fractures.

The BMD measurement is expressed as the number of standard deviations from the mean for normal young adults of the same sex (*T-score*) and as the number of standard deviations from the mean for persons of the same sex and age (*Z-score*). The World Health Organization diagnostic criterion for *osteoporosis* is a *T-score below -2.5*. *Osteopenia* is defined as a *T-score between -1.0 and -2.5*. The finding of a *Z-score below -1.5* suggests a *secondary cause* of osteoporosis. The risk for osteoporotic fracture increases twofold to fourfold for every standard deviation of reduction in BMD.

If BMD measurements will affect clinical decision making, then testing should be performed. A perimenopausal woman already committed to hormonal replacement therapy need not be studied, but the untreated, newly menopausal woman at above-average risk for osteoporosis should be tested if the finding of a BMD below

average would lead to the initiation of prophylactic therapy. Additionally, patients being treated for osteoporosis may require BMD measurements to determine therapeutic efficacy. Results of routine *chemistries* are normal and of little use.

Workup for Osteomalacia and Assessment for Other Secondary Causes of Osteopenia. When osteopenia is encountered radiologically or a hip fracture is noted, osteomalacia should be considered. Osteomalacia is defined as the inadequate deposition of calcium and phosphorus in bone tissue matrix. It is found in 10% to 15% of patients with hip fracture. *Vitamin D deficiency* is an important cause of osteomalacia in home-bound elderly persons, who are unlikely to eat dairy products or go out in the sun. Other causes include *impaired vitamin D metabolism, malabsorption, systemic acidosis*, and *phosphate depletion.* Osteomalacia should be suspected in patients with hypocalcemia or hypophosphatemia. Measurement of the urine pH and serum levels of 25-hydroxyvitamin D, phosphate, calcium, and bicarbonate help detect the cause. If the 24-hour urinary calcium is above 100 mg, osteomalacia is unlikely.

In the absence of pseudofractures on x-ray films, it is not possible to distinguish osteoporosis from osteomalacia radiographically. A bone biopsy is necessary for the definitive diagnosis of osteomalacia, but this is usually reserved for patients undergoing orthopedic procedures. Osteomalacia responds dramatically to treatment with *dietary vitamin D* and *calcium* and *phosphate supplements*.

The finding on DEXA determination of a Z-score below -1.5 suggests a secondary cause of osteopenia. In addition to the causes of osteomalacia noted above, other causes to be considered should include hyperthyroidism, hyperparathyroidism, anorexia nervosa, hyperprolactinemia, malignancy (e.g., myeloma, lymphoma), pernicious anemia, disease of the gastrointestinal tract (e.g., inflammatory bowel disease, chronic liver disease), rheumatoid arthritis, ankylosing spondylitis, and medications (e.g., excessive thyroid hormone, anticonvulsants, lithium, tamoxifen). Workup should be specific to the conditions suggested by the history and physical examination. In the absence of clinical clues, one might consider ordering a complete blood cell count and measurement of serum calcium and thyrotropin (TSH).

PRINCIPLES OF THERAPY

Prevention and Treatment of Osteoporosis

The goal is to reduce the risk for fracture by reducing the loss of bone mass. Prevention is more effective than treating established disease, but both require attention. Available therapies include estrogen replacement (in combination with progesterone), selective estrogen receptor modulators (e.g., raloxifene), calcium supplementation, weight-bearing exercise, vitamin D, and bisphosphonates. If a fracture has occurred, symptomatic relief and aggressive therapy to halt further bone loss are indicated. PTH and calcitonin are options in this setting. | **Updated: 10/06/03**

From a skeletal perspective, patients with known risk factors for osteoporosis (e.g., maternal fracture, current smoker, small frame, lack of exercise, low calcium intake) are probably among the better candidates for prophylactic therapy, but these factors are not as predictive as bone density. Menopausal women who have an increased rate of decline in bone mass or a bone mass between 1.0 and 2.5 standard deviations below the mean for young adult women (i.e., a T-score between -1.0 and -2.5) should be considered for prophylactic therapy. When osteoporosis is clinically manifested by fractures or appears radiographically as osteopenia, indicating at least a 30% to 40% loss of bone mass, risk of further fracture can be reduced by treatment. | **Updated: 10/06/03**

Estrogen. Hormone replacement therapy with estrogen in combination with progesterone (HRT) had been the treatment of choice for the prevention of postmenopausal osteoporosis, but emerging data from major randomized trials (e.g., the Women's Health Initiative, HERS) reveal an unfavorable risk-benefit ratio when other important disease outcomes (e.g., breast cancer, cardiovascular disease) are factored into the analysis. Estrogen stops bone loss and can produce a modest degree of skeletal mineral accretion (on the order of 2% to 4%). Observational studies have consistently noted a 35% to 50% reduction in hip, wrist, and vertebral fractures in women who have used estrogen for at least 5 years after menopause. The risk for vertebral fracture can be reduced by up to 80%. Estrogen treatment needs to be long-term, if not indefinite, for its beneficial effect on bone to last. | **Updated: 10/06/03**

Preparations. Natural estrogens (estradiol, conjugated estrogens) are preferred for replacement therapy over the synthetic estrogens (ethinyl estradiol) because they are shorter-acting and less likely to cause adverse effects. *Estradiol* is the principal estrogen secreted by the ovary. It is available as *17b-estradiol* by *transdermal patch* or in a micronized *oral* preparation. The most widely used natural oral formulation, *conjugated estrogen*, is prepared from the urine of pregnant mares (hence the "marin" in the brand name). Oral preparations undergo first-pass metabolism by the liver, which converts about half of estradiol to estrone. Transdermal 17b-estradiol does not undergo hepatic first-pass metabolism, so that its duration of action is prolonged but its effect on lipid metabolism is markedly reduced.

New *synthetic conjugated estrogens*, A (Cenestin) are coming to market. They are approved only for the treatment of vasomotor symptoms, not for osteoporosis. *Phytoestrogens* (isoflavones) present in soy protein are currently very popular among women as a nonprescription or "natural estrogen" treatment for hot flashes; the estrogenic effect on bone afforded by even large quantities of dietary isoflavones appears too small to be of significance. Synthetic preparations of phytoestrogens are available, but data regarding their effect on bone are too limited at present for their role in the treatment of osteoporosis to be assessed.

Estrogen is given with *progesterone* in women with an intact uterus to avoid precipitating endometrial cancer (see below). The addition of progesterone does not cancel the positive effect of estrogen on osteoporotic bone or LDL cholesterol, but it does increase other risks (see below). | **Updated: 10/06/03**

Dosage and Administration. The daily dose necessary to prevent bone loss is 0.625 mg of conjugated estrogen, 1.0 mg of estradiol, or 0.05 mg of transcutaneous estrogen. Low-dose conjugated estrogen therapy (0.3 mg/d) has been found as effective as standard-dose estrogen therapy in older women (age above 65 years) when taken with calcium and vitamin D.

The estrogen and progesterone can be given cyclically or continuously. Most postmenopausal women prefer to avoid the withdrawal bleeding of cyclic therapy and opt for a *continuous program* (e.g., 0.625 mg of conjugated estrogen per day plus 2.5 to 5.0 mg of medroxyprogesterone per day). At the very onset of menopause, a *cyclic program* (e.g., daily conjugated estrogen for 28 days plus progestin for the first 14 days) may be temporarily preferred because it is less likely to precipitate excessive, unpredictable bleeding (see Chapter 118).

Initiation and Duration of Therapy. The decision to use HRT for prevention or treatment of osteoporosis must include consideration of its increasingly recognized risks, which include increased rates of breast cancer and cardiovascular disease (see below and Chapter 118). If maximum prevention of bone loss is to be achieved, treatment should begin at the onset of menopause and be continued indefinitely. Once established, it is difficult to reverse the significant bone loss that occurs in the first few years of menopause. Estrogen therapy needs to be continued indefinitely because skeletal loss resumes if treatment is halted, and after several years the beneficial effects of estrogen are lost. Patients over the age of 75 not taking estrogen show little or no benefit after as many as 10 to 12 years of estrogen therapy started at the time of menopause. | **Updated: 10/06/03**

Adverse Effects (See also Chapter 118). For the woman with a uterus, one of the most serious adverse effects of unopposed estrogen is a marked increase in the risk for *endometrial cancer*. The risk can be eliminated by the concurrent use of progesterone, which prevents unopposed endometrial stimulation. Risk of breast cancer also increases as does the risk of ovarian cancer. The magnitude of the increase in breast cancer absolute risk from estrogen alone is only a few percentage points, but the relative increase is more alarming to patients (about 35%). Estrogen and progestin use is associated with an even larger increase in breast cancer risk. Risk is a function of duration of therapy and insignificant if HRT is continued for less than 5 years; however, tumor growth can be stimulated by the initiation of estrogen therapy in the presence of an underlying breast cancer (see also Chapter 118 and Chapter 122). The recent realization from major randomized trials that HRT has an adverse effect on cardiovascular outcomes and perhaps dementia has tilted the risk-benefit ratio further against its widespread use. There is no evidence that equivalent doses of "natural" phytoestrogens are any safer than prescription estrogen preparations. | **Updated: 10/06/03**

Patient Selection. The risks of long-term estrogen therapy (which is required for achieving sustained benefit) outweigh the benefits for almost all women, even those at high risk of fracture. The advent of effective safe alternative therapies relegates estrogen to consideration only in persons who require estrogen for another compelling reason (e.g., incapacitating hot flashes). Only after full consideration of risks and benefits should estrogen therapy be prescribed as a means of preventing osteoporosis. The decision to start HRT requires full discussion with the patient not only of the potential skeletal benefit but also of cardiovascular and cancer risks (see Chapter 118). | **Updated: 10/06/03**

Selective Estrogen Receptor Modulators: Raloxifene. These so-called SERMs "designer estrogens" bind to estrogen-receptors and elicit a mix of agonist and antagonist responses that are tissue-dependent. Raloxifene inhibits bone resorption through the same mechanism as estrogen. A modest increase (1% to 2%) in

bone density occurs in the spine and hip, about half the increase achieved with estrogen or alendronate. Reduction in the risk for vertebral fracture is about 50%. The risk for breast cancer is reduced by more than 50%, and raloxifene produces no stimulative effect on the postmenopausal endometrium. At the doses used for osteoporosis, no increase or decrease in the frequency of hot flashes is noted, but LDL cholesterol levels decline. The risk for thrombosis may be modestly increased, about the same as with estrogen. More data on long-term safety and efficacy are needed, but barring any major new findings, raloxifene may prove to be preferable or at least a reasonable alternative to estrogen therapy for the prevention of osteoporosis. The drug is approved by the Food and Drug Administration for the prevention of osteoporosis. Its cost is about two to three times that of estrogen and progestin therapy. *Tamoxifen* is not recommended for postmenopausal osteoporosis because its effect on bone resorption is not well defined and the risks for thrombosis and endometrial cancer are increased.

Calcium. A daily total calcium intake of 1.0 to 1.5 g is needed to help preserve cortical bone mass. Although calcium therapy does not prevent bone loss to the degree that estrogen therapy does, it does represent an essential component of all treatment programs. Its effect on bone loss falls between those of estrogen and placebo. The inadequate dietary calcium intake of most women (about 600 to 800 mg/d) and the declining fractional absorption of calcium associated with aging make it important to ensure a total intake of 1.0 to 1.5 g/d in adolescent and young women and up to 2 g/d in older women. Serious complications such as renal stones or hypercalcemia are extremely uncommon with a daily intake of 1 to 2 g of elemental calcium. **Updated: 10/06/03**

Dietary calcium is readily available, more nutritious, and better absorbed than calcium tablets, and it is less likely to cause kidney stones (possibly by inhibiting oxalate absorption). A cup of skim milk provides 303 mg of calcium; 8 oz of low-fat yogurt provides 345 mg; a serving of canned sardines has 354 mg. Of the supplement preparations, the carbonate salt is the least costly. Chewable preparations are the best-absorbed. Splitting the daily supplement dose facilitates absorption and minimizes gastrointestinal upset. A reasonable supplemental dose of calcium is in the range of 500 to 1,500 mg/d. Larger doses, particularly in conjunction with vitamin D, may predispose the patient to hypercalcemia and hypercalciuric renal stone disease. Taking calcium with meals increases its absorption because of the favorable action of gastric acid. Concern about the solubility and gut absorption of calcium carbonate has led to the marketing of other calcium preparations (citrate, gluconate, lactate). They are often more expensive than calcium carbonate (especially the gluconate) and of little proven advantage.

Vitamin D. The principal effect of vitamin D is on gut absorption of calcium. It also directly affects osteoblasts and osteoclasts. When vitamin D is taken together with calcium, fracture rates are reduced by 30% to 70%. The benefit appears greatest in vitamin D–deficient institutionalized and home-bound elderly persons, but it is also evident among those who are living independently in the community. When vitamin D supplementation is given in conjunction with calcium to otherwise healthy persons over the age of 65 with a low calcium intake, the BMD improves significantly and the risk for nonvertebral osteoporotic fracture is reduced by more than 50%. Daily dose requirements are in the range of 400 to 800 IU, with the higher dose recommended for those who get no exposure to sunlight.

Exercise. An important component of the preventive therapy of osteoporosis is ensuring the maximal development of skeletal mass. The amount of bone accumulated in *premenopausal women* may be critical to the appearance of osteoporosis later in life, as evidenced by the low incidence of osteoporosis in African-American women (and in men), who have a greater skeletal mass than white women. Exercise and physical activity have been shown to increase skeletal mass and increase total body calcium. Physical activity, in conjunction with dietary supplementation of 1,500 mg of calcium and 400 U of vitamin D daily, offers the best hope for increasing skeletal mass during skeletal growth. However, exercise programs so intensive as to induce amenorrhea and estrogen deficiency (e.g., competitive marathon running) may lead to osteoporosis.

In *postmenopausal women*, regular weight-bearing exercise (e.g., walking, low-impact aerobics, weight lifting, tennis) three times per week can substantially retard bone mineral loss (down to 0.5% of the baseline value per year), especially when combined with calcium supplementation. A more ambitious program of formal exercise training (e.g., 50 minutes of walking and jogging three times per week) in combination with calcium supplementation may have even more pronounced effects (e.g., increase in lumbar bone mineral content). Care must be taken to ensure that the exercise program in older women is safe and does not subject the patient to an increased risk for falls or other injuries.

The efficacy of a program of exercise with calcium and vitamin D supplementation suggests that it should be the core of every treatment program, be it for prophylaxis or treatment of osteoporosis. Whether it is sufficient to obviate the need for hormone replacement or other therapies remains to be established, but it can lower the doses of medication required.

Bisphosphonates. These synthetic carbon phosphate compounds, which include alendronate, etidronate, and risedronate, bind avidly to pyrophosphate in bone and inhibit bone resorption by osteoclasts. At full doses, they increase the BMD to at least the same degree as estrogen therapy and decrease the rate of fractures in the spine and hip by 30% to 50%, so that they are very useful for the treatment of established osteoporosis. Their effects are greatest in the setting of low bone density. At low doses, they provide effective prophylaxis against postmenopausal osteoporosis. Second-generation bisphosphonates (e.g., alendronate, risedronate) are more effective than first-generation agents (e.g., etidronate) and are not associated with the risk for demineralization seen when first-generation agents are taken on a daily basis. Their main drawbacks are poor intestinal absorption (uptake almost totally impaired by food intake) and *esophageal irritation and ulceration*. Careful use is essential. They must be taken on an empty stomach with a large volume of water, and the patient must remain in an upright position for a subsequent 30 minutes before food or recumbency is permitted. They should not be given to persons with active upper gastrointestinal disease or achalasia, and they must be used with caution, if at all, by those with a prior history of esophageal reflux or peptic ulceration.

The second-generation bisphosphonates appear to represent a genuine alternative to hormone therapy. Efficacy in long-term, head-to-head comparison study is equivalent to that of estrogen. A unique feature is some residual effect up to 2 years after cessation of treatment, believed to be a consequence of bisphosphonate deposition in and tight bonding to bone mineral. Alendronate and risedronate are approved by the Food and Drug Administration for the prevention and treatment of osteoporosis. These agents have also demonstrated efficacy in the prevention of bone loss and fracture associated with premature menopause, corticosteroid use, and immobilization. Cost is two to three times that of HRT and about the same as that for raloxifene. Myalgias and arthralgias are sometimes reported with use. Data on long-term safety and efficacy should be forthcoming. Once-weekly preparations are available that greatly enhance convenience and compliance. **Updated: 10/06/03**

Parathyroid Hormone Intermittent administration of PTH (either its 1-34 or 1-84 amino-acid preparation) by daily subcutaneous injection can induce anabolic effects on bone, stimulating new bone formation, particularly of trabecular bone, and improving calcium balance while producing chemically and histologically normal bone without hypercalcemia. Bone resorption is also increased, but the overall net effect is increased bone formation. It was hoped that PTH's anabolic effects could be enhanced by combination with bisphosphonate therapy, but results have been disappointing, with inhibition rather than enhancement noted in randomized clinical trials. Because of its high cost and inconvenience, PTH therapy is currently reserved for severe cases (e.g., osteoporotic fracture and T score <-2.5), especially when bisphosphonate therapy has not proven adequate. In this setting, PTH is substituted for bisphosphonate rather than added to it because of the inhibitory effect of bisphosphonate on PTH action. **Updated: 10/04/03**

Calcitonin Daily subcutaneous injections of 100 U of salmon calcitonin or 200 IU of nasally inhaled calcitonin in combination with calcium supplementation will increase the total body calcium in postmenopausal osteoporotic women by several percentage points; this increase presumably reflects an increase in skeletal mass. The risk for vertebral fracture may decline by as much as 40%, but the risk for hip fracture is not reduced, and changes in specific bones are often too small to measure. After a year of use, no further increase in total body calcium is noted, and total body calcium declines at the same rate as in untreated control patients. Moreover, bone loss is not prevented in early menopause. The high cost and minimal sustained benefit of calcitonin make it a poor choice for long-term prophylaxis or treatment of osteoporosis. However, its initially positive effect on the risk for vertebral fracture and its coincident analgesic properties make it potentially useful as short-term therapy in elderly osteoporotic women who have sustained a painful vertebral compression fracture (see below). Nasal administration is the best-tolerated route. **Updated: 10/06/03**

Sodium Fluoride therapy leads to a striking increase in trabecular bone density if given in doses ranging from 40 to 60 mg/d, but cortical bone density decreases, so that skeletal fragility increases. The dense fluorotic bone is abnormal both chemically and on crystallography and has undesirable mechanical properties *in vitro*. More promising results have been associated with long-term low-dose fluoride therapy (20 mg/d given as monofluorophosphate) taken in conjunction with calcium. The rate of vertebral fracture is markedly reduced without the production of any noticeable adverse bony effects. More data are needed. Fluoride is not approved by the Food and Drug Administration for use in osteoporosis.

Follow-up and Monitoring

The risk for sustaining an osteoporotic fracture is related to the severity of bone mineral loss and the chance of falling. Because compliance with therapy is often poor (50% discontinue estrogen therapy within 12 months), return visits at 6- to 12-month intervals to review and reinforce diet and exercise programs and monitor the medical regimen are warranted, especially in women with established osteoporosis. A repeated DEXA scan at 12 to 24 months is indicated to measure the BMD if the

result will be useful for clinical decision making. A lack of improvement in the BMD at the time of the first repeated study may be a sign of poor compliance, but in patients taking bisphosphonate therapy, it should not be an indication to halt or switch treatment because it may also represent a statistical deviation that is likely to be corrected on the next determination. Monitoring serum bone chemistries is of no proven benefit.

Prevention of Falls

Although the prevention and treatment of osteoporosis have been the focus of this chapter, the ultimate objective is to reduce the risk for fracture. Hip fracture in the elderly can be a major source of disability and a potentially life-threatening event. Community survey reveals that about a third of community-dwelling persons over the age of 75 years report at least one recent fall. Often, many factors are involved, such as sedative use, cognitive and visual impairments, gait and balance disturbances, disabled lower extremities, and foot problems. A host of mundane but very important steps help reduce the risk for falling and sustaining a hip fracture; they correlate strongly with outcomes. Included among them are avoidance of long-acting tranquilizer use, treatment of impaired vision, and walking for exercise. Good podiatric care is essential, and physical and occupational therapy can be especially helpful in selected cases. Attention is directed toward any conditions that may impair gait or balance (see Chapter 166). Patients with a neurologic or orthopedic impairment who would benefit from using a cane or walker ought to be taught its proper use, both in the home and outside. Periodically, one should undertake a review of all medications to eliminate or reduce those that can cause postural hypotension (see Chapter 26) or sedation (see Chapter 226, Chapter 227, and Chapter 232).

Attention to the home environment is essential. Elimination of slippery surfaces and obstacle-laden paths, adequate illumination on stairways, installation of handrails in the bathroom, and the provision of seating from which it is possible to arise easily all help to ensure safety. Personal items deserve attention, such as footwear that provides good stance and stability and eyeglass prescriptions that are up to date.

Management of Vertebral Fractures

For patients who have sustained a painful osteoporotic vertebral fracture, periodic bed rest and adequate *analgesics* should be prescribed until the acute pain of the fracture subsides, often within several weeks. Thereafter, ambulation and daily exercise, such as swimming and walking, should be encouraged as tolerated. Lifting and vigorous physical activity are best avoided. Corsets and back braces, if comfortable, may facilitate ambulation in formerly bedridden patients. A course of intranasal *calcitonin* is sometimes helpful in this situation because of its analgesic effect in addition to its ability to increase bone density modestly.

Persons who have sustained a vertebral fracture should be treated aggressively for osteoporosis. Treatment options include PTH, calcitonin, and bisphosphonates. All increase BMD and significantly reduce the risk for a new fracture. PTH provides the best results in terms of new bone formation and BMD compared to bisphosphonates and combination therapy. Calcitonin helps provide immediate pain relief. The few controlled studies of *estrogen* therapy in this situation also suggest a benefit, but the response to estrogen can be muted in the later phases of menopause. | **Updated: 10/06/03**

Determining the efficacy of therapy can be problematic in the individual patient. Symptomatic improvement cannot be used to measure the response to therapy because fracture-free intervals may be long. The risk for fracture is not fully predictable by BMD because it is only one determinant of bone fragility. Despite these limitations, BMD measurement by DEXA can still be helpful, particularly as an objective indicator of bony response to treatment that can help guide therapy.

Preventing and Treating Steroid-induced Osteoporosis

Glucocorticoids inhibit new bone formation and calcium absorption and increase bone resorption and renal calcium excretion. Steroid-induced hypogonadism contributes to the problem in both men and women. Some degree of osteoporosis develops in more than 50% of patients on long-term steroids. Bone loss can be greatest during the first 3 to 12 months of steroid therapy; it then slows but persists for as long as steroid treatment continues. Some but not all bone mineral loss is reversible; the potential for recovery appears greatest in young persons. Patients who will be taking glucocorticoids on a daily basis for several months should be considered for prophylactic therapy. If high doses are to be used (e.g., the equivalent of >20 mg of prednisone daily), then prophylaxis should be considered even if the course of therapy will be relatively short because substantial bony changes can occur in as little as 3 months.

The first priority should be to use the least harmful steroid program possible (i.e., lowest dose, shortest time period, alternate-day schedule; see Chapter 105). In addition, it is essential to maintain physical activity and ensure adequate daily intake of calcium and vitamin D. Sodium restriction can help improve the absorption and reduce the renal excretion of calcium. Antiresorptive therapy with low-dose bisphosphonate therapy (e.g., 5 mg of *alendronate* per day or 35 mg once weekly or 400 mg of *etidronate* per day for 2 weeks every 3 months) begun close to the outset of steroid use can increase the BMD during steroid therapy and reduce the chances for development of osteoporosis and osteoporotic fractures. | **Updated: 10/06/03**

In patients already manifesting steroid-induced osteoporosis, *bisphosphonate* therapy (e.g., 10 mg of alendronate per day or 70 mg once weekly) can significantly increase bone density and reduce the risk for fracture. Hypercalciuria is an indication for *thiazide* therapy (supplemented by potassium replacement or a potassium-sparing agent). Small supplements of vitamin D can be given to those who become vitamin D–deficient, but large doses are to be avoided because of the risk for hypercalcemia. | **Updated: 10/06/03**

PATIENT EDUCATION

Patient education is essential. The time spent educating patients about osteoporosis is extremely well spent, because prevention and compliance are so important to effective management. Perimenopausal women are highly concerned about osteoporosis and come in eager to discuss prevention and treatment. The full range of options and their associated risks and benefits must be reviewed and patient preferences elicited; failure to do so is likely to result in disappointing outcomes. One should seek to design a program that is tailored to the patient's risk profile and life-style. Of particular importance is thorough discussion of HRT, given the increasingly worrisome data on associated risks of cancer and cardiovascular disease. The decision to initiate prophylactic HRT requires a consideration of all risks and benefits, not just those related to osteoporosis (see Chapter 118). Patients already taking HRT need to be updated on the risks associated with long-term use (see Chapter 118). | **Updated: 10/06/03**

THERAPEUTIC RECOMMENDATIONS

Prevention of Postmenopausal Osteoporosis

- Advise young women, especially if they are pregnant, to maintain a daily dietary intake of at least 1.0 to 1.5 g of *calcium* and 400 IU of *vitamin D*. Also encourage a program of regular physical activity. Advise against smoking and alcohol excess.
- For perimenopausal and postmenopausal women, prescribe a program of 30 minutes of *weight-bearing exercise* (e.g., walking, jogging, aerobics, dancing, tennis, weight lifting) at least three times weekly, a daily total calcium intake of 1.0 to 1.5 g, and 400 to 800 IU of vitamin D daily.
- If necessary, supplement the diet with *calcium carbonate* tablets (least expensive) or *calcium citrate* (more expensive, slightly better tolerated) to achieve the desired daily total; encourage supplement intake during meals to minimize gastrointestinal upset and risk for kidney stones, and encourage splitting the dose to maximize uptake and minimize gastrointestinal upset.
- Perform *BMD testing* (see Chapter 144).
  - Obtain DEXA scan of the hip and spine at the onset of menopause in women at increased risk for osteoporosis (i.e., maternal history of osteoporotic fracture, current smoking, history of fracture as adult, body mass index below 22 kg/m^2). | **Updated: 10/06/03**
  - Screen all women over the age of 65 by DEXA scan.
  - Obtain T- and Z-scores for BMD (see Chapter 144).
- **For patients with a T-score above -1.0** (i.e., BMD within one standard deviation of the mean for young women), continue calcium, vitamin D, and exercise; repeat bone density measurement in 1 to 2 years (depending on degree of osteoporosis risk).

- **For patients with a T-score between -1.0 and -2.5,** begin a more aggressive prevention program and avoid delaying the initiation of therapy because the rate of bone loss is maximal during the first few years after menopause. In addition to calcium, vitamin D, and exercise, choose one of the following based on patient preferences and total health considerations (refer to Chapter 118): **Updated: 10/06/03**
  - *Alendronate*: 5 mg every morning or 35 mg once weekly, taken on an empty stomach with 8 oz of water half an hour before breakfast while remaining in an upright position (to limit the risk for esophageal ulceration); or **Updated: 10/06/03**
  - *Raloxifene*: 60 mg/d, or **Updated: 10/06/03**
  - *Estrogen*: 0.625 mg of *conjugated estrogens* daily (in conjunction with 2.5 to 5.0 mg/d of medroxyprogesterone for the women with an intact uterus), but only in those persons who require HRT because of incapacitating hot flashes and are willing to assume the associated cancer and cardiovascular risks. Alternative hormone replacement regimens (e.g., transdermal estrogen patch, 50 µg/d; cyclic estrogen and progesterone) are available; careful monitoring is required (see Chapter 118); or **Updated: 10/06/03**
  - For those who refuse or cannot take such treatment, but might be candidates if osteoporotic risk increased still further, monitor bone loss by DEXA scan every 1 to 2 years and reconsider treatment if rate of loss is marked or T-score falls below -2.5. **Updated: 10/06/03**
- Continue therapy indefinitely unless it is replaced by a therapy of nearly equal efficacy or a complication develops.
- **For patients with a T-score below -2.5,** begin a program for established postmenopausal osteoporosis (see below).

Established Postmenopausal Osteoporosis

- For asymptomatic postmenopausal patients who are found incidentally to have radiographic osteopenia or a bone densitometry T-score below -2.5, begin as follows:
  - *Calcium, vitamin D*, and *weight-bearing exercise* (adjusted to minimize fracture risk) as detailed above; plus
  - *Alendronate*: 10 mg every morning (as detailed above) or 70 mg once weekly, or **Updated: 10/06/03**
  - *Raloxifene*: 60 mg/d; or
  - *Calcitonin*: 200 IU/d nasally, administered in alternating nostrils.
- Continue therapy indefinitely unless it is replaced by a therapy of nearly equal efficacy or a complication develops.

Osteoporotic Compression Fracture

- Treat initially with *bed rest* and *analgesics*. When the pain subsides, begin ambulation, followed by mild exercise such as walking or swimming. Avoid lifting and other weight-bearing stresses. Strongly consider treatment for osteoporosis.
- Begin *alendronate* (10 mg/d or 70 mg once weekly) and continue indefinitely to reduce the risk for recurrent fracture; consider *etidronate* if alendronate is not tolerated or cannot be used; prescribe 400 mg/d for 2 weeks every 3 months; no food 2 hours before intake and none for 2 hours after, or **Updated: 10/06/03**
- Consider PTH (either its 1-34 or 1-84 preparation) administered subcutaneously daily, especially if T-score <-2.5. **Updated: 10/06/03**
- Consider a course of intranasal *calcitonin* (200 IU/d) for pain while marked discomfort persists.
- Institute a program of *calcium* and *vitamin D* supplementation as detailed above.

Prevention of Glucocorticoid-induced Osteoporosis

- *Calcium* and *vitamin D* supplementation (as detailed above); plus **Updated: 10/06/03**
- Consider a program of osteoporosis antiresorptive prophylaxis with a bisphosphonate preparation (e.g., alendronate 35 mg once weekly or 70 mg once weekly if postmenopausal) in persons who are going to require high-dose steroids (e.g., >20 mg of prednisone per day) for at least a few months or lesser doses for a longer period, or **Updated: 10/06/03**
- *Etidronate*: 400 mg/d for 2 weeks every 3 months if alendronate is not tolerated. **Updated: 10/06/03**
- Give highest priority to those at greatest risk for osteoporosis (e.g., postmenopausal women; those with prior vertebral fracture).
- Consider DEXA determination of spinal BMD at the outset of therapy to determine pretreatment risk and establish a baseline.

PART 11 NEUROLOGIC PROBLEMS

CHAPTER 165 APPROACH TO THE PATIENT WITH HEADACHE

AMY A. PRUITT

A complaint of headache raises numerous diagnostic possibilities. Fortunately, fewer than 1% of cases of headache that come to medical attention represent serious intracranial disease. Still, headache poses a diagnostic challenge for the primary physician, who must distinguish between the rare headache that represents a potentially life-threatening process and the vast majority, which are harmless. Both physicians and patients worry about headaches that are persistent, severe, sudden in onset, or different from a patient's usual headache. The primary physician's most immediate task is to identify efficiently by history and physical examination the occasional patient who requires aggressive workup. Additional priorities are to provide symptomatic relief and to diagnose the type of headache and its cause systematically while formulating a long-term plan for management.

Headache can be a difficult problem to evaluate and manage. Of patients who come for help, only one third claim they are satisfied with the care received. Fortunately for neurologists and primary physicians alike, recent advances in our understanding of clinical presentation and pathophysiology have greatly facilitated diagnosis and treatment.

PATHOPHYSIOLOGY AND CLINICAL PRESENTATION

Headache may originate in either intracranial or extracranial structures, with the mechanisms and presentations of pain depending on the source.

Intracranial Sources

Intracranial sources of pain referable to the head include fibers of the fifth, ninth, and tenth cranial nerves and the upper cervical nerves, the venous sinuses, parts of the dura at the base of the skull, the dural arteries (anterior and middle meningeal), and the large arteries at the base of the brain that give rise to the circle of Willis. Brain parenchyma is not pain-sensitive.

Postulated *mechanisms* include (a) *traction* resulting from direct or indirect displacement of intracranial structures;(b) *distention* of intracranial arteries; (c) *inflammation* of pain-sensitive structures; and (d) *obstruction* of cerebrospinal fluid flow by a mass lesion distorting the brain contents. If the intracranial source of pain is above the tentorium, pain is usually felt in the distribution of the fifth cranial nerve. Pain from a site in the posterior fossa is usually felt in the posterior half of the head, conveyed by the glossopharyngeal and vagus nerves and also by the upper cervical spinal roots.

Mass Lesions can cause headache by displacing a pain-sensitive structure. About one third of patients with a mass lesion have headache as an early symptom, often with the pain *localized to the side of the lesion.* Presentations vary widely, with none particularly diagnostic. The headache may be mild or severe, intermittent or persistent, aching, sharp, pressure-like, or even throbbing in quality. Characteristically, the headache remains in the *same location* but is *progressive;* increases in the duration and severity of pain over several months occur in conjunction with subtle changes in mental status or the development of focal neurologic deficits. As intracranial pressure increases, lying down may exacerbate the headache, as may straining at stool, coughing, or bending over, and a more generalized headache may develop. Nocturnal awakening is common but not diagnostic. Projectile vomiting is a late complication.

In *brain tumor,* headache may be the sole initial complaint, unaccompanied by focal neurologic deficits. However, as the condition progresses, new neurologic deficits usually ensue.*Brain abscess* may present as a mass lesion causing headache, especially in its later stages. Parenteral drug abuse, lung abscess, or parameningeal infection may serve as the source of infection. Fever and focal neurologic deficits are often absent. *Chronic subdural hematoma,* another important mass lesion, typically presents in a subtle fashion, with head trauma followed by a symptom-free interval. The injury may be forgotten, but changes in mental status and, eventually, focal neurologic deficits begin to develop.

Pseudotumor cerebri can mimic the clinical presentation of tumor. Characteristic features include onset of headache in an obese, young woman, papilledema on funduscopic examination, and compressed ventricles on computed tomography.

Nonmigrainous Cerebrovascular Sources. *Ischemic events* may be associated with acute headache. The pain most often occurs on the side of the lesion but may be frontal or diffuse. In some instances, the headache is a consequence of the ensuing cerebral edema. *Arteriovenous malformation* and berry*aneurysm* are much-feared causes of vascular intracranial headache. Acute rupture of an aneurysm produces a headache of sudden onset that reaches maximum intensity immediately and is often accompanied by meningeal irritation. In the absence of any rupture, 10% to 15% of patients with an arteriovenous malformation may experience a chronic headache characterized by unilateral (always the same side) throbbing pain. Unlike migraine, such headaches are not associated with prodromal or other symptoms. Berry aneurysms are silent until they rupture unless they are larger than 2 cm, in which case they may present with headache similar to that caused by a mass lesion.

Migraine Headache affects about 10% of adults, women three times more frequently than men. Despite the fact that migraine is associated with high rates of disability, most patients with migraine have never had their condition diagnosed by a doctor or treated with prescription medications. *Family history* is present in nearly two thirds of cases, especially in patients who have a history of migraine with aura. Migraine headaches usually begin in childhood or young adult life, although in about 16% of women afflicted by migraine, the headaches first develop at the time of menopause. The condition tends to improve in many women during pregnancy, although *oral contraceptives* have been known to precipitate migraine or convert migraine without aura to migraine with aura. In roughly one in seven women with migraine, headache occurs only during the first few days of *menses,* although many women experience an exacerbation at this time.

Mechanisms. A number of hypotheses have been advanced to explain migraine and account for its phases. The *neurogenic–inflammatory hypothesis* currently enjoys considerable support. It views migraine as a primary neuronal event, with secondary neurotransmitter-mediated changes in vasculature and blood flow. Neuropeptides are thought to act as neurotransmitters at trigeminal nerve branches, precipitating an inflammatory process with vasodilation. *Serotonin receptors* are believed to be important in mediating these events, which can be triggered by a variety of stimuli (mechanical, electrical, or chemical). The observed decrease in blood flow during migraine is now believed to be caused by a slowly spreading cortical band of decreased neuronal function elicited by such stimuli. Bidirectional influences of *depression* and migraine appear to exist. The estimated relative risk for major depression associated with prior migraine is 3.2, and the adjusted relative risk for migraine associated with prior major depression is 3.1.

Classification. Migraine formerly was designated as "*classic*" if accompanied by aural symptoms (see below) and as "*common*" if not. This taxonomy has been replaced by the more specific classifications of *migraine with aura* and *migraine without aura*. Table 165.1 and Table 165.2 show the diagnostic criteria for migraine without aura and migraine with aura. Both types of migraine are accompanied by nausea and photophobia. The new classification system requires that at least two of the following be present to establish a diagnosis of migraine headache: unilateral location, pulsating quality, moderate to severe intensity, and exacerbation by physical activity. At least one of the following must accompany the headache: nausea or vomiting, photophobia, and phonophobia. Precipitants of migraine include emotional upset, menstruation, and, in some people, ingestion of tyramine- or tryptophan-rich foods (e.g., ripe cheeses, red wine, chocolate). Headache may occur shortly after or just before a period of psychological stress. Some patients experience a seemingly paradoxical flare-up of migraine on weekends or vacations. The risk for stroke is increased, particularly in patients who have migraine with aura.

Diagnostic Criteria
A. At least five attacks fulfilling B–D
B. Headache lasting 4 to 72 hours (untreated or unsuccessfully treated)
C. Headache with at least two of the following characteristics:
1. Unilateral location
2. Pulsating quality
3. Moderate or severe intensity (inhibits or prohibits daily activities)
4. Aggravated by walking stairs or similar routine physical activity
D. During headache, at least one of the following:
1. Nausea and/or vomiting
2. Photophobia and phonophobia

From Headache Classification Committee of the International Headache Society. Classification and diagnostic criteria for headache disorders, cranial neuralgias, and facial pain. Cephalalgia 1988; 8[Suppl 7]:1, with permission.

Table 165.1. International Headache Society Definition of Migraine without Aura (Common Migraine)

Previously used terms: classic migraine; ophthalmic, hemiparesthetic, hemiplegic, or aphasic migraine

Diagnostic Criteria
A. At least two attacks fulfilling B
B. At least three of the following four characteristics:
1. One or more fully reversible aura symptoms indicating focal cerebral cortical or brainstem dysfunction.
2. At least one aura symptom develops gradually over more than 4 minutes, or two or more symptoms occur in succession.
3. No aura symptom lasts more than 60 minutes. If more than one aura symptom is present, accepted duration is proportionally increased.
4. Headache follows aura with a free interval of less than 60 minutes. (It may also begin before or simultaneously with the aura.)

From Headache Classification Committee of the International Headache Society. Classification and diagnostic criteria for headache disorders, cranial neuralgias, and facial pain. Cephalalgia 1988; 8[Suppl 7]:1, with permission.

Table 165.2. International Headache Society Definition of Migraine with Aura (Classic Migraine)

Clinical Presentation. Attacks may comprise as many as five phases: prodrome, aura, headache, termination, and postdrome. The *prodrome* is characterized by lassitude, irritability, difficulty concentrating, and nausea. Patients with *aura* often report visual phenomena (scintillating scotomas, zigzag patterns, hemianopsia, diplopia), vertigo, aphasia, or even hemiplegia preceding the onset of the *headache,* which is typically unilateral and throbbing, although it may begin as a dull sensation and take a while to reach maximum intensity. Headache *termination* usually occurs within 24 hours but sometimes not until after 48 hours. The *postdrome* phase includes feelings of fatigue, sleepiness, or irritability. Epidemiologic studies suggest that migraineurs suffer a median of about 12 attacks per year. Many have headaches both with and without aura.

Variants. A number of variants are seen. The most common is *migraine without aura.* Another is *acephalgic migraine*, in which a focal neurologic deficit may evolve during an aura but is not succeeded by headache. In rare instances, the symptoms of acephalgic migraine may persist for 1 to 2 days, simulating a stroke. *Basilar migraine* produces focal symptoms referable to the posterior circulation; it is more common in children.

Meningitis resulting from infection or hemorrhage produces pain that is acute in onset, severe, generalized, and constant. Symptoms may be particularly intense at the base of the skull and aggravated by forward flexion of the neck or by leg raising in conjunction with knee extension and foot dorsiflexion.

Postconcussion Headache occurs when the wrenching and displacement of pain-sensitive structures in the central nervous system during head trauma have been severe enough to cause concussion. *Postconcussion syndrome* (posttraumatic nervous instability) is a complicated, poorly characterized state manifested by chronic refractory headache, neck pain, nervousness, emotional lability, crying spells, and inability to concentrate. The symptoms are suggestive of an agitated depression following trauma; the syndrome probably represents a variant of tension-type headache. The correlation between severity of symptoms and seriousness of the injury is minimal. Often, legal proceedings and litigation are pending. Symptoms may abate once legal issues are settled.

Extracranial Sources

Extracranial sites of headache include the skin, fascia, muscles, and blood vessels of the scalp; the extracranial arteries; mucous membranes of the nasal and perinasal spaces; the external and middle ear; teeth; and muscles of the scalp and facial region. Problems involving the eyes, sinuses, cervical spine, temporal mandibular joints, or cranial nerves can be important sources of headache, although some common attributions are not always correct.

Tension-type Headache ranks among the leading types of chronic and recurrent headache. More than 90% are bilateral and are often described as a feeling of pressure or a bandlike sensation about the head. The pain is dull and steady in most instances, characteristically worsening as the day progresses and sometimes accompanied by occipital and nuchal soreness. The headache may last days, weeks, or even months. Recording of myographic potentials from head and neck muscles reveals vigorous contractions in some but not all patients with this type of headache. Vasoconstriction can also be detected and may account for the migraine-like symptoms (nausea, throbbing pain) experienced by some patients.

Precipitants include *anxiety, depression,* and *situational stress.* Patients with underlying psychopathology often describe their headache pain in vivid terms (e.g.,"feels like an ax" or "lightning" or "something exploding"), yet they do so without demonstrating any apparent discomfort. So psychologically engaging is the headache that many of these patients are unaware of their underlying emotional problems. Tension-type headaches may also occur secondary to muscle strain from cervical spondylosis or temporomandibular joint disease (see below).

Sinusitis. True sinusitis produces a headache that characteristically is acute in onset and worse on awakening. It gets better on arising, only to worsen again as the day progresses. The patient reports a purulent nasal discharge, and pain and skin sensitivity are predominant over the involved sinus (see Chapter 219). Many patients with other forms of headache (e.g., frontal muscle-contraction headaches) mistakenly attribute their problem to "sinusitis" and self-treat with decongestants to no avail. Because the pain of sinusitis is sometimes described as throbbing in quality and can worsen when the patient bends over, it may be mistaken for migraine or the headache of a intracranial mass lesion.

Giant Cell Arteritis, also referred to as *temporal arteritis* or *cranial arteritis,* is a disease of older persons (almost all are older than age 50). It affects medium and large arteries (especially those of the extracranial vasculature) and can cause blindness if it spreads to the ophthalmic artery. The headache may begin as a throbbing discomfort and progress to a dull, aching pain. Some patients describe burning, and others note bouts of lancinating pain. Scalp tenderness (especially when the hair is combed) localized to the involved vessel(s) is characteristic. However, the inflamed artery may not always be tender or palpable, and although the temporal artery is commonly involved, it need not be. Jaw (masticatory muscle) claudication is often part of the clinical picture, and the condition is strongly associated with *polymyalgia rheumatica* (see Chapter 161).

The most feared complication is *blindness,* which occurs when arteritis results in occlusion of the ophthalmic artery, usually about 1 to 2 months after the onset of headache. Diplopia may precede and is predictive of visual impairment (50% risk). Once visual impairment sets in, it progresses quickly over several hours to total visual loss (see Chapter 161).

Temporomandibular Joint Dysfunction. "TMJ" has received much attention in the lay press as a common, sometimes overlooked cause of chronic refractory headache. Occasionally, the problem is caused by joint changes resulting from malocclusion. However, the problem in most cases is not malocclusion, but rather tension-induced jaw clenching and nocturnal teeth grinding (*bruxism*). Such chronic involuntary oral habits lead to masticator muscle fatigue and spasm. Chronic dull, aching, unilateral discomfort may be described about the jaw, behind the eyes and the ears, and even down the neck into the shoulders. Jaw pain, clicking sounds, and difficulty opening the mouth in the morning are characteristic. Chewing may exacerbate symptoms; locking of the jaw is common. On physical examination,

masticatory muscle tenderness, mandibular hypomotility, and joint clicking and deviation on opening are noted. Molar prominences may be flat from chronic grinding of the teeth (see Chapter 225).

Cluster Headache. The pathophysiology of cluster headache remains obscure, although extracerebral vasodilation appears to be a component. It occurs predominantly in middle-aged men and is the only type of headache more common in men than in women. Cluster headache is distinguished by its location, timing, and periodicity. In the most typical presentation, seen in more than 50% of cases, patients describe an intense, nonthrobbing, unilateral headache "behind the eye" that is searing, stabbing, or burning and accompanied by ipsilateral lacrimation, nasal stuffiness, and facial flushing. In 20% to 40% of cases, ipsilateral ptosis and miosis are also present. Headache typically begins a few hours after the patient goes to bed and lasts for 30 to 90 minutes. Attacks occur nightly for 2 to 3 months and then disappear, only to return several months to years later. About 10% of these patients have *chronic cluster headache,* in which attacks occur daily for 1 to 2 years; periodicity is not noted. These headaches are sometimes confused with migraine because they are unilateral and severe, but the pain is not throbbing and most of the other defining features of migraine are lacking. Stress and alcohol are believed to be precipitants, although alcohol is well tolerated between attacks.

Headaches Responsive to Indomethacin. Headaches in this group include chronic paroxysmal hemicrania, ice pick headache, and hemicrania continua. *Chronic paroxysmal hemicrania* is a rare cluster variant occurring predominantly among women and characterized by a similarly severe unilateral facial pain; unlike cluster, these headaches occur in short spasms of 10 to 20 minutes up to 20 or 30 times per day. Horner's syndrome and ipsilateral tearing are often noted. *Ice pick headache* occurs in patients suffering from migraine, although not exclusively. The headache is brief, sharp, and jabbing. *Hemicrania continua* differs from the other types in causing continuous unilateral aching discomfort, although it is accentuated by ipsilateral jabbing pain.

Systemic Infection and Fever. These conditions are among the most common causes of cranial vasodilation and diffuse, throbbing headache. The headache that frequently accompanies a *viral syndrome* is typical. Numerous *metabolic disturbances* and *drugs* may lead to vasodilation and headache. A pounding headache is a prominent symptom of early carbon monoxide poisoning and a common complaint of patients who take nitrates for angina or vasodilators for other conditions.

Hypertension. Moderate to severe *hypertension* (diastolic pressures >110 mm Hg) sometimes results in occipital headaches. The mechanism of the headache is unknown. The discomfort is worse in the morning and recedes as the day progresses. This headache resolves with correction of the hypertension. It should not be confused with the muscle-contraction and psychogenic headaches that account for most of the headaches occurring in hypertensive patients or with the headache caused by the increased intracranial pressure that accompanies malignant hypertension.

Ocular Sources. Headaches are often attributed to eye problems, especially when they are felt about the orbit. *Eyestrain* is often blamed for headaches, although in most instances the attribution is incorrect and refraction fails to improve the problem. However, in an occasional patient, astigmatism can cause difficulty when the eyes are used for close work for prolonged periods. It produces ocular muscle imbalance and sustained contraction of extraocular, frontal, and temporal muscles; aching discomfort about the orbit and the frontotemporal region results. Refraction corrects the problem. *Acute glaucoma* may produce an orbital headache of sudden onset that is accompanied by cloudy vision (see Chapter 201 and Chapter 207).

Cervical Radiculopathy. Headache is commonly the first symptom of cervical radiculopathy. The pain arises during mechanical irritation of an upper cervical root. Findings on radiography of the cervical spine are variable, ranging from normal to spondylotic. The pain is often localized to one side of the occiput or base of the skull, in conjunction with tenderness to palpation. It may start in the neck and at times even radiate to the forehead or eye. The discomfort is described as nagging or aching and is aggravated by *neck movement.* The headache tends to be worse on awakening, perhaps because of unconscious neck motion during sleep. The mechanism of pain is believed to involve entrapment of upper cervical nerve roots as they course toward the occiput through irritated nuchal ligaments and muscles. Occipital neuralgia is a particularly common variant. Patients describe sudden lancinating pain in the distribution of the greater occipital nerve, which may be precipitated by turning over in bed and is often relieved by sitting up.

Trigeminal Neuralgia (*Tic Douloureux*) is one of the most severe pain syndromes known to human beings. Paroxysms of lancinating facial or cranial pain occur in middle-aged or elderly patients; these may last only a few seconds but can be excruciating and recurrent. The jaw, gums, lips, or maxillary region may be involved. Characteristically, a trigger zone is located within the region of pain (see Chapter 176).

DIFFERENTIAL DIAGNOSIS

For differential diagnosis, headache can be divided into acute and chronic/recurrent types (Table 165.3). Of note, the International Headache Society now subdivides migraine into *migraine headache with aura* (previously called *classic migraine*) and *migraine headache without aura* (previously referred to as *common migraine*). *Tension-type headache,* with or without associated paracranial muscle spasm, has replaced the numerous designations of *muscle-contraction headache, psychogenic headache*, or *tension headache* previously used.

Table 165.3. Important Causes of Headache

WORKUP

As noted earlier, the first priority is to distinguish the worrisome headache from the harmless one. Headaches of concern are those that are sudden in onset, severe, or persistent. Despite the advent of elaborate imaging techniques, the history and physical examination remain indispensable.

The goal of the workup is to distinguish one of the primary headache syndromes (migraine with or without aura, cluster headache, tension-type headache) from a headache secondary to a mechanical or systemic process that would dictate a different therapy.

History

The time invested in obtaining a full description of the headache, particularly its clinical course, associated symptoms, precipitants, aggravating and alleviating factors, and patient concerns, is well worth the effort. The information obtained is often diagnostic, always critical to intelligent test selection, and essential to dealing effectively with patient worries and expectations. The medication history is also critical because a number of agents (e.g., indomethacin, nifedipine, cimetidine, captopril, nitrates, atenolol, trimethoprim/sulfamethoxazole, oral contraceptives) can trigger nonspecific headaches. Drug-related intracranial hypertension can be seen with minocy-cline, isoretinoin, nalidixic acid, tetracycline, trimethoprim/ sulfamethoxazole, cimetidine, corticosteroids, and tamoxifen.

The history pertinent to a new headache differs slightly from that for chronic or recurrent headache.

Headache of New Onset. History should include inquiry into any *associated neurologic deficits, fever,* or *neck stiffness*. The patient unaccustomed to having headaches who presents with the sudden onset of the "*worst headache ever experienced*" deserves prompt attention, particularly if fever, neck stiffness, ataxia, alteration in mental status, focal neurologic deficit, or visual impairment is reported. Diffuse headache in conjunction with a stiff neck and fever suggests acute meningitis. When acute headache and *stiff neck* occur in conjunction with *gait ataxia* and profuse nausea and vomiting, a midline cerebellar hemorrhage must be

considered. Early recognition is important because urgent surgical treatment can be life-saving. Abrupt onset of a headache that reaches maximum intensity immediately suggests rupture of a cerebral aneurysm. Hypertensive encephalopathy may be heralded by diffuse headache, nausea, vomiting, and altered mental status. Acute fever with frontal and orbital headache is suggestive of acute sinusitis. Eye pain and blurred vision raise the possibility of acute glaucoma. New onset of headache in an elderly patient requires consideration of temporal arteritis. Acute onset of a throbbing headache should trigger inquiry into migrainous epiphenomena (prodromal and aural symptoms), febrile illness, vasodilator use, carbon monoxide exposure, drug withdrawal, and hypoglycemia. A throbbing headache accompanied neurologic deficits may be migrainous, but if deficits persist beyond 12 hours, then stroke and other causes should be considered.

Recurrent or Persistent Headache. With migraine and tension-type headaches being the most common causes of chronic or recurrent headaches and brain tumor being the most feared, the history becomes critical to the evaluation. The *clinical course* can be particularly revealing. Increases in severity, frequency, or both with time raise the question of an intracranial mass lesion, whereas a headache pattern that remains constant or waxes and wanes is more typical of tension-type or migraine headache. The nightly occurrence of headache for some time followed by symptom-free intervals is among the most characteristic features of cluster headache.

In acute headache, the severity of the pain helps to identify an increased risk for serious pathology; however, in chronic or recurrent headache, the intensity of the pain is of little value. Most patients have headaches with different degrees of pain at different times. The headache of a brain tumor may begin as a relatively minor complaint, whereas the pain of a migraine, cluster, or tension-type headache may be excruciating. Careful attention to *associated symptoms* is always essential. Inquiry into migrainous epiphenomena can be diagnostic, and eliciting a report of a new neurologic deficit strongly increases the likelihood of tumor. *Location* and *quality* are sometimes helpful, although the overlap among headaches with different causes can be considerable. Whole-head, bandlike, and occipital–nuchal distributions suggest tension-type headache, as does tightness or a pressure-like quality, but such sensations may also be reported when intracranial pressure is increased. A unilateral location and throbbing are characteristic of migraine but sometimes are reported by patients with tension-type headache. Unilaterality and sameness of location suggest that the headache is caused by a mass lesion.

Associated symptoms are important for the identification of other causes of chronic or recurrent headache. Temporomandibular joint pain suggests bruxism, whereas jaw claudication and scalp vessel tenderness indicate giant cell arteritis. Concurrent shoulder and hip-girdle discomfort provide supporting evidence. Neck pain raises the question of a cervical radiculopathy. Purulent nasal discharge is indicative of sinus disease. A history of head trauma, parameningeal infection, depression, situational stress, or substance abuse and a family history of headache should always be sought, and a careful medication history must be taken. Of particular concern is *rebound headache,* a pattern of headache caused by overuse of analgesic medication, ergotamine compounds, or the serotonergic agonists known as triptans. Patients with rebound headache have fallen into a pattern of overuse of medication with consequent withdrawal headache.

Aggravating and *precipitating factors* deserve investigation. Headache worsened by straining, coughing, or bending over is characteristic of an intracranial mass lesion; bending over may also exacerbate the headache of sinusitis. Headache brought on by ingesting certain foods or beverages (chocolate, cheese, red wine) is typical of migraine, which is also exacerbated by noise, odors, and bright light. Alcohol may also trigger cluster headache during a period of disease activity. Migraine can be induced or exacerbated by a host of drugs, including cimetidine, ethinyl estradiol, atenolol, indomethacin, danazol, nifedipine, selegiline, and oral contraceptives.

Physical Examination

Acute Headache. The physical examination contributes importantly to the search for serious underlying disease. The blood pressure and temperature should be checked for elevations, the scalp for cranial artery tenderness, the sinuses for purulent discharge and tenderness, the pupils for loss of reactivity, the corneas for clouding (indicative of acute glaucoma), the disc margins for papilledema, and the neck for rigidity on anterior flexion. A neurologic examination should be performed to check for ataxia, alteration of mental status, focal deficits, and meningeal signs.

Chronic or Recurrent Headache. The physical examination begins with a check of all the areas mentioned in the evaluation of acute headache and expands into other areas based on findings from the history. For example, in a patient with a headache history that includes facial pain, the oral cavity should be examined for a trigger zone indicative of trigeminal neuralgia, the teeth for signs of bruxism, the temporomandibular joint for limitation of motion and crepitus, and the neck for signs of degenerative disease (see Chapter 148) and movements that reproduce head pain. Excessively taut muscles and focal tenderness about the shoulders, neck, and occiput are noted in many patients with tension-type headache. A careful and complete neurologic examination is essential because the finding of a fixed focal deficit is important evidence of intracranial pathology. Suspicion of a mass lesion necessitates consideration of brain abscess in addition to malignancy and subdural hematoma. Under such circumstances, the nasal cavity is examined for purulent discharge, the sinuses for tenderness, and the ears for signs of chronic otitis media (see Chapter 218). Both sinusitis and chronic otitis are potential foci for parameningeal infection that can lead to brain abscess.

Laboratory Studies

Acute Headache. Patients with acute onset of the "worst headache ever," especially if accompanied by meningeal signs or evidence of increased intracranial pressure, require prompt hospitalization. In such settings, emergency *computed tomography* is the test of choice for prompt detection of potentially life-threatening but treatable lesions (e.g., midline cerebellar hemorrhage or central nervous system mass). In patients with signs of meningeal irritation, *lumbar puncture* and examination and culture of the cerebrospinal fluid should follow computed tomography to rule out an infectious cause, provided no evidence of markedly increased intracranial pressure is found. New onset of headache in an elderly patient, especially if accompanied by cranial artery or scalp tenderness, dictates determination of the *erythrocyte sedimentation rate* to check for giant cell arteritis. In addition, a *temporal artery biopsy* should be considered (see Chapter 161).

Chronic or Recurrent Headache. Much of the controversy and discrepancies regarding the proper evaluation of headache result from the failure to differentiate patients who present with a first headache from those who have a chronic recurring headache. In the presence of normal physical examination findings and a headache history that does not suggest intracranial disease but classifies the patient's headache clearly into a recurring migrainous type, ancillary studies are not likely to be useful.

A disturbing trend toward uncritically ordering neuroimaging studies (initially *computed tomography* and now *magnetic resonance imaging*) for all patients with recurrent or chronic headache has led to escalating costs for evaluations that provide no more information than did the initial headache history and physical examination. The probability of a patient with chronic headache and normal neurologic examination findings having a positive neuroimaging study is exceedingly small. The yield is so low that in the absence of a very worrisome history or a neurologic deficit on physical examination, an imaging study is not needed. Some feel that the reassurance value of such testing can be helpful, but most patients with benign chronic headache who fear serious underlying disease can be adequately reassured if time is taken to review the clinical findings and directly address patient concerns. Such steps are essential to providing meaningful reassurance and usually obviate the need for an otherwise medically unnecessary imaging procedure.

Nonetheless, there are a few instances when a neuroimaging study might still be appropriate in the absence of abnormalities on physical and neurologic examinations. These exceptions include patients with a headache of *recent onset* (<6 months) the cause of which is still not apparent after a thorough history and physical examination. In addition, those with a persistent headache that is *worsening* with time and does not fit the pattern of a tension-type headache should be considered for imaging study. When one uncovers a history of *aura symptoms* or *loss of consciousness* suggestive of a seizure (see Chapter 170), then a search for an intracranial mass lesion is warranted. If the patient or family member reports a *persistent personality change,* a tumor of the frontal or temporal regions might be suspected. Finally, if a *change in the character* of long-standing headache is noted or if the headache fails to respond to treatment directed at a diagnosis initially suspected, such as migraine, the utility of magnetic resonance imaging or computed tomography increases.

The efforts taken to perform a careful history and physical examination are well worth the time, for these methods remain the best means available for efficient test selection and accurate diagnosis of headache.

PRINCIPLES OF MANAGEMENT

Migraine

Migraine is the one headache disorder for which relatively specific therapy currently exists; therefore, establishing its presence is extremely important to the patient. The neurogenic hypothesis has refocused attention from vasodilators to drugs designed to act on serotonin receptors. Several older drugs useful in the prophylaxis of migraine (e.g., methysergide, cyproheptadine) have been found to act as 5-HT_2 serotonin receptor antagonists. The drugs most useful in acute migraine attacks (e.g.,

ergotamine, triptans) interact with the presynaptic serotonin 5-HT$_{1D}$ and 5-HT$_{1A}$ receptors, inhibiting the release of neurotransmitters.

For most patients, the combination of a tolerable prophylactic medication with occasional use of analgesics or abortive regimens should minimize the intrusion of this highly disabling condition into their daily lives. Because most prophylactic drugs require several weeks to several months to establish efficacy, it is particularly important to maintain a strong and sympathetic relationship with each patient being treated for migraine.

Prophylaxis. Most patients with migraine can be helped by the implementation of both prophylactic and abortive measures. Once the diagnosis is established by the criteria of the most recent classification system, the physician should ascertain the frequency of disabling headache. As a general rule, if headaches are interfering with work or other activities more than once a week, it is reasonable to consider prophylactic medication. Educating the migraine-prone patient to avoid precipitants such as certain foods (cheese, chocolates, citrus fruits, nuts, red wine—although not invariably in all patients), inadequate sleep, and prolonged fasting may help prevent some headaches. Useful information on precipitants is sometimes derived by keeping a *headache diary.*

Nonpharmacologic Measures. Prevention of attacks involves *nonpharmacologic measures* in addition to drug treatment. Because migraine may be precipitated by emotional stress or psychological conflict, it is important to investigate family, work, and social circumstances to design a program of prevention. Regular *exercise* and *relaxation techniques* (see Chapter 226) may significantly decrease the frequency and severity of headaches. These activities help reduce the impact of stress. Many patients prefer to try them before attempting other forms of therapy. Patients under significant psychological stress may benefit from informal supportive psychotherapy, which helps them to express their feelings and deal with the stress. Although extensive psychotherapy may not reduce the number of attacks, it is worth trying to pinpoint areas of stress and search with the patient for ways to resolve them. Recommending rest or a vacation may not suffice; in fact, flare-ups are common during vacations and weekends. *Biofeedback* is of unproven benefit and probably no better than relaxation exercises and other nonpharmacologic methods. The lack of adequately designed studies limits conclusions regarding biofeedback.

Pharmacologic Measures. Drug therapy should be added when nonpharmacologic measures do not suffice. Several different classes of drugs have been useful in the prophylaxis of migraine; the doses and side effects are outlined in Table 165.4. An approach of trial and error is often necessary before the appropriate medication that is most effective with the fewest side effects in any individual patient can be found. Each drug should be given at least a 2-month trial, and many patients require longer than this before full benefit is obtained. In general, a *tricyclic antidepressant* (e.g., *nortriptyline* or *amitriptyline*) is an appropriate first-line choice, especially in view of the increasingly evident relationship between migraine and major depression. b- *Blockers* are another first-line prophylactic agent, but sometimes such high doses are required that fatigue or even depression develops. Another alternative is verapamil, the most widely prescribed calcium channel blocker for migraine prophylaxis. *NSAIDs* (e.g., naproxen) have been useful, especially for patients with menstrual migraine. They are prescribed for several days before, during, and after menstruation. *Valproate,* an anticonvulsant drug that interacts with the g-aminobutyric acid neurotransmitter system and turns off serotonergic raphe neurons, has also attracted interest, but its usefulness in patients with migraine is limited by its tendency to cause hair loss and weight gain and its teratogenic potential (neural tube defects). Promising results in small-scale, short-term studies suggest a possible prophylactic role for high-dose *riboflavin* (*vitamin B$_2$*); when given in doses of 400 mg/d, it reduces the frequency and total number of headache days. The purported mechanism is an improvement in mitochondrial function. Longer-term, larger-scale studies are needed before this treatment can be recommended.

Table 165.4. Drugs for Migraine Headache Prophylaxis

Abortive Therapy. For the patient with only occasional migraine headaches and for patients with generally well-controlled but occasional severe breakthrough headaches, it is important to establish an effective abortive regimen. The advent of triptan therapy has greatly enhanced the ability to abort migraine attacks. However, despite the demonstrated safety and efficacy of the triptans, this class of drugs is prescribed for only about 30% of patients with migraine. Analgesics remain the most frequently prescribed remedy for migraine, even though they are not an effective treatment for this type of headache.

Treatment of Aural Symptoms. Most medicines that treat migraine episodes do not blunt aural symptoms. *NSAIDs* and prokinetic and antiemetic compounds such as *metoclopramide* and *compazine* may provide significant relief of aural symptoms. The administration of antiemetics and metoclopramide 30 minutes before analgesics improves oral absorption, combats nausea, and increases the efficacy of aspirin, acetaminophen, and caffeine-containing compounds.

Dihydroergotamine. The SQ, IM, IV, or nasal administration of ergot is highly effective. Parenteral administration in emergency department settings has helped to terminate severe, acute attacks of migraine. Although the vasoconstrictive effects of dihydroergotamine on peripheral arteries are minimal, it is contraindicated in patients with coronary disease, peripheral vascular disease, transient ischemic attacks, pregnancy, or sepsis. Nausea is a significant problem and may be minimized by prior IV administration of metoclopramide (Reglan).

Selective 5-HT$_{1B/1C}$ Agonists (Triptans) have revolutionized the management of migraine headache. Several are now on the market. The participants in the "triptan wars" are outlined in Table 165.5. Both sumatriptan and the second-generation triptans are cerebral and coronary vasoconstrictors; they act by both vasoconstriction and inhibition of neurogenic inflammation. The drugs differ in their bioavailability and half-lives. A single 6-mg SQ dose of sumatriptan has proved highly effective; it acts rapidly and is well tolerated in the treatment of severe migraine attacks. Sumatriptan is now available as an SQ autoinjection formulation, tablets, and nasal spray. In general, the second-generation triptans have better oral pharmacokinetic properties than sumatriptan does, and they last longer. Therefore, the initial relief of headache is at least as good as that with oral sumatriptan, and the recurrence rate may be lower. Recurrence may be minimized with the longer-acting triptans, such as naratriptan. A second dose of any of the triptans may be effective, but overuse of the triptans can result in a *rebound* phenomenon. The use of sumatriptan and other triptans should be restricted to no more than 1 to 2 days weekly.

Table 165.5. Triptans[a]

Contraindications to triptan use include recent use of monoamine oxidase inhibitors, uncontrolled hypertension, coronary artery disease, and pregnancy. Patients should not take triptans during the aura phase of the migraine, and patients with complicated auras such as hemiparesis or dysphasia should not receive triptan therapy. Those on selective serotonin reuptake inhibitors may take triptans, but the dosage of both medicines should be monitored carefully.

Side effects. Sumatriptan injection is safe for large numbers of patients despite the fact up to 40% of patients report *chest-related symptoms* when specifically asked about them. The initial theoretical concerns about possible ischemia have been allayed by large-scale follow-up studies that found not a single clear incident of myocardial infarction within 24 hours of sumatriptan injection, no deaths, and no increased incidence of stroke.

Analgesics and Sedatives. In general, it is best to avoid the regular use of *analgesics* and *sedatives.* Popular combination analgesic and sedative formulations containing either acetaminophen or aspirin with butalbital and caffeine (e.g., *Fioricet* and *Fiorinal*) are often requested by patients, as they were widely prescribed in the past. Although they may be helpful for occasional use, marked caution is warranted in prescribing such combination agents because of their potential for habituation when used regularly in a chronic recurring condition such as migraine and because of the development of rebound headache patterns. *Narcotic analgesics* are sometimes needed, but their regular use can lead to a vicious cycle of headache, narcotic intake, drug withdrawal, more headache, and more narcotic intake (see below).

Migraine and Risk for Stroke. Although the risk for ischemic stroke is low in patients who have migraine without aura, the odds ratio for stroke in patients who have migraine with aura is increased (to approximately 6). *Oral contraceptives,* even those with a low estrogen content of less than 50 mg, appear to cause an increase in ischemic stroke risk, with an odds ratio of about 2. Many neurologists discourage the use of oral contraceptives in patients who have migraine with aura and in older female patients who have migraine with other risk factors for stroke.

Cluster Headache

As with migraine, both abortive and prophylactic treatments are available. One abortive treatment for an acute attack consists of inhalation of *oxygen* (5 to 8 L/min for 10 minutes). *Ergotamine suppositories* may be effective and can be taken at bedtime during a cluster by a patient whose symptoms occur at night. *Dihydroergotamine* (IM or IV, as outlined above) is effective, as is sumatriptan, particularly the SQ form. A corticosteroid bolus of 8 mg of *dexamethasone* or *prednisone* started at 20 mg three times a day and tapered during 2 weeks has also been helpful in aborting a cluster.

Prophylaxis for patients with chronic cluster headaches or for those with severe frequent cluster episodes includes 360 mg of *verapamil* daily, given in divided doses. *Methysergide* at a dosage of 2 mg three times a day or *lithium* at doses achieving a therapeutic level identical to that for bipolar disease is useful. Sphenopalatine ganglion block performed by an anesthesiologist may provide significant temporary relief. A radio-frequency *trigeminal rhizotomy* is reserved for patients whose headaches are completely refractory to all the medical therapies described above.

Tension-type Headache

For the vast majority of patients with mild or occasional tension headache, mild analgesics (aspirin, acetaminophen, nonprescription doses of NSAIDs) usually suffice. Such patients usually do not consult the physician. Patients with chronic or persistent tension-type headaches are candidates for evaluation of underlying anxiety and depression (see Chapter 226 and Chapter 227). Often, definitive treatment of such headaches requires that the underlying sources of psychological distress be addressed. *Stress reduction* measures may be of considerable help for those with an anxiety state (see Appendix, Chapter 226), and *antidepressant therapy* may benefit depressed patients (see Chapter 227). Patients with chronic headache subsequent to trauma should be encouraged to conclude any pending legal proceedings.

Chronic Daily Headaches

Chronic daily headache is among the most difficult types of headache encountered by primary physicians. In some patients, a migraine syndrome evolves into a daily headache more typical of tension-type headache with superimposed migrainous events. Depression, anxiety, and drug abuse may all complicate the picture at this stage. While counseling this group of patients about precipitating factors and lifestyle modification, it is important that the physician elicit a history of analgesic and ergotamine use. Ergotamine or analgesic abuse can lead to a vicious cycle of headache, medication, and headache. As the effect of a previous dose of ergotamine or analgesic wanes, headache begins to recur and leads to further use of medication. Drug-induced sleep disturbances and psychological dependence ensue, leading to a self-sustaining rhythmic cycle of headache and medication. Thus, caution must be exerted to avoid prescribing large amounts of ergotamine or analgesics (both narcotic and non-narcotic) for a patient with migraine or tension-type headache. Total elimination of analgesics and ergotamine compounds may improve the therapeutic results of other medications chosen for the prophylaxis of headache. Hospitalization for withdrawal of medication and institution of a comprehensive program may be beneficial.

Management of Other Conditions Causing Headache

(For the treatment of temporomandibular joint dysfunction and bruxism, see Chapter 225. See Chapter 161 for the management of temporal arteritis, and Chapter 219 for the treatment of sinusitis.)

INDICATIONS FOR ADMISSION AND REFERRAL

Admission or Urgent Referral. Urgent hospitalization is indicated for the patient with acute onset of a severe headache accompanied by signs of meningeal irritation. Intracranial hemorrhage or meningeal infection may be responsible. Evidence of increased intracranial pressure is another indication for prompt admission. Severe, intractable migraine may require prompt hospital admission for one of the abortive treatments outlined above. The ophthalmologist needs to be consulted at once if acute glaucoma is thought to be the cause of an acute orbital headache.

Referral. Less urgent situations involving headache that deserve neurologic consultation include episodes of transient neurologic dysfunction, unilateral headache increasing in frequency and severity, change in personality, and new onset of progressive deficits suggestive of an evolving process or a mass lesion. Sometimes, patients with an intractable tension-type headache or severe migraine syndrome can benefit from the reassurance and suggestions provided by the neurologist. Dental consultation is indicated if temporomandibular joint problems appear refractory to conservative therapy. Surgical referral for a temporal artery biopsy may be necessary when an elderly patient is suspected of having giant cell arteritis but more definitive evidence that long-term steroid therapy is warranted is required (see Chapter 161). Ophthalmologic consultation for a vision check and assessment of the need for refraction is indicated if prolonged close work is resulting in headaches.

For patients with chronic, intractable, tension-type headache, a diagnostic consultation with a psychiatrist may serve as an important learning experience. However, many of these patients are reluctant to consider a psychological cause for theirsymptoms. Thus, it is important that a full medical evaluation be conducted before a psychiatric referral is suggested. This obviates any misunderstanding by patients who believe that their problem has a medical basis and who may view the referral as an inappropriate dismissal of their symptoms.

CHAPTER 166 EVALUATION OF DIZZINESS

AMY A. PRUITT

Dizziness can be one of the more frustrating complaints to assess; the task is often made difficult by a vague history and a large number of possible causes, ranging from psychiatric disease and cardiovascular disorders to peripheral and central defects within the nervous system. However, with a bit of patience and careful attention to the history and physical examination findings, the primary physician can conduct a remarkably sophisticated clinical evaluation, one that will help direct further workup and treatment. With the problem of true vertigo, an additional goal of the clinical examination is at times to provide immediate bedside relief from the symptom for those patients who are found to have benign positional vertigo.

PATHOPHYSIOLOGY AND CLINICAL PRESENTATION

The patient complaining of "dizziness" may have a malfunction of virtually any organ system, including vestibular dysfunction, cardiovascular insufficiency, psychiatric illness, metabolic derangement, multiple sensory deficits, cerebellar disease, or a combination of problems.

Vestibular Disease

Patients with vestibular disease experience *true vertigo,* which is defined as a head sensation of abnormal movement or (and the distinction does not matter) abnormal movement of the environment. Descriptive terms include not only "spinning" but also "weaving," "seasickness," "ground rising and falling," "rocking," "things moving," and "merry-go-round" sensation. Nausea, vomiting, and diaphoresis accompany severe cases. Tinnitus and hearing loss indicate associated injury to the auditory component of the eighth cranial nerve. Nystagmus is frequently found on examination (see below) or can be induced.

The vestibular problem may be *central* or *peripheral;* peripheral lesions include those that are *cochlear* or *retrocochlear.* Central lesions differ from peripheral ones in that they typically present with vertigo in association with other brainstem deficits; in peripheral disease, vertigo occurs in isolation except for accompanying tinnitus or hearing loss.

Peripheral Lesions. In *benign positional vertigo,* a common problem in the elderly, vertigo is experienced only in specific positions. Onset is sudden, usually within a few seconds after the triggering position has been assumed. Symptoms cease after several minutes if the patient does not move, but they resume with further change in position. In many patients, the condition resolves within 6 months; recovery is usually complete. Head trauma sometimes results in this type of temporary vertigo. The mechanism is stimulation of the labyrinth by free-floating particulate matter in the posterior semicircular canal. A less common but more persistent cause of positional vertigo is thought to be vascular compression of the vestibular nerve. Patients with this condition have constant positional vertigo and severe nausea; it has been labeled *"disabling positional vertigo'* to distinguish it from the more common forms of positional vertiginous disease.

Ménière's disease ensues from idiopathic endolymphatic hydrops, with damage to the hair cells caused by swelling of the semicircular ducts. Patients report tinnitus, pressure in the ear, and hearing loss in conjunction with vertigo. Episodes are paroxysmal, last minutes to hours, and then decrease in frequency after multiple attacks, only to recur in several months or years. Hearing loss and tinnitus usually accompany the episodes of vertigo, and the hearing loss, although initially reversible, eventually becomes permanent.

Acute labyrinthitis develops as a consequence of viral infection involving the cochlea and labyrinth. The patient reports a viral upper respiratory syndrome followed by onset of vertigo, tinnitus, and hearing loss. Symptoms resolve entirely by 3 to 6 weeks, with no residual deficits. Vestibular neuronitis is believed to be the same illness, without any cochlear involvement; it is characterized by isolated vertigo, no hearing loss, and full clearing.

Ototoxins can injure the peripheral vestibular apparatus, although hearing impairment usually predominates. Streptomycin and gentamicin are among the toxins that are most injurious to the vestibular portion of the eighth cranial nerve.

Acoustic neuroma (Benign schwannoma of the eighth cranial nerve), the most worrisome of the peripheral lesions, is retrocochlear in location. It is distinguished from the others in that it causes the retrocochlear type of hearing loss (see below) and can produce serious brainstem compression if untreated. Symptoms start almost imperceptibly, with mild hearing loss, tinnitus, and vague dizziness, and may resemble those of other forms of peripheral vestibular disease. However, the clinical course is progressive and the hearing loss is asymmetric, which differentiates it from that associated with other peripheral lesions.

Central Lesions, as already noted, are accompanied in most instances by other brainstem symptoms. In addition, the vertigo and any accompanying nystagmus can be bidirectional or vertical, which does not occur in peripheral vestibular disease.

Multiple sclerosis associated with focal demyelination in the vestibular pathways of the brainstem is an important central cause of vertigo. Because of the often transient nature of attacks (days to weeks) and the subtlety of accompanying symptoms (slight facial numbness or huskiness of voice), multiple sclerosis may at first be mistaken for one of the self-limited peripheral causes of vertigo. Only with repeated episodes might the diagnosis become evident. The population afflicted with multiple sclerosis in general is younger than the patients (median age of 54 years) with canalithiasis as a cause of benign positional vertigo. In the aftermath of an acute attack, a central type of positional nystagmus may persist after the vertigo resolves. The vertigo has no characteristic features; attacks can be sudden, transient, recurrent, or persistent. Diagnosis depends on magnetic resonance imaging (MRI) evidence of discrete central nervous system lesions and a course of recurrent dysfunction and intervals of remission.

Vertebrobasilar insufficiency usually produces vertigo in conjunction with diplopia, sensory loss, dysarthria, dysphagia, hemiparesis, and other brainstem deficits. Self-limited episodes are manifestations of transient ischemic attacks. In about one fourth of cases, transient vertigo may be the initial and sole complaint and may indicate impending infarction in the territory of the anterior inferior cerebellar artery. A more subtle, progressive form of dizziness, usually without true vertigo, can be seen when multiple lacunar infarctions are present, particularly if the pons is involved. The MRI appearance of this so-called *ischemic pontine rarefaction* can be quite dramatic.

Migraine-associated vertigo has been diagnosed by some neurologists. The dizziness often antedates the headache phase of the syndrome and can persist in a less vivid form after the migraine headache is over. This is an atypical form of migraine with aura and may respond to migraine prophylactic medicines (see Chapter 165).

Drugs that suppress the reticular activating system of the brainstem (e.g., sedatives, anticonvulsants) can cause vertigo of a central nature, especially when taken in excess. Therapeutic doses of some drugs (e.g., phenytoin, carbamazepine) produce nystagmus.

Cardiovascular Disease

Cardiac and vascular insufficiency leading to inadequate cerebral perfusion can result in dizziness, which patients tend to describe as *"light-headedness'* or a sense of faintness (see Chapter 24). This form of dizziness is seen in patients with fixed or limited cardiac output, serious cardiac dysrhythmias, diminished vascular tone, or severe intravascular volume depletion. Symptoms typically worsen on standing and improve on lying down; postural changes in blood pressure and pulse are characteristic.

Multiple Sensory Deficits, Cerebellar Disease, and Other Causes of Disequilibrium

These neurologic problems produce sensations of *impaired balance* and *disequilibrium.* In this form of dizziness, patients report the sensation to be in the feet rather than in the head. Like light-headedness, it may come on with standing; like true vertigo, it can be aggravated by walking or turning. Multiple sensory deficits are the most common cause. Patients with multiple sensory deficits are usually elderly and have diabetes or other conditions that impair eyesight, sense of position, and motor function. Symptoms typically worsen in the dark (because of elimination of visual positional data) and improve with use of a cane or holding onto a railing. Elderly patients with disequilibrium may also have degenerative cerebellar disease, but the presence of multiple lacunar infarctions leading to ischemic pontine disease should be considered. The physical examination findings are notable for ataxia and other cerebellar signs. Acute disequilibrium may be caused by a midline cerebellar hemorrhage and present as severe dizziness, marked gait ataxia, headache, and stiff neck.

Psychiatric Illness

Patients with psychiatric difficulties complain of ill-defined dizziness ("I just feel dizzy"), constant "light-headedness," or a "foggy" feeling. *Depression, anxiety states,* and *psychosis,* in addition to the *medications* used to treat such conditions, are common precipitants. The precise mechanism of the light-headedness is unknown, but it is thought to be related to a confusional state induced by these illnesses or by the medications used to treat them. In the case of a panic attack leading to hyperventilation (see Chapter 226), the ensuing metabolic alkalosis usually causes paresthesias and light-headedness, although sometimes vertigo is reported.

Metabolic Disturbances

Alterations in central nervous system metabolic homeostasis can cause dizziness resembling that associated with inadequate cerebral perfusion. The patient describes light-headedness or feeling faint. Precipitants of acute symptoms include *hypoglycemia, hypoxia, hypocarbia, hypercarbia,* and *drugs.*

DIFFERENTIAL DIAGNOSIS

Conditions that cause dizziness can be grouped according to pathophysiologic mechanism (Table 166.1). Vestibular disease is divided into central and peripheral types. Central lesions are mostly caused by basilar artery disease and multiple sclerosis. Peripheral causes include acoustic neuroma, benign positional vertigo, vestibular neuronitis, Ménière's disease, and ototoxic drugs.

Vestibular Disease
  Benign positional vertigo
  Vestibular neuronitis and ototoxic drugs
  Ménière's disease
  Acoustic neuroma and other tumors of the cerebellopontine
    angle
  Basilar insufficiency
  Multiple sclerosis
Cardiac and Vascular Disease
  Critical aortic stenosis
  Carotid sinus hypersensitivity
  Volume depletion and severe anemia
  Autonomic insufficiency (drugs, diabetes)
  Diminished vascular reflexes of the elderly
Multiple Sensory Deficits
  Diabetes mellitus
  Cataract surgery
  Some cases of multiple sclerosis
  Cervical spondylosis
  Cerebellar disease
Psychiatric Illness
  Anxiety
  Depression
  Psychosis
Metabolic Disturbances
  Hypoxia
  Severe hypoglycemia
  Hypocapnia and hypercapnia

Table 166.1. Differential Diagnosis of Dizziness

Cardiac and vascular diseases are a second important group. Faintness on standing may be caused by critical aortic stenosis, severe volume depletion, the use of antihypertensive drugs, autonomic insufficiency, or prolonged confinement to bed. Carotid sinus hypersensitivity results in inappropriate reduction of vascular tone.

Multiple sensory deficits are most common in diabetics and others with poor vision and peripheral neuropathies. Cervical spondylosis disturbs cervical sensory input and contributes to dizziness. Lenses used by patients following cataract surgery distort peripheral vision and can confuse their sense of position. Cerebellar dysfunction leads to a similar clinical presentation of gait unsteadiness. Less commonly, idiopathic normal pressure hydrocephalus can present with unsteadiness of gait or disequilibrium.

Psychiatric problems are often associated with light-headedness. Patients with anxiety, depression, and psychosis report feeling light-headed. At times, tranquilizers and antidepressants are responsible. Panic attacks frequently are accompanied by feelings of light-headedness or dizziness. Metabolic disturbances affecting the central nervous system have a similar presentation; hypoxia, hypoglycemia, hypocapnia, and hypercapnia are among the most important features.

In a study of 104 consecutive cases referred for evaluation of dizziness, 38% of patients had peripheral vestibular disease, 23% had hyperventilation, 13% had multiple sensory deficits, 9% had psychiatric problems, and 5% had cardiovascular or central neurologic illness. Many cases are multifactorial.

WORKUP

History

The most important initial step in the evaluation of dizziness is to obtain from the patient the best possible description of the experience and what is meant by "dizziness." A history taken without leading questions or suggested descriptions is most likely to provide meaningful clues. *True vertigo* suggests *vestibular disease; faintness* that is *postural* or paroxysmal implies a *cardiovascular* disorder; constant *ill-defined dizziness* or light-headedness unrelated to posture points toward a *psychogenic* cause; a feeling of *poor balance* or disequilibrium typifies *multiple sensory deficits* and *cerebellar* causes.

When the problem is light-headedness, it is worth asking if standing or turning brings on symptoms. If standing does, the use of antihypertensive, tranquilizer, or antidepressant medications should be investigated. During the examination, postural signs, carotid upstroke, and cardiac function should be evaluated, especially for signs of hemodynamically significant aortic stenosis. If turning worsens the situation, it is important to evaluate vision, search for other sensory deficits, and check for cerebellar signs (see below). If light-headedness is a constant sensation, an underlying psychiatric or metabolic disorder is likely. Anxiety and depression are frequent causes and warrant investigation (see Chapter 226 and Chapter 227).

Central versus Peripheral Disease. If the patient has *true vertigo,* then the task shifts to determining whether the lesion is *central* or *peripheral.* The most direct way of making this distinction is to inquire about brainstem symptoms (e.g., diplopia, facial numbness, weakness, hemiplegia, dysphasia). Evidence of brainstem involvement rules out a peripheral lesion. The absence of brainstem symptoms does not rule out a central lesion but does make it improbable. Even the very confusing picture of apparently isolated vertigo resulting from vertebrobasilar insufficiency or multiple sclerosis eventually becomes clearer as accompanying brainstem symptoms become more evident. The pattern of discrete central nervous system lesions and a course of recurrent episodes followed by remissions further suggest the diagnosis of multiple sclerosis (see Chapter 172). Vertebrobasilar insufficiency should be considered in the patient with multiple atherosclerotic risk factors or a prior history of cardiovascular or cerebrovascular disease.

Distinguishing among Peripheral Causes. In the patient with a suspected *peripheral lesion,* the focus turns to distinguishing *cochlear* from *retrocochlear* disease–that is, relatively benign causes from acoustic neuroma. The latter has a variable presentation and can initially mimic other peripheral types of vertigo. Episodes of vertigo, tinnitus, pressure in the ear, and hearing loss may take place, simulating Ménière's disease. However, the hearing loss is slowly and steadily progressive, rather than fluctuating or episodic. The development of brainstem symptoms (facial weakness or numbness) is a late occurrence and not very helpful for early diagnosis. When doubt still persists, physical examination and audiologic testing can be used to help make the differentiation between cochlear and retrocochlear disease (see below).

Timing and *precipitating factors* help elucidate most other peripheral causes of vertigo. If symptoms occur only on change of position and last but a few moments, the

diagnosis is benign positional vertigo, a condition mostly affecting people older than age 60. It may be a recurrent problem. A single bout of severe spontaneous vertigo, sudden in onset, sometimes after a *viral illness,* is usually vestibular neuronitis. When seen in the context of inner ear infection, it is properly called *acute labyrinthitis.* Some degree of positional vertigo may remain after the acute illness resolves. Ménière's disease is suggested by acute, recurrent paroxysms of vertigo that are accompanied by *tinnitus* and temporary *hearing loss.* Tinnitus, *pressure* in the ear, and hearing loss are episodic and may precede the other symptoms. Attacks can last for hours to days; residual positional vertigo occurs in 25% of cases.

Drug History. Obtaining a thorough *drug history* is important. The ototoxic effects of the aminoglycoside antibiotics have been well documented; the diuretic ethacrynic acid also can cause injury to the eighth nerve, especially in patients with compromised renal function. Diuretics may be responsible for severe volume depletion. Vasodilators, phenothiazines, and antihypertensive agents can produce postural light-headedness. Antidepressants and minor tranquilizers cause some patients to feel dizzy.

Physical Examination

The *general appearance* of the patient can be quite informative (e.g., the anxious person will appear overly nervous and may hyperventilate or sigh frequently during the interview). *Blood pressure* and pulse should be measured, and changes between readings taken in the *supine* and *standing* positions should be noted. The skin is examined for pallor, the eyes for *nystagmus* (a few beats of nystagmus on extreme lateral gaze are normal), and the ears for tympanic membrane lesions and *hearing acuity* (see below). The carotid arteries in the neck are checked for bruits (suggestive of cerebrovascular disease) and delay in upstroke (characteristic of severe aortic stenosis). A forceful, sustained left ventricular impulse, single second heart sound, and loud ejection quality murmur on cardiac examination also support a diagnosis of significant aortic stenosis (see Chapter 21).

A thorough and careful *neurologic examination* is essential, particularly when the possibility of central vestibular disease is being considered. Most important is examination for a brainstem lesion, which suggests central pathology or extrinsic compression by an acoustic neuroma. *Cranial nerves* V, VII, and X can be affected by a large acoustic neuroma pressing at the cerebellopontine angle of the brainstem. Testing of sensory function, peripheral vision, and gait often reveals multiple defects in elderly patients troubled by dizziness. Results of the *Romberg test* (standing with feet together, eyes closed) will also be abnormal in such patients, and also in some with vestibular disease. The side to which the vertiginous patient sways helps to localize the lesion. Cerebellar testing helps to detect any ataxia.

Provocative Maneuvers designed to trigger symptoms and reproduce the patient's problem can be extremely useful. Asking the anxious patient to *hyperventilate* voluntarily for 30 to 120 seconds will often reproduce "dizziness" and associated symptoms, whereas vestibular maneuvers (see below) will not. *Standing up* from a supine position will cause the patient with cardiac or vascular disease to feel faint; it may trigger vertigo in the patient with vestibular disease. *Walking* and *turning* will cause a feeling of disequilibrium in the patient with multiple sensory deficits, cerebellar disease, or vestibular dysfunction. The *Dix-Hallpike* or *Bárány maneuver* and other forms of vestibular stimulation (see below) will trigger vertigo and associated symptoms.

Maneuvers Alleviating Symptoms are also of diagnostic use. Getting up slowly lessens the faint feeling associated with cardiovascular causes; *rebreathing into a paper bag* reduces the light, giddy feeling that follows hyperventilation; *lying still* in one position may halt positional vertigo; touching the examiner's hand or using a cane to walk helps the patient with sensory deficits or cerebellar dysfunction. Withholding suspected drugs may be informative.

Simple Office Tests of hearing and stimulation of the vestibular apparatus can be very helpful in distinguishing central from peripheral disease and cochlear from retrocochlear peripheral disease. The *Rinne test* (see Chapter 212) identifies which eighth cranial nerve is involved and helps differentiate between conductive and sensorineural hearing loss. Patients with a sensorineural hearing deficit may have a cochlear or a retrocochlear lesion. The distinction can be made by testing *speech discrimination,* which is easily performed in the office by whispering a series of 10 two-syllable, closely linked words (e.g., baseball, ice cream) into the patient's ear while making a sound in the other ear to limit its participation. The patient is asked to repeat each whispered word. Correctly identifying fewer than 20% of the words is very suggestive of a retrocochlear lesion (which causes a disproportionate loss of speech discrimination); a score of 70% or better indicates that the problem is cochlear. Scores in between these are indeterminate and necessitate formal audiologic testing (see Chapter 212).

Vestibular Stimulation Testing serves both as a good provocative test for reproducing symptoms (useful when the description of dizziness remains unclear) and as a means of distinguishing peripheral from central vestibular disease. The *Dix-Hallpike (Bárány) maneuver* is the least noxious of the standard forms of vestibular stimulation. The patient starts in a sitting position on the examination table and lies down with the head extending over the edge of the table, tilted back, and turned 45 degrees to one side. The assumption of this position need not be overly abrupt, but it should be held for at least 30 seconds. The maneuver is repeated, this time with the head turned 45 degrees to the opposite side. For a final time, the test is repeated without turning the head. (Fig. 166.1)

FIG. 166.1. Bárány's test for vestibular disease. (©1981, Ciba Pharmaceutical Company, Division of Ciba-Geigy Corporation. Reproduced from Clinical Symposia by Frank H. Netter, M.D., with permission. All rights reserved.)

The Dix-Hallpike maneuver provides simultaneous stimulation of all three semicircular canals. It is a useful provocative maneuver for identifying vestibular disease and potentially helpful in separating peripheral from central lesions. One asks the patient to look straight ahead and watches for onset of nystagmus (horizontal or rotatory) and reproduction of symptoms. If symptoms occur, one asks to which side things seem to be spinning; if nystagmus ensues, one notes to which side the slow phase moves. By combining these results with findings from the Romberg and Rinne tests, one can make a diagnosis of a peripheral lesion if (a) the slow phase of nystagmus moves toward the same side as the hearing loss, (b) the patient reports that the spinning is away from the side of the hearing loss, (c) the Romberg test result is positive and the patient sways toward the side of the hearing deficit. Absence of any one of these findings suggests a central lesion.

Other findings on head position testing suggestive of central vestibular disease are immediate onset of nystagmus and vertigo (peripheral disease has a latency period of 3 to 40 seconds), failure of nystagmus and vertigo to resolve (symptoms usually disappear within 30 seconds), and failure of the patient to adapt on repeated testing.

Laboratory Studies

Electronystagmography and *audiologic testing* are indicated when clinical and provocative data are insufficient to differentiate between central and peripheral causes of vertigo (see Chapter 212).An extensive battery of posturographic and other vestibular tests is reserved for those patients in whom the diagnosis is not apparent after history and initial physical examination. If acoustic neuroma is suspected, then one should consider *brainstem auditory evoked response* testing. It represents a cost-effective audiologic means of differentiating cochlear from retrocochlear disease. *MRI* of the internal auditory canal and cerebellopontine angle should follow if evidence of a retrocochlear lesion emerges from the clinical examination and audiologic testing. MRI is the most sensitive test for a small intracanalicular schwannoma. However, MRI is too often obtained simply to rule out a schwannoma in any dizzy patient. The probability of a patient with vertigo and no characteristic hearing loss having a vestibular schwannoma is less than 1in 9,000; the probability increases slightly (to 1 in 600) for patients with dizziness and asymmetric hearing loss. If basilar transient ischemic attacks are suggested by transient, isolated vertiginous spells in a person with multiple atherosclerotic risk factors, then MRI with *magnetic resonance angiography* should be considered; it provides an excellent (although expensive) noninvasive means of detecting atheromatous disease of the

vertebrobasilar circulation.

SYMPTOMATIC THERAPY AND PATIENT EDUCATION

Dizziness can be controlled in most instances and in some situations cured virtually at the first visit. Therapy is aimed at the underlying pathophysiology. The vast majority of people with dizziness have benign disorders. Symptomatic therapy combined with explanation and reassurance is always comforting and appreciated. In particular, patients tolerate their problems better when they know that in most instances the symptom can be controlled or will resolve on its own.

Peripheral Vestibular Disease. *Benign positional vertigo* responds to a bedside *maneuver* introduced by Epley. The maneuver relocates free-floating debris from the posterior semicircular canal into the vestibule of the vestibular labyrinth, where it no longer causes vertigo during head movement (Fig. 166.1). An 80% success rate after a single treatment is reported. The recurrence rate for a 30-month period is about 30%. Patients with a more widespread balance problem may benefit from *balance–vestibular rehabilitation therapy*. When carried out under the supervision of a trained therapist, such therapy can effectively reduce positionally provoked vertigo through vestibular "retraining" (i.e., adaptation of the central nervous system to a peripheral vestibular abnormality). The use of drugs such as *meclizine* (25 to 50 mg every 6 hours as needed) and *promethazine* (25 mg every 6 hours as needed) is now reserved for patients who have not responded satisfactorily to the Epley maneuver. Indeed, prolonged use of such vestibular suppressants may delay central adaptation. Moreover, these drugs are sedating and can cause drowsiness (which may be welcome to a patient having an acute attack but is an adverse effect in the treatment of chronic disease). Low-dose meclizine (12.5 mg three times daily) is quite sufficient in elderly patients and causes less sedation. Other drugs used to decrease acute vertigo include *dimenhydrinate* (Dramamine; 50 mg every 6 hours), which is more rapid in onset than meclizine, and the *benzodiazepines*.

Ménière's disease is usually managed with salt restriction and diuretics. Strong empiric evidence exists for restricting salt intake to the range of 1 g of sodium per day for 6 months to 1 year. Caffeine and alcohol should also be avoided. Diuretics (e.g., 250 mg of acetazolamide twice daily or 50 mg of hydrochlorothiazide twice daily) provide additional benefit.

Central Vestibular Disease. Whereas patients with peripheral causes of dizziness typically recover within months, patients with central causes of dizziness may be bothered for years. Some patients may be helped with *lorazepam* (Ativan; 1 to 2 mg twice daily). *Gait training* and *vestibular exercises* under the supervision of a trained therapist may be beneficial. In patients with chronic vertigo, the goal is to retrain the eye and body musculature to compensate for the loss of vestibular input.

Multiple Sensory Deficits or Cerebellar Dysfunction benefits from the placement of handrails in the home, good lighting, and the use of a cane or walker. Vertigo and disequilibrium caused by lesions of the cerebellum, the area around and including the vestibular nucleus, or the floor of the fourth ventricle may be associated with persistent ataxia and nausea.

Cardiovascular Faintness also requires etiologic therapy supplemented by adequate hydration, standing up slowly, and discontinuing or reducing offending drugs (see Chapter 24). The patient with critical aortic stenosis should undergo evaluation for valve replacement (see Chapter 33).

Psychogenic Light-headedness may be refractory to symptomatic therapy, although *rebreathing into a paper bag* is effective for acute hyperventilation. Treatment with an *anxiolytic* agent may help, but it can also cause symptoms (see Chapter 226). *Antidepressant* therapy is indicated when depression is the predominant cause, although a side effect of some antidepressants is postural light-headedness (see Chapter 227).

CHAPTER 167 FOCAL NEUROLOGIC COMPLAINTS: EVALUATION OF NERVE ROOT AND PERIPHERAL NERVE SYNDROMES

AMY A. PRUITT

Primary physicians are frequently asked to evaluate complaints of focal numbness, tingling, weakness, pain, or some combination of these. In general, major acute neurologic disease is not at issue during an office visit. Nevertheless, the broad range of outpatient problems encountered encompasses lesions throughout the nervous system. Disorders of the nerve roots and peripheral nerves in the upper and lower extremities are especially common. The primary physician should be able to analyze several of these syndromes. The identification and localization of such problems can facilitate a thorough neurologic evaluation and accurately segregate those cases that must be referred to a neurologist.

PATHOPHYSIOLOGY AND CLINICAL PRESENTATION

Many peripheral nerves, because of their superficial location, are easily injured mechanically, and others are vulnerable because of specific anatomic variants or because of alterations in anatomy caused by degenerative disease.

Upper Extremity Syndromes

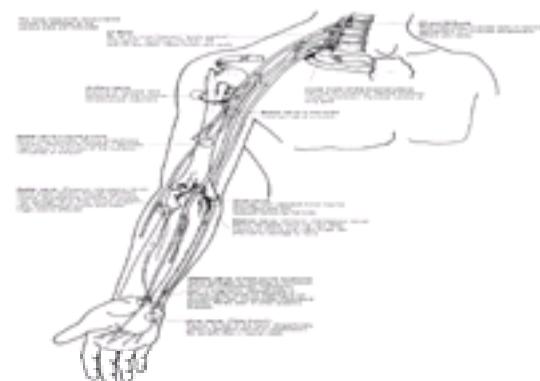
Cervical Radiculopathy and Myelopathy. Age-related loss of water and elasticity in cervical disks leads to increased stress on the vertebral bodies. Osteophytic spurs develop and may encroach on nerve roots. More serious but less common is encroachment on the spinal cord itself by progressive cervical spondylotic changes. Usually, a combination of radiculopathy involving the C-5, C-6, or C-7 roots (Fig. 167.1 and Fig. 167.2) and myelopathy is present. Cord compression resulting from spondylosis is indicated by radicular pain, variable weakness, diminished reflexes, and atrophy in the arms, with spastic weakness and hyperreflexia in the lower extremities.


FIG. 167.1. Peripheral nerve distribution to the upper limb. (From Patten J. Neurological differential diagnosis. New York: Springer-Verlag, 1977, with permission.)
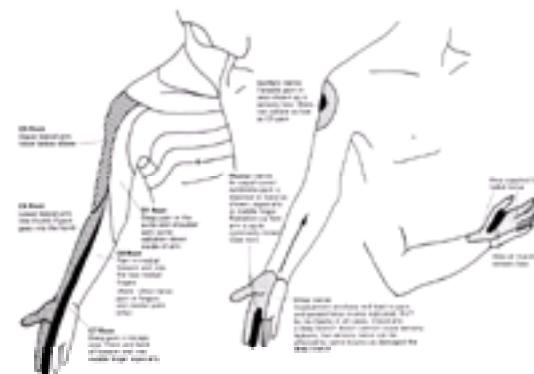

FIG. 167.2. Left: Distribution of root pain and paresthesia. **Right:** Distribution of peripheral nerve pain and paresthesia. (From Patten J. Neurological differential diagnosis. New York: Springer-Verlag, 1977, with permission.)

It may be difficult to distinguish cervical spondylotic myelopathy from other progressive myelopathies, which include multiple sclerosis, subacute combined degeneration associated with vitamin B$_{12}$ deficiency, spinal tumor, and syringomyelia. Suspicion of myelopathy should prompt referral to a neurologist.

Radiologic assessment usually includes *cervical spinal radiography.* Unfortunately, nearly 50% of patients older than age 50 show degenerative changes of the cervical spine on radiographic films, and these do not correlate well with the degree of abnormality found clinically in either radiculopathy or myelopathy. Nevertheless, plain films of the cervical spine with oblique views to visualize the neural foramina are often informative. *Magnetic resonance imaging* (MRI) is the best noninvasive test to assess the degree of cervical spondylosis or disk protrusion. It should be ordered when radicular pain is severe or when a motor or sensory deficit, reflex change, or myelopathic finding is present.

If the patient has only radiculopathy, a conservative trial of cervical traction is sometimes helpful (see Chapter 148). If myelopathy is suspected, myelography may be necessary to define the extent of compression, rule out neoplastic lesions, and assist the surgeon in making a decision about decompressive laminectomy.

Brachial Plexus Neuritis, a painfully disabling condition, develops in some patients after an immunization or viral infection and in others without any antecedent illness. It presents with severe pain in the shoulder and upper arm followed by weakness. Usually, the upper roots of the plexus are involved more than the lower ones. The prognosis is ultimately good, but recovery may be prolonged. Clinical examination reveals variable weakness and sensory loss in the C-5 to T-1 root distributions (Fig. 167.2), with diminished deep tendon reflexes. Because many nerve roots are involved, confusion with a cervical disk problem does not usually arise. Electromyography and nerve conduction studies help to localize the abnormality. MRI of the brachial plexus with gadolinium enhancement may be valuable in excluding neoplastic disease of the plexus.

Thoracic Outlet Syndrome. A cervical rib or bony abnormality of the first rib may cause pressure on the subclavian artery or brachial plexus as it passes through the thoracic outlet (Fig. 167.1). The diagnosis is primarily clinical and is based on the presence of pain in the arm in certain positions, color changes in the hand, and a pattern of sensory loss and weakness most pronounced in the fourth and fifth fingers. Deep tendon reflexes are usually normal. A bruit may be heard over the subclavian artery. The differential diagnosis includes Raynaud's phenomenon, ulnar nerve entrapment at the elbow, and compression of the brachial plexus by neoplasm or fibrosis resulting from radiation.

Radiography of the cervical spine is extremely important to demonstrate cervical ribs or elongated transverse processes of the seventh cervical vertebra. Results of electromyography may be entirely normal, but it will help to exclude a defect at the elbow or a carpal tunnel syndrome. Ultrasonography of the subclavian artery with the arm held in different positions may help define the extent of compression.

Most surgeons advocate removal of the potentially constricting structures (cervical rib, fascial band to first rib, or first rib). Shoulder exercises to improve posture are often advised first, and orthopedic advice should be sought in each case.

Long Thoracic Nerve Entrapment. This nerve arises from the brachial plexus and innervates the serratus anterior. It is vulnerableto injury in workers who lift or push heavy loads, occurs after direct trauma from heavy backpacks, and may evolve for several months after the injury. The patient notes a change in the appearance of the shoulder, and examination reveals winging of the scapula. Most cases have a good prognosis.

Carpal Tunnel Syndrome. In this disorder, the median nerve is entrapped at the carpal tunnel (Fig. 167.1) because of pressure from ligamentous thickening. Most cases are idiopathic, but the disorder may be seen with rheumatoid arthritis, pregnancy, acromegaly, hypothyroidism, fractures of the carpalbones, amyloidosis, and myeloma. Occupational causes involving repetitive traumatic actions have been implicated. A combination of pain, paresthesias, and numbness in the median nerve distribution is the earliest complaint; symptoms are often worse at night (Fig. 167.2). Later, muscle weakness (particularly of thumb abduction and apposition) occurs, and thenar atrophy may be seen. Importantly, aching pain can be felt as far up as the shoulder and should not distract the examiner's attention from the wrist. Tapping on the wrist or anywhere else along the median nerve may reproduce the pain (*Tinel's sign*).

The differential diagnosis includes radiculopathy from cervical spine disease, but the exact location of the pain should conform to the median nerve rather than to the distribution of just one nerve root. Electromyography and *nerve conduction studies* with motor and sensory conduction latencies of the median nerve provide the most useful data. Although some cases respond to conservative therapy (wrist splints, antiinflammatory medications), surgical relief is relatively easy and effective. Failure to respond to surgical therapy should prompt rechecking of the nerve conduction studies, careful reexamination, and consideration of the possibility of coexistent cervical spine disease or of median nerve compression higher in the forearm.

Ulnar Nerve Entrapment. The most common location of ulnar entrapment is the elbow (Fig. 167.1). Causes include fracture deformities, arthritis, faulty positioning of the arm during surgery, or repetitive occupational or recreational trauma (e.g., tennis). Sensation is usually spared in the forearm, but sensory loss occurs in the fifth finger and half of the fourth (Fig. 167.2). Wasting of the intrinsic muscles of the hand with weakness of grip occurs later. Nerve conduction studies can accurately localize the site of compression. If focal entrapment is present, repositioning of the nerve or elbow synovectomy may be necessary, but patients with trauma, diabetes, or the so-called "tardy"ulnar palsies (dysfunction developing late after injury) may not improve.

Radial Nerve Injuries. Compression of the radial nerve most often occurs in the axilla or upper arm. It may be caused by improperly used crutches, prolonged pressure during sleep (the "Saturday night" palsy), or direct injury. Wrist drop is the prominent feature. Vasomotor or atrophic changes are rarely present, and prognosis is good (recovery within 6 to 8 weeks).

Lower Extremity Syndromes

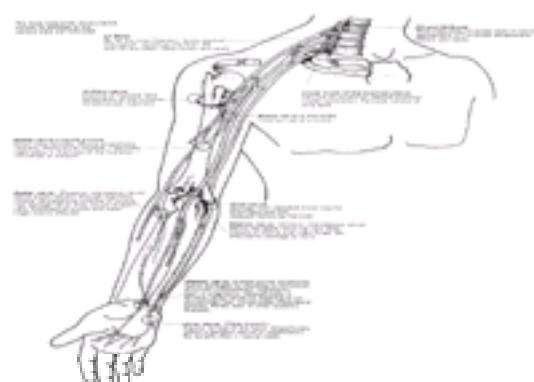
Lateral Femoral Cutaneous Nerve Compression. Also known as *meralgia paresthetica,* this syndrome involves a nerve formed by branches arising from the second and third lumbar roots. The nerve enters the thigh in close relation to the inguinal ligament, the anterior superior iliac spine, and the sartorius muscle insertion (Fig. 167.3). It is purely sensory and supplies the anterolateral and lateral aspects of the thigh almost as far as the knee (Fig. 167.4). Compression causes an extremely unpleasant, characteristic burning pain with increasedcutaneous sensitivity. Sitting or lying usually provides relief, but standing or walking exacerbates the pain. The syndrome often occurs in obesity, in pregnancy, or when tight corsets are worn. It is more common in diabetics. The differential diagnosis includes a lesion of the second or third lumbar roots, usually associated with low back pain radiating into the lower leg. Sensory changes in this case will extend further down the leg and more medially, and iliopsoas or quadriceps weakness is present. Weakness and reflex changes do not occur in meralgia paresthetica. The neuropathy tends to regress spontaneously, but weight loss should be encouraged.


FIG. 167.3. Peripheral nerve distribution to the lower limb. (From Patten J. Neurological differential diagnosis. New York: Springer-Verlag, 1977, with permission)
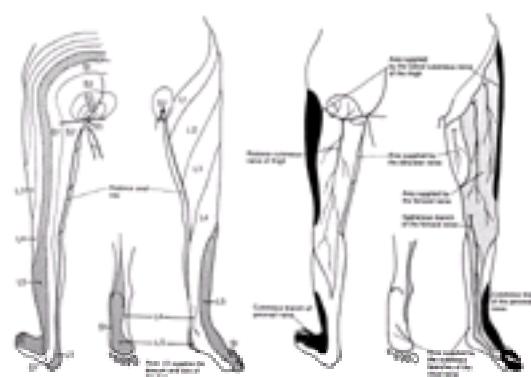

FIG. 167.4. Left: Lumbosacral dermatomes. **Right:** Peripheral nerve distribution to the lower limb. (From Patten J. Neurological differential diagnosis. New York: Springer-Verlag, 1977, with permission.)

Femoral Neuropathy. The femoral nerve derives from the second, third, and fourth lumbar roots. Its posterior division is the major innervation to the quadriceps and terminates as the saphenous nerve, which supplies sensation to the medial aspect of the leg as far as the medial malleolus (Fig. 167.3). The onset of femoral neuropathy is frequently sudden and painful and is followed quickly by wasting and weakness in the quadriceps, loss of knee jerk, and sensory impairment over the anteromedial thigh (Fig. 167.4). If marked hip flexion weakness is also present, the site of the lesion is usually in the lumbar plexus. Sensory symptoms in the saphenous distribution are uncommon in lesions of the main trunk of the femoral nerve.

Entrapment may occur in the inguinal region and from direct retroperitoneal compression by tumor or hematoma. However, the most common cause is presumed to be nerve infarction, seen usually in diabetics. A combination of thigh pain, weakness, and sensory deficit can be a manifestation of an isolated diabetic femoral neuropathy, although electromyographically, the involvement in such cases is frequently more widespread. Although some improvement may occur, the patient is often left quite weak.

Sciatic Nerve Syndromes. The sciatic nerve arises from the lumbosacral plexus (L-4 through S-3) and terminates in the common peroneal and tibial nerves (Fig. 167.3). The tibial nerve supplies the gastrocnemius, plantaris, soleus, and popliteus muscles, and its extension into the calf, the posterior tibial nerve, supplies muscles of the calf. All these muscles are involved in plantar flexion. The common peroneal nerve divides into the superficial and deep peroneal nerves. The latter supplies the muscles of dorsiflexion of the foot and toes. The superficial peroneal nerve innervates the muscles that evert the foot.

Sciatic nerve compression may result from tumors within the pelvis or from prolonged sitting or lying on the buttocks. Gluteal abscesses and misplaced buttock injections have caused sciatic injury. Weakness of the gluteal muscles and pain in the area of the sciatic notch imply compression within the pelvis. Lesions just beyond the sciatic notch cause weakness in the hamstrings and in all the muscles of the lower leg.

Common peroneal compression usually occurs at the level of the fibular head (Fig. 167.3) and is seen in cachectic patients following prolonged bed rest, alcoholics, diabetics, and patients placed in tight casts. Injury leads to faulty dorsiflexion and eversion of the foot, which produces a characteristic foot drop with a slapping gait. Complete or partial recovery can be expected when paralysis results from transient pressure. Treatment consists of a foot brace and careful avoidance of compressive positions.

Lumbar Disk Syndromes. Compressive neuropathies of the lower limbs must be distinguished from the very common lumbar disk syndromes. In the lumbar region, the fourth and fifth disks are most frequently affected (i.e., the disks between the L-4 and L-5 vertebral bodies and between the L-5 and S-1 vertebrae). The most common complaint is the sudden onset of severe low back pain (see Chapter 147). The inciting event is often trivial, although heavy lifting or an acute twisting motion is sometimes reported. The pain is worsened by bending forward, sneezing, or straining.

The herniated disk can compress one or more nerve roots, but a disk herniation at a particular level generally causes a distinctive picture (see Chapter 147). *Herniation of the L4-5 disk* usually affects the L-5 root, causing pain over the sciatic notch, lateral thigh, and leg; numbness of the web of the great toe and lateral leg; weakness of dorsiflexion of the great toe and foot; and no reflex changes (Fig. 167.4). *Herniation of the disk between L-5 and S-1* catches the S-1 root, producing pain down the back of the leg to the heel; numbness in the lateral heel, foot, and toe; weakness of plantar flexion; and loss of the ankle jerk (Fig. 167.4). Once the root level is defined, the usual course is a trial of conservative therapy (see Chapter 147). However, when any combination of progressive limb weakness and numbness (especially if bilateral), uncontrollable pain, saddle anesthesia (numbness in the distribution of S-2 and S-3), and bladder and bowel dysfunction is noted, then emergent MRI examination (or myelography if MRI is not available) is needed to rule out *cauda equina syndrome.* Imaging of the spinal canal is required to detect any caudal compression and to rule out more unusual causes of lumbar radiculopathy, such as neurofibroma. MRI may also be helpful in predicting the response of a patient with disk disease to conservative therapy.

Peripheral Polyneuropathy. When patients present with distal, symmetric sensorimotor or predominantly motor symptoms and are found to have diminished sensation or motor abnormalities in a "stocking–glove" distribution with variably hypoactive deep tendon reflexes, they are likely to have a peripheral polyneuropathy. The list of causes is extensive (Table 167.1). Although most produce some degree of motor and sensory dysfunction, usually one component predominates. Sensorimotor conditions present principally with sensory deficits, although a more mixed picture develops later. Diabetes is a common source of sensorimotor polyneuropathy; symptoms respond to a tightening of glucose control (see Chapter 102). Alcoholism, deficiencies of B vitamins, renal failure, hypothyroidism, AIDS, and paraneoplastic syndromes are among the other causes. The most dramatic of the predominantly motor polyneuropathies is Guillain-Barré syndrome, an acquired autoimmune disease; the typical presentation is one of acute onset following a viral illness and rapid progression of ascending weakness over a few days in conjunction with a loss of deep tendon reflexes. Other predominantly motor polyneuropathies include those associated with monoclonal gammopathy, toxin exposure, and porphyria. A predominantly sensory polyneuropathy is seen with amyloidosis, paraneoplastic syndromes, vitamin B$_6$ excess, and Sjögren's syndrome.

Table 167.1. Important Peripheral Polyneuropathies

WORKUP

Peripheral Polyneuropathy

The primary physician's objective should be to discern by history and physical examination any diagnostically important variations in the peripheral polyneuropathy theme.

History includes a review of duration (years suggests a hereditary cause; weeks to months, a toxic/metabolic cause or a paraproteinemia; days, a toxin or Guillain-Barré syndrome). The distribution helps distinguish between polyneuropathy and diabetic mononeuropathy multiplex, which is more multifocal. Medication exposure is essential to review (e.g., cisplatin, isoniazid, vincristine), as are habits (alcohol abuse), diet (especially in regard to deficiencies of B vitamins), and concurrent medical illnesses (diabetes, renal failure, liver disease, cancer).

Physical Examination clarifies the relative sensory and motor components of the problem, helpful in differentiation. Signs of systemic disease may also be revealed.

Laboratory Studies should include a complete blood cell count and a determination of the erythrocyte sedimentation rate and values for blood glucose, serum liver chemistries, blood urea nitrogen, creatinine, and thyroid-stimulating hormone. Chest radiography and immunoelectrophoresis should be performed. Although patients whose neuropathy is apparent from the results of the above studies (e.g., diabetic polyneuropathy) may not require *electromyography,* this procedure helps to differentiate between demyelinating disease and axonal polyneuropathy, and between root or plexus and more distal nerve trunk involvements, distinctions that are of considerable diagnostic importance. Electromyography also distinguishes upper from lower motor neuron weakness. *Nerve biopsy* is infrequently recommended; its main indication is in hereditary disorders, multifocal mononeuropathy multiplex, or asymmetric clinical syndromes, in which it can reveal such underlying conditions as vasculitis, amyloidosis, or sarcoidosis. Patients with monoclonal gammopathy may profit from tests for *antibody to myelin-associated glycoprotein (anti-MAG antibody)* and *anti-GM1 antibody;* these tests can identify patients who are candidates for plasmapheresis or immunosuppressive therapy.

Other Peripheral Nerve Syndromes

Identification of the nerve root or peripheral nerve syndrome and precise localization of the neurologic lesion is possible in the office setting. Assessment is facilitated by determining (a) whether the problem is peripheral (in a nerve root or peripheral nerve) or central (in the cord or above); (b) whether the problem, if peripheral, is caused by a lesion in the peripheral nerve or by nerve root injury; (c) whether evidence of cord compression (manifested by signs of myelopathy) is present, particularly in upper extremity syndromes; (d) whether evidence (in other extremities) of more widespread peripheral neuropathy is present (e.g., the diabetic patient with afemoral neuropathy who also has a diffuse peripheral neuropathy); and (e) whether weakness is caused by a muscle or nerve lesion.

The neurologic examination should be organized to address these issues and answer the following questions:

1. Is the lesion an upper motor neuron or a lower motor neuron lesion? Fasciculations, flaccidity, and a lack of reflexes indicate a lower motor neuron lesion and

suggest that the disorder originates at the anterior horn cell or peripheral nerve level. Spasticity and increased reflexes are evidence for a lesion above the anterior horn cell that supplies the involved musculature. Thus, a cervical disk at the C-6 level might decrease the biceps reflex and cause biceps weakness and atrophy, while increasing reflexes and causing spasticity below that level.

2. Is the nerve dysfunction confined to one root or dermatome or to one peripheral nerve? A positive answer to this question suggests a compression neuropathy such as a radial, ulnar, or median nerve palsy. Findings of more generalized dysfunction, such as diffusely decreased deep tendon reflexes, absent vibration sense at the ankles, and a stocking–glove pattern of sensory loss, suggest a more diffuse peripheral neuropathy. Commonly seen forms of peripheral neuropathy include those associated with diabetes mellitus, excess alcohol consumption, toxin and drug exposure, and genetic conditions such as Charcot-Marie-Tooth disease. An electromyogram can localize the individual nerve abnormality and confirm the presence of a generalized neuropathy.

3. Is the weakness caused by nerve or by muscle disease? Weakness in conjunction with altered tendon reflexes and sensory loss suggests nerve disease. In primary muscle disease, reflexes and normal sensation are preserved. Characteristic patterns of muscle weakness occur in the genetically determined muscular dystrophies. The toxic and metabolic myopathies produce largely proximal muscle weakness, in contrast to almost all the primary nerve diseases, which affect distal musculature early and preferentially. Serum muscle enzyme elevations are seen in muscle disease, and some muscular disorders are associated with myotonia. The electromyogram, coupled with nerve conduction studies, can distinguish primary muscle disease from neuropathic processes.

The clinical identification of nerve root and peripheral nerve syndromes is often facilitated by the selective use of radiologic, nerve conduction, electromyographic, and serologic studies (detailed in discussions of each of the important syndromes). However, laboratory studies are usually not necessary during the initial assessment.

INDICATIONS FOR REFERRAL AND ADMISSION

Evidence of acute spinal cord or cauda equina compression is an indication for immediate neurosurgical consultation and hospitalization. The patient with symptoms and signs of a slowly progressive myelopathy requires neurologic consultation and MRI. Vitamin B$_{12}$ deficiency, multiple sclerosis, and tumor all need to be considered in patients with a progressive myelopathy if mechanical cord compression is excluded by MRI. A root or peripheral nerve compression syndrome may require surgical repair, and the patient with such a problem will need to see a neurosurgeon or orthopedist skilled in its treatment. Nevertheless, before referral, the primary physician should have localized the problem and instituted appropriate initial therapy.

SYMPTOMATIC MANAGEMENT OF PAINFUL PERIPHERAL NEUROPATHY

The mainstay of therapy for painful peripheral neuropathy has been the *tricyclic antidepressants* (e.g., amitriptyline, nortriptyline). *Gabapentin* (Neurontin) has proved similarly effective and is reasonably well tolerated but is much more expensive than generic tricyclic therapy. Other drugs used to treat painful polyneuropathy include mexiletine and topical agents such as *capsaicin* and *lidocaine.* The treatment of painful polyneuropathy requires frequent adjustments of medication type and dose. Some patients may inquire about the efficacy of *plasmapheresis,* which is extremely useful in myasthenia gravis and chronic inflammatory demyelinating polyneuropathy. It is now administered less often in acute Guillain-Barré syndrome in part because IV immune globulin is being increasingly used to treat this condition. Plasmapheresis is also useful in monoclonal gammopathy–associated peripheral neuropathy. Patients with other peripheral neuropathic syndromes are less likely to benefit, and the primary physician should be aware of the limited value of expensive plasmapheresis in conditions other than those mentioned above.

CHAPTER 168 EVALUATION OF TREMOR

AMY A. PRUITT

Tremor is best defined as a regular oscillation of a body part, and it must be distinguished from other rapid, involuntary movements. Many patients assume that the development of "shakiness" is a natural concomitant of aging. The physician must determine the significance of a variety of clinically similar tremors that may have widely dissimilar diagnostic, therapeutic, and prognostic implications. Workup involves differentiating the resting tremor of early parkinsonism from essential tremor, and differentiating essential tremor from an exaggerated physiologic tremor. As new specific treatments are developed, accurate clinical distinction becomes increasingly valuable. Unfortunately, it may be difficult to differentiate tremors by clinical observation alone, and evaluation requires a working knowledge of simple electrophysiologic and pharmacologic characteristics.

PATHOPHYSIOLOGY AND CLINICAL PRESENTATION

The precise neural mechanisms of tremor remain unknown despite some clinicopathologic correlations, such as abolition of the parkinsonian and essential tremors by lesions in the ventrolateral nucleus of the thalamus. Drugs such as L-dopa, which are known to act centrally to increase catecholamines, may worsen essential tremor; this observation has led to the suggestion that b-adrenergic blockers such as propranolol may exert their therapeutic action by central antagonism of b-adrenergic receptors.

The patient most frequently reports the insidious onset of "shaking" of a limb. Very likely, the patient will have ignored the symptom initially, assuming it was a consequence of nervousness or fatigue. However, steady progression impels the patient to see the physician. Tremors can be present during maintenance of a posture, at rest, or during an action (intention tremor).

Postural or Physiologic Tremors are fine tremors with a frequency of 8 to 12 Hz; they occur normally in everyone during movement and while a fixed position is held. A true physiologic tremor is defined as one that does not produce symptoms and is within the given frequency range. The movement is usually invisible to the naked eye, but it may become exaggerated by anxiety, ingestion of coffee, or hyperthyroidism. Drugs, notably lithium and tricyclic antidepressants, may also accentuate this tremor. Amplitude and frequency vary among different people and in the same person at different times. Physiologic tremors are unaffected by propranolol or alcohol.

Intention Tremors. The major intention tremors are those labeled *"essential"* (also referred to as *"familial"* or *"senile"*). Half of cases are transmitted as an autosomal dominant trait, and half are sporadic. The condition is characterized by an intention tremor of the hands, head, voice, and sometimes legs or trunk. Typically, the tremor is most prominent when the hands or head are held outstretched in a position against gravity, and least noticeable at rest (although the tremor of early parkinsonism may also be seen best in an outstretched hand). Tremor may be accentuated by tasks that require precision, such as writing, carrying full cups of liquid (also seen in some patients with parkinsonism). Many patients report that the ingestion of a small amount of alcohol will temporarily reduce their tremor. Essential tremor may begin at any age, although early and late adult life are the most common periods of onset (which helps to differentiate the condition from parkinsonism, which typically begins in middle age).

A more dramatic action tremor is displayed by patients with *cerebellar diseases* and is characterized by progressively increasing amplitude of the tremor as the patient brings the limb toward a target. In younger patients, this is most frequently caused by multiple sclerosis, but similar clinical states may be produced by cerebellar infarction, degenerative disorders of the spinocerebellar pathways, and chronic relapsing steroid-sensitive polyneuropathy. This tremor is multiplanar, with large, irregular, and relatively slow (2 to 4 Hz) oscillations. The tremor often is worsened by alcohol. Propranolol has no effect, and no satisfactory therapy is available.

Rest Tremors. The most common rest tremor in a relaxed, supported limb is that caused by *Parkinson's disease.* It characteristically begins in the fingers and may later involve the arm and the leg. Flexion and extension of the fingers, abduction and adduction of the thumbs, and pronation and supination of the wrist produce the well-known "pill-rolling" movement. Frequently, this is the symptom that brings parkinsonian patients to the physician, and it may occur well in advance of the bradykinesia and postural difficulties characteristic of the full-blown syndrome. It is important, of course, to distinguish this tremor from essential tremor, which requires a different treatment and portends a different prognosis. The parkinsonian tremor is slow (3 to 8 Hz), and its electromyogragraphic (EMG) pattern, quite unlike that of essential tremor, shows alternating discharge in antagonistic muscle groups. This EMG activity is suppressed with voluntary movement.

A few parkinsonian patients may also have a typical action (essential) tremor, and L-dopa therapy may worsen it. Phenothiazines and haloperidol worsen the rest tremor (see [Chapter 174](#)).

Other Abnormal Movements. The definition of tremor as a regular oscillation of a body part serves to distinguish it from other rapid, intermittent movements that bespeak a different neurologic state. For diagnostic, therapeutic, and prognostic purposes, several categories of abnormal involuntary movements should be distinguished from tremor. All the following involuntary movements (and most true tremors) are greatly reduced or disappear altogether with sleep.

Tics are repetitive, coordinated, usually stereotyped movements that are seen widely in the population and increase in frequency in a given patient in response to stress. They usually involve face or hand muscles, may initially be a conscious mannerism, and usually can be suppressed by voluntary effort. *Hemifacial spasm* is a kind of oscillating movement usually beginning in a middle-aged or elderly person, localized to the facial muscles. It is thought to be caused by degenerative lesions of the facial nucleus or peripheral nerve, but the exact mechanism is unknown, and treatment is unsatisfactory.

Asterixis is an irregular contraction of skeletal muscles that results in flapping of the hands; it is electromyographically coincident with brief pauses at irregular intervals. *Chorea* is an irregular, jerking movement usually involving the fingers and often accompanied by *athetosis,* in which writhing movements of limbs or trunk may be added. *Epilepsia partialis continua* refers to a focal seizure in which continuous seizure activity may result in a somewhat rhythmic jerking of one body part. Sudden onset of the illness is the most useful distinguishing feature here.

Dyskinesias are rhythmic, involuntary movements of the orofacial musculature resulting in tongue protrusion and chewing movements. These are important to recognize because of the frequency with which they occur as early manifestations of the tardive dyskinesia syndrome caused by use of phenothiazines and other major tranquilizers.

DIFFERENTIAL DIAGNOSIS

Tremors can be divided clinically into postural, intention, and resting types. Most postural tremors are physiologic. Among the intention tremors are the essential, senile, and cerebellar varieties. Most resting tremors are caused by Parkinson's disease. Tremors must be distinguished from other voluntary movements such as dyskinesias, tics, myoclonus, and athetosis.

WORKUP

History. The clinical assessment of tremor is greatly aided by first ascertaining the circumstances under which the tremor occurs. Some tremors are present during maintenance of a posture, some during rest, and others only during an action (the intention tremors). Careful questioning will often identify the type of tremor. Common diagnostic problems include distinguishing the resting tremor of early Parkinson's disease from an essential tremor, and an essential tremor from an exaggerated physiologic tremor. All these are common, and some may in fact be present simultaneously in a given patient.

Physical Examination is directed primarily at determining whether the tremor is better or worse with activity. Patients should be asked to hold out their hands, write, perform rapid alternating movements, and touch their nose with a finger repeatedly; the objective is to detect evidence of cerebellar or extrapyramidal disease. They should be observed discretely during the history and other parts of the physical examination because calling attention to the tremor may worsen it.

Laboratory Studies. If some question remains at the end of the examination regarding whether a tremor is primarily a resting or an action tremor, a tremor recording (EMG) may be requested. Many parkinsonian patients have no other extrapyramidal signs at the time they present with tremor. The EMG can separate the two types, sometimes confirming that both tremors are present simultaneously. Thyroid function should be checked in any case of tremor.

SYMPTOMATIC MANAGEMENT

Essential Tremor. A major advance in treatment was made with the discovery of the beneficial effect of b-blockers (e.g., 120 mg of propranolol daily). Long-acting preparations are more convenient and equally effective. A decade later, the anticonvulsant drug *primidone* (Mysoline) was found to be extremely effective at reducing or eliminating essential tremor in doses far smaller than those necessary for antiepileptic activity. The mechanism of action of primidone in tremor is unknown. No consensus has been reached regarding which of these two agents is the drug of choice for tremor. Because primidone is somewhat more effective for the majority of patients, starting with a low dose of 50 mg/d and working up to as much as 250 mg/d in divided doses is a very reasonable approach to treatment. Sedation is the major side effect, but it is generally tolerated if the drug is increased slowly. Propranolol is also well tolerated in most patients, although it is relatively contraindicated in those with underlying asthma, insulin-dependent diabetes, heart block, or congestive heart failure (see Chapter 25, Chapter 32, Chapter 48 andChapter 102). *Alprazolam* (Xanax) and other benzodiazepines have been used for essential tremor and may be effective as intermittent adjunctive agents in a patient on b-blockers or primidone.

Physiologic Tremor. Performance anxiety sometimes exaggerates an otherwise inconsequential physiologic tremor in performers (e.g., concert musicians, public speakers), and the problem can sometimes be alleviated by a small pre-performance dose of a b-blocker or a short-acting *benzodiazepine* (see Chapter 226). However, too large a dose of either can have an overly sedating effect and hinder performance. Moreover, regular use of benzodiazepines is associated with a risk for habituation (see Chapter 226), and b-blockers usually have little effect on baseline physiologic tremors.

Parkinson's Disease. The tremor of Parkinson's disease, although it does not respond as well as bradykinesia and rigidity to dopaminergic agents, may benefit from *anticholinergic therapy* (see Chapter 174).

Cerebellar Disease. The tremor of cerebellar disease is notoriously unresponsive, although b-blockers, primidone, baclofen, gabapentin, and benzodiazepines are usually tried. Wrist weights may dampen the amplitude of these tremors and make the limb more functional.

PATIENT EDUCATION AND INDICATIONS FOR REFERRAL

The cause of the tremor and the fact that it can be controlled should be discussed with the patient. Avoidance of agents that worsen symptoms must be stressed. Patients with intention tremors and cerebellar signs must be referred to a neurologist, as demyelinating or hereditary degenerative diseases may be responsible.Disabling tremors refractory to simple therapy may benefit from neurologic consultation. Neurosurgical techniques to control drug-refractory essentialtremor include thalamotomy and deep brain stimulation. Patients should be referred to a center that specializes in the surgical treatment of movement disorders.

CHAPTER 169 EVALUATION OF DEMENTIA

AMY A. PRUITT

INTRODUCTION

Dementia is the progressive decline of intellectual ability from a previously attained level. Speech, memory, judgment, and mood may all be altered in varying proportions. The prevalence rises rapidly with age, starting at 1% at age 60 and doubling every 5 years to nearly 50% by the age of 85. At present, an estimated 600,000 persons with advanced dementia in the United States require institutional care. With the aging of the U.S. population, the social consequences of the problem are likely to be staggering if no major changes in prevention and treatment are implemented. By 2030, when nearly 20% of the U.S. population will be over the age of 65, approximately 6% will have severe dementia and an additional 10% to 15% will have mild to moderate impairment. The current annual dementia-related expense of long-term care either at home or in a nursing facility is more than $50 billion. Dementia also accounts for more admissions and hospital inpatient days than does any other geriatric psychiatric condition.

It has been estimated that more than 55 illnesses can cause dementia. Although in one sense all are treatable, at least with psychosocial intervention, the 15% of patients with significantly reversible causes or complicating conditions are depressed or exhibit drug-induced changes in mental status. When a decline in mental functioning is noted, fear of Alzheimer's disease arises in patients and their families. Each patient requires a careful workup for dementia and proper identification of the underlying cause. Primary physicians should know how to distinguish dementia from other, more specific cortical deficits (aphasia, agnosia, isolated memory deficit) and should be able to perform a screening examination for potentially reversible disease. Prompt recognition of dementia is essential, not only for the initiation of a diagnostic workup but also to protect the patient from avoidable harm, such as a fall, drug overdose, fire, or inadequate nutrition.

PATHOPHYSIOLOGY AND CLINICAL PRESENTATION

Definition and Description. Dementia is a syndrome characterized by a *generalized* and *sustained* decline in *intellectual functioning* from a previously attained level. It is a characteristically *progressive* disorder, measurable in months or years rather than days or weeks. The decline from a previously attained level of mental ability is broad-based, usually involving *memory, cognitive capacities*, and *adaptive behavior without alteration of consciousness*. Initially, the patient may be aware of some difficulties, but later seems mostly not to be disturbed by them. It is important, but not always possible, to distinguish the early stages of dementia from nonprogressive cognitive changes ("benign forgetfulness") that occur in normal aging.

Presentation. The onset of dementia is usually insidious, although a few conditions evolve rapidly. Patients initially may be noted to be slightly *forgetful*, with *attention* and *concentration deficits* and increasing *repetitiousness* or *inconsistencies* in their usual behavior. Later in the course of the process, patients may display increasingly impaired judgment, an inability to abstract or generalize, and *personality changes*, reacting with rigidity, perseveration, irritability, and confusion to minor changes in the environment. *Affective disturbances* or *aggressive behavior* may be prominent, and in extreme forms, patients lose all vestiges of their original personality, are unable to participate in matters of personal hygiene and nutrition, and are left helpless.

Dementia is often progressive (as in degenerative diseases), but it may be static (as in a posttraumatic brain injury state). Depending on the pathologic condition that causes dementia, indications of disease outside the areas of the brain responsible for cognitive and behavioral change may or may not be found. Concomitant disorders of extrapyramidal function are particularly common.

Some conditions that result in dementia may also cause mental retardation (e.g., Down syndrome). Patients with dementia may or may not be psychotic, and a patient with psychosis may or may not have any evidence of cognitive decline consistent with dementia.

Primary Neurologic Conditions

Alzheimer's Disease. The leading cause of dementia, Alzheimer's disease accounts for well over half of cases among the elderly and affects 15 million people worldwide. Its incidence increases with advancing age. Because many patients survive for a decade, the prevalence increases from 43% at age 65 to 47% after age 85. Most cases are *sporadic*, but a *familial autosomal dominant* form of the disease exists. Mutations in the gene for the amyloid precursor protein and the genes for presenilin 1 and 2 cause the uncommon, dominantly inherited forms of the disease that become symptomatic before the age of 60, and the *e4 variant* of *apolipoprotein E* is associated with the sporadic form and some later-onset familial forms.

No specific physical signs are characteristic, although frontal lobe release signs and secondary mild extrapyramidal features may be present. Although this disease cannot be diagnosed with certainty during life, a high probability of the diagnosis can be determined according to the criteria established by the Alzheimer's Disease and Related Disorders Work Group of 1984. Progressive worsening of memory with impairment of at least one other cognitive function is the hallmark of the disease. About two thirds of patients with moderate to severe dementia who have no other illness that can cause dementia (e.g., cerebrovascular disease, hypothyroidism) are given the diagnosis of probable Alzheimer's disease.

The diagnosis of Alzheimer's disease can be confirmed only at postmortem examination. The *brain* is *atrophied*, the *ventricles* are *enlarged*, and evidence of severe vascular disease is minimal or absent. Neuropathologic study reveals *neuronal loss, neurofibrillary tangles* composed of t-protein, and *senile plaques* containing the b-amyloid peptide. Basal forebrain degeneration reduces the acetylcholine content. Loss of this transmitter correlates with memory impairment.

Dementia with Lewy Bodies. This recently appreciated but probably widespread idiopathic condition has features of Alzheimer's and Parkinson's diseases, which leads to considerable diagnostic confusion and the potential for therapeutic mismanagement. Recognition is important because these patients manifest marked sensitivity to neuroleptic drugs, which may exacerbate symptoms (see Chapter 173). The pathologic hallmarks are the widespread presence of *Lewy bodies* (intracytoplasmic inclusions) in the cortex, amygdala, hippocampus, and pars compacta of the substantia nigra and nucleus ceruleus, with loss of neuronal density in the latter areas. Unlike patients with Alzheimer's disease, these patients have only mild brain atrophy grossly and normal density of the neocortex. The initial presentation is often one of *visual hallucinations, episodic delirium, fluctuating cognitive difficulties*, and *parkinsonism* and *extrapyramidal motor symptoms* (dysarthria, poor coordination of voluntary movements). As in Alzheimer's disease, short-term memory impairment and a progressive decline in cognition interfere with social and occupational functioning. In early stages, the memory impairment may be mild, and periods of nearly normal functioning occur intermittently. Deficits in attention and visual–spatial and frontal–subcortical skills are nonetheless evident. Core features include recurrent visual hallucinations that are well formed and detailed, fluctuating consciousness, and spontaneous motor features of parkinsonism and extrapyramidal disease. Other characteristics include falls, syncope, transient loss of consciousness, hallucinations in other domains, systematized delusions, and, as noted, sensitivity to neuroleptic medications. The rate of clinical decline is generally more rapid than that of Alzheimer's disease.

Multiinfarct Dementia. "Hardening of the arteries" with cerebral hypoperfusion has been a common, although mistaken, lay view of the cause of dementia. However, multiple strokes can leave a patient with impaired cognition and produce a true dementia, often referred to as "*multiinfarct dementia*." Recent data from Scandinavia suggest that among the very elderly (over age 85), vascular dementia rivals Alzheimer's disease as the type of dementia. Although the exact contribution of vascular dementia to the overall rate of dementia remains a subject of debate, groups with a high prevalence of vascular risk factors (e.g., African-Americans, Japanese) are an increased risk. An elderly patient with hypertension, diabetes, atrial fibrillation, or known carotid disease or who smokes should be considered at risk. The clinical course may progress stepwise if discrete large-vessel occlusions occur, and is more gradual if the infarctions are primarily lacunar (see Chapter 171). Multiinfarct dementia is sometimes referred to as a *subcortical dementia* characterized by apathy, slowness, and decreased memory retrieval.

Inadequately controlled *hypertension* causing multiple cerebral infarctions is one of the more frequent and treatable conditions associated with vascular dementia.

The infarctions may be large and heralded by clearly defined episodes of neurologic injury, or develop subclinically as small lacunar strokes contributing to a slow decline in intellectual function. Most patients have evidence of upper motor neuron injury (lateralized weakness, brisk reflexes, or Babinski signs.) Magnetic resonance imaging (MRI) may reveal multiple lacunar infarctions and a loss of periventricular white matter. Recent studies with positron emission tomography (PET) have shown that the degree of dementia correlates with abnormalities of cerebral glucose utilization, particularly in the frontal lobes.

Mixed Disease. As patients age, the brain becomes increasingly vulnerable to insult. Moreover, the risks for vascular and degenerative diseases increase. For this reason, it is likely that a large percentage of cases of dementia in the very elderly are of a mixed type, with both vascular disease and Alzheimer's disease as underlying conditions. The significance of this notion of mixed disease is that it focuses attention on various potential causes of dementia and the importance of controlling risk factors (e.g., improving diabetic or hypertensive control).

Normal-Pressure Hydrocephalus. Normal-pressure hydrocephalus deserves special mention, both because it is reversible and because it is generally overdiagnosed. The name of this entity denotes slow ventricular enlargement without cortical atrophy resulting from poor resorption of cerebrospinal fluid over the cerebral convexities. Most often, the precipitant is unknown, but the condition can occur when cerebrospinal fluid resorption is blocked as a consequence of remote meningeal inflammation or subarachnoid hemorrhage. *Dementia, gait disturbance*, and urinary and fecal *incontinence* comprise the classic triad. Some patients respond dramatically to ventricular–peritoneal shunting, and the diagnosis is suspected clinically and radiographically. Serial lumbar punctures with removal of large volumes (>30 mL) of cerebrospinal fluid are undertaken to try to predict which patients will respond to this maneuver.

Space-Occupying Lesions. Space-occupying lesions such as *chronic subdural hematoma* or slowly growing *tumors* of the brain produce variable dementia depending on their size and location. When they are located on the orbital surface of the *frontal lobe* or the medial surface of the *temporal lobe*, patients may present primarily with *cognitive defects* and no other focal signs of cerebral tumor. The development of a progressive unilateral headache (see Chapter 165), a new neurologic deficit, or change in personality may provide a clue to the presence of a mass lesion.

Depression. Depression can produce the rapid onset of a true cognitive deficit that is reversible with appropriate treatment. Other symptoms of depression (hopelessness, low self-esteem, early morning awakening, fatigue, anhedonia; see Chapter 227) almost always predate the onset of the dementia and help suggest the diagnosis. Unlike patients with Alzheimer's disease, depressed patients will complain of memory loss during a mental status examination. Although depression alone can produce significant reversible cognitive impairment, severe mood disturbance may also accompany other causes of dementia, such as Alzheimer's disease or Parkinson's disease.

Other Primary Neurologic Conditions. Other primary neurologic conditions associated with dementia and specific neurologic deficits include Pick's disease, *Parkinson's* disease (see Chapter 174), Wilson's disease, severe *multiple sclerosis* (see Chapter 172), Creutzfeldt-Jakob disease, neurosyphilis, and *Huntington's* disease (Table 169-1). Pick's disease or frontal lobe dementia is associated with predominantly frontal and temporal lobe pathologic involvement. The cognitive deficits differ from those of Alzheimer's disease, with early impairment of executive function (the ability to modify behavior in response to changing stimuli, solve problems, organize, think abstractly, and avoid perseveration.) Parkinson's disease and Huntington's disease are sometimes referred to as "*subcortical dementias*" because they present with significant motor dysfunction and no prominent aphasia or agnosia. Proper identification is essential to initiating effective treatment and providing accurate prognostic information.

Table 169-1. Neurologic Diseases Associated with Intellectual Dysfunction

Other Causes of Dementia

Toxins, infections, metabolic disorders, and nutritional disorders may affect the brain and result in dementia (Table 169-2). Frequently, more than one pathologic cause is present.

Table 169-2. Systemic Conditions Associated with Intellectual Impairment

Intoxication. The patient with a progressive degenerative dementia may be taking an excess of a medication that is exacerbating the primary process, or the drug itself may be causing an apparent loss of cognitive abilities. Medications capable of producing dementia in patients without other underlying conditions include opiates and the numerous neurotropic agents available. Less obvious but frequently prescribed medications causing or aggravating dementia include the *anticholinergic preparations* used in movement disorders, *antihypertensives*, and *sedatives*. These agents are high on the list of causes of disease that can be arrested or reversed.

Infection. Any infection involving the brain can produce a picture of diffuse cognitive impairment. *Neurosyphilis*, *HIV infection* (see Chapter 13), and *cryptococcal infection* spread into the central nervous system to produce dementia, often with great regularity. Infectious agents responsible for subacute conditions like Creutzfeldt-Jakob disease and progressive multifocal leukoencephalopathy are resistant to treatment.

Endocrinologic, Metabolic, and Nutritional Disorders. Endocrinologic, metabolic, and nutritional disorders, including *hyperthyroidism*, *hypothyroidism*, and *panhypopituitarism*, and the administration of *high-dose corticosteroid therapy* can cause a generally reversible loss in cognitive abilities. The metabolic derangements resulting from advanced renal or hepatocellular failure usually cause an encephalopathic picture that differs from true dementia in that consciousness is altered. However, milder forms of metabolic disease may exacerbate an underlying dementia, as may *dehydration*. Of the hereditary metabolic diseases associated with prominent cognitive alteration, *Wilson's disease, metachromatic leukodystrophy*, and the *adrenal leukodystrophies* are among the most notable. *Nutritional disorders* may result in prominent altered mental status. *Thiamine deficiency*, if untreated, may lead to Korsakoff's dementia, which is largely irreversible. Thiamine deficiency is a preventable condition seen with alcoholism, pernicious vomiting of any cause, depression, or inadequate diet. *Pernicious anemia* can produce dementia that may be

partly reversible with administration of vitamin B$_{12}$. *Pellagra*, uncommon in developed countries, shows a dramatic response to niacin, even when mental changes have been present for a long time.

DIFFERENTIAL DIAGNOSIS

A useful way of organizing the differential diagnosis of dementia is to divide the dementing conditions into pathologic processes that originate in the brain (Table 169-1) and those that affect the brain secondarily, such as exogenous intoxication, infections, and metabolic derangements (Table 169-2). Diseases that are primary in the brain may be accompanied by signs of neurologic disease other than cognitive change. Diseases that affect the brain secondarily are more likely to be accompanied by signs and symptoms of medical disease and perhaps are more reversible. Among patients presenting with dementia, Alzheimer's disease accounts for some 65% of cases, vascular disease with multiple infarctions for 10% to 20%, and brain tumors for 5%; all other and unknown causes account for 10% to 15%. Among the very old (over age 85), vascular dementia and Alzheimer's disease account for the vast majority of cases.

WORKUP

The goal of the workup is to distinguish dementia from other causes of mental impairment and to identify the cause as either a primary neurologic condition or a condition that secondarily affects the brain. Differentiating among neurologic conditions is essential, not only to identify and treat reversible conditions promptly, but also to optimize the care of those with incurable disease. Not all neurologic dementia is Alzheimer's disease, and not all of these conditions respond similarly to symptomatic measures (see Chapter 173). Careful workup is essential for proper management.

History

A careful history is the most important component of the initial evaluation. The help of a family member is critical to taking an adequate history because the patient's recall may be inadequate.

Differentiating Dementia from Other Neurologic Impairments. Differentiating dementia from other neurologic impairments requires a description by the patient or family of the specific *cognitive, memory,* and *behavioral problems* the patient is experiencing and the *consequences* of such deficits in the patient's daily life, such as difficulties with driving, work, or family relationships. Detailed questioning should define the *temporal course* of the illness and enable the physician to ascertain whether the process is indeed chronic and progressive, stepwise, or static. A stepwise pattern in conjunction with focal deficits raises the question of a multiinfarct basis. An episode of severe hypotension followed by the onset of dementia points to hypoperfusion as the mechanism of what may be a static (nonprogressive) post-hypoxic encephalopathy. A story of progressive, generalized intellectual impairment without alteration of consciousness is indicative of Alzheimer's disease and other neurodegenerative conditions, but multiple lacunar strokes may also be associated with this temporal pattern. Finally, the examiner should check for important epidemiologic *risk factors* for dementia, including a prior severe episode of *head trauma, diabetes, never having been married*, and a *low level of education*.

Identifying Treatable Causes and Differentiating among Etiologies. Once dementia is strongly suspected, the history should then focus on identifying potentially treatable causes, be they primarily neurologic or secondary. The search for neurologic disease includes inquiry into risk factors and specific neurologic accompaniments. *Cardiovascular risk factors* (e.g., smoking, hypertension, hyperlipidemia, diabetes) should be ascertained for identification of the patient at risk for vascular dementia. Questioning about *gait, incontinence*, and a prior history of *meningitis* or *subarachnoid hemorrhage* helps identify the patient at increased risk for normal-pressure hydrocephalus. A prior history of *head trauma*, unexplained onset of a *focal neurologic deficit*, and unilateral *headache* worsening over time are potential clues to a mass lesion. A history of *resting tremor* and *rigidity* are likely manifestations of Parkinson's disease. *Extrapyramidal symptoms* (dysarthria, poor coordination of voluntary movements) raise the question of Lewy body disease; if concurrent hepatocellular dysfunction is present, then Wilson's disease should be considered. Reports of vivid *visual hallucinations* suggests Lewydody disease. *High-risk sexual behavior* raises the probabilities of HIV infection and neurosyphilis. Any symptoms or prior history of *depression* need to be reviewed (see Chapter 227). A *family history* of dementia, Down syndrome, or psychiatric disorders is the basis for identifying patients at risk for one of the hereditary causes of dementia.

The history is also critical to identify non-neurologic conditions that may be causing or exacerbating a loss of mental capacity. Concurrent illnesses and precipitating factors are reviewed. For example, one asks about previous *gastric surgery* (leading to vitamin B$_{12}$ deficiency) and adequacy of *nutrition* (for thiamine, niacin, and vitamin B$_{12}$ deficiencies). A detailed review of *medications* (particularly opiates, sedative-hypnotics, analgesics, anticholinergics, anticonvulsants, corticosteroids, centrally acting antihypertensives, and psychotropics) should be elicited. *Alcohol* abuse and other forms of substance abuse are critical to rule out (see Chapter 228 and Chapter 235). It is important to check for symptoms of *hypothyroidism* (see Chapter 104) and *pituitary insufficiency* (see Chapter 101). The *occupational history* may reveal exposure to toxic substances (e.g., aniline dyes, heavy metals).

Physical Examination

Mental Status Examination. Assessment begins with a mental status examination to confirm the presence of dementia. A standardized instrument such as the Mini-Mental State Examination is easy to use and is adjusted for age and education. More detailed testing is also necessary. The complex faculties that constitute intellect are usually divided into functions, not necessarily anatomically or pathologically exclusive, that can be tested. This part of the examination should be geared both to the *detection of focal lesions* and to *signs of general brain dysfunction*. The mental status examination in the office can include immediate memory testing, with a request to remember three objects, recite digits forward and backward that are given by the examiner, and recall a short story. Remote memory testing can be approached by asking about historical events of note, family milestones, or more recent happenings in the newspaper. Language function testing should include the naming of parts of objects, following complex commands, and generating word lists. The patient should be asked to reproduce simple drawings and discern similarities among objects, a test that offers insight into categorizing ability. Judgment can be ascertained by presenting the patient with decision-requiring situations ("finding a stamped letter" or "seeing a fire in a theater"). Attention and concentration are assessed by having the patient reverse sequences, as in naming the months of the year backwards.

General Physical and Neurologic Examinations. The physician should examine the patient to help uncover evidence of any coexisting abnormalities that may be causing or contributing to the problem. One checks for physical evidence of neurovascular risk factors (see Chapter 171) and carefully palpates and auscultates the carotid arteries. In addition, the physician notes any signs of alcoholism (see Chapter 228), hepatocellular injury (see Chapter 71), renal insufficiency (see Chapter 142), and other systemic illnesses. Specific neurologic abnormalities, such as frontal lobe release signs (grasp, suck, snout, root), visual field cut, limitation of extraocular movement, or abnormal pupillary reaction should be elicited. Nystagmus may indicate recent drug ingestion or the presence of brainstem disease. The motor examination should pay particular attention to extrapyramidal features or involuntary movements such as tardive dyskinesias, tremors, asterixis, chorea, or myoclonus. The sensory examination may reveal evidence of peripheral neuropathy or combined system disease (vitamin B$_{12}$ deficiency). Gait should be observed carefully; the small, rigid steps of frontal lobe gait apraxia can be distinguished from a wide-based cerebellar gait or the small steps associated with extrapyramidal disease.

Laboratory Studies

Diagnostic Criteria for Alzheimer's Disease. Those established by the U.S. Department of Health and Human Services require the presence of dementia "established by clinical examination and documented by the *Mini-Mental State Examination* or similar examination, with evidence of deficits in two or more areas of cognition; progressive worsening of memory and other cognitive function; no disturbance of consciousness; and absence of systemic disorders or other brain disease that in and of themselves could account for the deficits." No single test will establish the presence of dementia, and a poor score on a Mini-Mental State Examination should not be the sole criterion for the diagnosis of dementia. The score should be considered clinically significant if it is corroborated by other components of the initial evaluation and history. Several clinical drug trials have confirmed what neurologic clinicians have long suspected—namely, that considerable variability in the annual Mini-Mental State Examination score is noted in patients with probable Alzheimer's disease and that variability of scores between examiners is prominent. Similarly, the existence of several different sets of criteria for vascular dementia confound both the longitudinal assessment of patients and initial diagnostic certainty. Continuing observation over time may be necessary to establish the diagnosis for some patients and to identify complicating conditions.

Screening Laboratory Studies. The laboratory tests recommended should be individualized based on the patient's history and physical and mental status examination results. Because the history and physical examination will limit the differential possibilities, the patient should be spared the inconvenience and costs of excessive testing. Undertesting is also hazardous because elderly patients in whom medical diseases may underlie nonspecific presentations of dementia comprise

the usual patient population.

The guidelines specified by the National Institute of Aging Task Force on Mental Impairment in the Elderly have become the standard for investigating patients with dementia, although they are probably more appropriate for assessing an alteration in mental functioning than for detecting a treatable cause of dementia. They include determination of the following:

1. Complete blood cell count and sedimentation rate
2. Chemistry panel (electrolytes, calcium, albumin, blood urea nitrogen, creatinine, transaminase levels)
3. Thyroid-stimulating hormone level
4. VDRL (Venereal Disease Research Laboratory) test for syphilis
5. Urinalysis
6. Serum vitamin B_{12} and folate levels
7. Chest radiography
8. Electrocardiography
9. Computed tomography (CT) of the head

Because this panel was not designed to be a cost-effective workup for uncovering treatable causes of dementia, it should not be applied routinely to all patients; rather, it should be considered a menu from which tests can be selected based on the patient's clinical presentation. Some of these tests will be useful in detecting conditions that might exacerbate the mental decline of a patient with dementia. Because this list was compiled before HIV infection and AIDS were appreciated as important causes of dementia, *HIV testing* should be added to it, especially in the evaluation of younger patients with a history of high-risk activity or exposure (see Chapter 13).

The American Academy of Neurology practice parameters for the evaluation of dementia are more parsimonious than the above recommendations; they suggest that the diagnostic workup include a complete blood cell count; determination of serum electrolytes, calcium, glucose, blood urea nitrogen, and creatinine; liver function tests; thyroid function tests; determination of serum vitamin B_{12}; and syphilis serology. However, all other studies, including measurement of folate levels, chest radiography, and neuroimaging studies, are considered optional. Four clinical indicators (early onset of symptoms, noninsidious course, focal signs or symptoms, and early gait disturbance) predict the diagnostic utility of neuroimaging studies. The use of these four indicators is estimated to reduce the frequency of imaging studies by 33%, but clinically meaningful disease will be missed in 5%.

Neuroimaging. Neuroimaging of the brain by *CT* or *MRI* is appropriate in the presence of (a) a history suggestive of a mass lesion; (b) focal neurologic signs or symptoms; (c) dementia of abrupt onset; (d) a history of seizures; and (e) a history of stroke. Subdural hematomas and intracranial tumors can be readily identified, especially when contrast-enhanced studies are performed, and radiologic evidence of normal-pressure hydrocephalus also may be provided. MRI with gadolinium contrast enhancement is superior to CT for the diagnosis of multiinfarct dementia and for the elucidation of problems referable to the posterior fossa. If the clinical suspicion of tumor is high, MRI is the more sensitive test.

Other Ancillary Studies. *Lumbar puncture* may be indicated when other clinical findings suggest an active infection or vasculitis, and it is part of the evaluation of normal-pressure hydrocephalus, as described above. Sugar, protein, and gamma globulin levels, cultures, a cell count, and serology for syphilis should be obtained. Lumbar puncture for the initial evaluation of dementia is not justified. However, the primary care physician should be aware that *levels of* t-*protein in the cerebrospinal fluid* are highly sensitive and specific for differentiating Alzheimer's disease from normal aging and depression, and they may be seen early in the disease process at a time when the Mini-Mental State Examination score is above 23. Thus, it is possible that this test will be more routinely used to make the diagnosis of Alzheimer's disease earlier and offer patient access to potentially disease-modifying drug therapy.

Electroencephalographic patterns may be normal even in advanced states of dementia, or nonspecific slowing of the baseline rhythm may be found. For patients who have episodes of altered consciousness and in whom seizures may therefore be suspected, this is an indicated procedure. Occasionally, the electroencephalogram may raise suspicion of a particular disease process; focal delta slowing is seen with tumor, unilateral attenuation of voltage may suggest an extracranial mass such as subdural hematoma, and excessive beta activity may be consistent with drug ingestion. Finally, Creutzfeldt-Jakob disease has a highly specific electroencephalographic pattern.

Formal neuropsychological evaluation would be appropriate to obtain more specific information when the diagnosis is in doubt and is also helpful in providing additional information about the nature of impairment following focal brain injury. *Speech analysis* with speech therapy may improve patient and family communication. Formal *psychiatric assessment* may be desirable if depression is suspected in addition to dementia.

Studies of Limited or Uncertain Utility. Measurements of *cerebral blood flow* and *metabolism* (positron emission tomography and single-photon emission computed tomography) are not routinely used at present. Their value in predicting Huntington's disease and Alzheimer's disease is being investigated.

Brain biopsy for non-neoplastic and noninfectious diseases is rarely justified. Very occasionally, progressive multifocal leukoencephalopathy or Creutzfeldt-Jakob disease is diagnosed by this technique.

Noninvasive neurovascular studies (carotid ultrasonography, Doppler flow studies; see Chapter 171) are not of routine value in the workup of dementia unless the clinical course or physical examination findings are suggestive of cerebrovascular disease or the MRI or CT demonstrates infarction.

Genetic Testing. Genetic testing is controversial and poses ethical issues. When the family history suggests early-onset Alzheimer's disease, tests for mutations on chromosomes 1, 14, and 21 can be considered. Clinicians can expect to be asked by patients and families about the "test for dementia" (the search for the *e4 allele* of the *gene encoding apolipoprotein E* [*APOE*e4*], which is encoded on protein 19 and has been associated with Alzheimer's disease). *APOE* genotyping is not accurate enough to serve alone as a test for Alzheimer's disease, but at least one *APOE*e4* allele can be found in 65% of pathologically confirmed cases of Alzheimer's disease. When combined with clinical evaluation, *APOE* genotyping can improve diagnostic specificity, but the test lacks sufficient sensitivity to be used to rule out Alzheimer's disease. Moreover, it is not sufficiently predictive of developing dementing illness to be of prognostic value. These features of the apolipoprotein E test should be shared with patients inquiring about the "test for Alzheimer's disease." Taking a mail order test for *APOE* genotyping should be discouraged because of the shortcomings of the test and the high probability of misinterpreting the results.

MANAGEMENT

Alzheimer's Disease and Lewy Body Disease. See Chapter 173.

Other Causes. For the patient with vascular dementia, control of such cerebrovascular risk factors as hypertension, hyperlipidemia, smoking, and diabetes mellitus is essential (see Chapter 26, Chapter 27, Chapter 54, and Chapter 102, respectively). The question of the need for endarterectomy deserves consideration when a vascular problem is strongly suspected and a significant stenosis is found (see Chapter 171). Attention to embolic risk (see Chapter 28, Chapter 33, and Chapter 83) is also critical. Patients with dementia secondary to HIV infection may respond to intensive antiretroviral therapy (see Chapter 13), and those with Lyme disease may improve with a prolonged course of parenteral antibiotics (see Chapter 141). In cases of vitamin deficiency, correction is essential (see Chapter 82). Avoidance of toxins and discontinuation of causative drugs are the basic approaches to substance-induced disease (see Chapter 228 and Chapter 235). In those with hormonal deficiency, replacement therapy is key (see Chapter 101 and Chapter 104).

INDICATIONS FOR REFERRAL AND ADMISSION

Some families will request a neurologic consultation when a diagnostic evaluation has been completed by the primary physician and no cause is apparent other than Alzheimer's disease. Such a consultation can provide reassurance to the family that a comprehensive workup has been performed and that the diagnosis is correct. If the primary physician has conducted a thoughtful and complete examination as outlined above, the referral need not generate additional testing. If the means for conducting a full workup are not available to the primary physician, then a referral can be used to complete the evaluation. Additionally, patients suspected of having a a potentially treatable neurologic condition (Parkinson's disease, normal-pressure hydrocephalus, mass lesion, carotid artery disease) are candidates for neurologic or neurosurgical evaluation. Finally, when a suspected hereditary condition is under consideration, referral for confirmation and genetic counseling is indicated.

Admission to a hospital for behavioral management or for the treatment of intercurrent medical illness can be very stressful for patient and family. Careful attention to

factors associated with the development of delirium in the hospitalized patient and use of the lowest possible doses of analgesic and sedative-hypnotic medications are essential (see also Chapter 173).

CHAPTER 170 APPROACH TO THE PATIENT WITH A SEIZURE

AMY A. PRUITT

The occurrence of a convulsion is a dramatic and frightening event. One of every 11 Americans who lives to be 80 years old has had at least one seizure. The first experience of a seizure is likely to trigger an immediate visit to an emergency department. Retrospective clarification of a "spell" is the diagnostic challenge in the office setting. In the context of evaluating an episode of lost or altered consciousness, the primary care physician needs to consider seizure (see Chapter 24). If a seizure is likely, then one should attempt to determine its type and plan to prevent future episodes while conducting a diagnostic evaluation for the underlying cause.

PATHOPHYSIOLOGY AND CLINICAL PRESENTATION

A *seizure* is a paroxysmal alteration in consciousness or other cerebral cortical function. It results from a synchronous activation of a population of neurons, either in one focal area or generally throughout the brain. The occurrence of a single seizure does *not* constitute *epilepsy*, which connotes recurrent, unprovoked seizures. Many people have a single seizure without recurrence—for example, as a consequence of a transient metabolic disturbance, such as severe hypoglycemia or hypoperfusion. Only about 1% of the U.S. population actually has epilepsy. Epileptic seizures can result from many different types of diseases, ranging from hereditary conditions to vascular, traumatic, and neoplastic causes. Seizures can be classified as *localization-related* (previously known as *partial*) or *generalized* (Table 170.1).

Table 170.1. International Classification of Epilepsies and Epileptic Syndromes

Localization-related Seizures may begin in one area of the brain and initially produce symptoms that are referable to the region of cortex involved. *Simple* partial seizures are focal neurologic events in which consciousness remains intact, whereas in *complex* partial seizures, consciousness is impaired. Simple seizures may evolve into complex partial seizures, and both these types of focal seizures may evolve into secondarily generalized seizures. The spread of symptoms may follow the cortical representation of body parts, beginning, for example, in the fingers and spreading up the arm or down the leg.

Symptoms of complex partial seizures are numerous and include coordinated, involuntary motor activity (automatisms), such as lip smacking or chewing, olfactory or gustatory hallucinations, and behavioral automatisms. Seizure activity typically begins in the temporal lobe or its connections. Premonitory symptoms include olfactory hallucinations, epigastric discomfort, and a sense of fear or *déjà vu*. At times, the symptoms may resemble those of a psychosis. Episodes last 1 to 3 minutes, followed by a period of confusion with consciousness usually impaired but not lost. Localization-related seizures are the most common type of epilepsy in adults, accounting for 70% of patients presenting with epilepsy after age 18. More than 50% of all patients with localization-related epilepsy have both partial and secondarily generalized tonic–clonic seizures.

Generalized Seizures are bilaterally symmetric and without focal onset. An episode may begin with a premonitory aura that is followed by a sudden loss of consciousness. A *tonic phase* of limb extension ensues, lasting 10 to 30 seconds, followed by a *clonic phase* of limb jerking of at least 30 seconds. The patient then becomes flaccid and comatose before regaining consciousness. *Postictal confusion* is characteristic and can last for hours, although 10 to 30 minutes is more typical. *Tongue biting* and *incontinence* are other characteristic features.

Important Precipitants of Seizures and Pertinent Misconceptions. A number of factors have been implicated as causes of seizures, including fever, stroke, alcohol and drug use, and head trauma. Although these factors are often important, a number of misconceptions about their role are prevalent and need to be addressed.

1. Adults rarely have convulsions with *high fever*; a temperature higher than 102°F does not suffice to explain the occurrence of a seizure in an adult.
2. Seizures are rare during the initial presentation of an *embolic stroke,* although 20% to 25% of such patients may have seizures at some time after the initial stroke.
3. *Subarachnoid hemorrhage* and *lacunar strokes* rarely have seizure activity as a sequela, although *emboli* and *cortical vein thrombosis* are more likely to lead to symptomatic epilepsy.
4. *Alcohol withdrawal* seizures occur between 7 and 48 hours after cessation of drinking, with a peak at 13 to 24 hours. Usually, only one or two convulsions occur, and status epilepticus is rare. Alcohol withdrawal is more likely to produce seizures in an epileptic patient than in a normal person, and less drinking is required to precipitate a seizure in patients with epilepsy who drink alcohol. *Other drugs* are associated with seizures, either when they are taken in overdose or when they are withdrawn (Table 170.2).

Table 170.2. Drugs Commonly Associated with Seizures

5. *Trauma* is frequently invoked as a cause for seizures. However, in two large studies, unless the trauma was severe, causing a loss of consciousness for more than a half hour or a lobar hematoma or depressed skull fracture, the incidence of posttraumatic seizures was not greater than that in the general population. With a history of closed head trauma, epilepsy usually develops within 2 years, whereas with open head trauma, seizures may develop at a longer interval after

the original injury.

DIFFERENTIAL DIAGNOSIS

Conditions Mimicking Seizures. Several conditions can mimic seizures, either by causing focal deficits or producing episodic loss of consciousness. Among the former are transient ischemic attacks, migraine, and local pathology, such as nerve compression. Among the latter are syncopal attacks of any cause, including transient diminished cerebral perfusion resulting from cardiac conditions and transient ischemic attacks (see Chapter 171). Panic attacks and altered mental status duringpsychotic episodes may cause confusion with complex partial seizures.

Conditions Causing Seizures. The differential diagnosis of conditions responsible for a seizure is based largely on the age of the patient at the time of the first seizure and the type of seizure as determined by the history, especially that obtained from observers. *Primary* or *idiopathic epilepsy* is the most common cause of recurrent seizures in children, but it becomes increasingly rare in the young adult population. After age 30, an *underlying cause* (*secondary epilepsy*) becomes increasingly likely when a patient presents with a first seizure. Among patients with more than one documented seizure of any type, a cause becomes obvious after thorough investigation and a 10-year follow-up in only 23%. Only 15% of seizures generalized from the outset have a demonstrable cause, whereas underlying disorders can be found in more than 30% of seizures with a focal component. In the *young adult* population (ages 18 to 45), the demonstrated causes include *drugs* (usually alcohol withdrawal), *neoplasm*, and *trauma*. In the *older adult* population, underlying pathology is divided about equally among *neoplasm*, *trauma*, and *cerebrovascular disease*. A nonpileptic convulsion may occur in the context of a transient metabolic disturbance, such as cerebral hypoperfusion, hypoglycemia, a hyperosmolar state, or hyponatremia.

WORKUP

For the patient who reports a "spell," the first step is to ascertain if it was a seizure and, if so, to characterize its type. Identifying the type facilitates ascertaining whether the cause is likely to be primary (idiopathic) or secondary (underlying central nervous system pathology) (Table 170.1). Generalized seizures with no initial focus are usually primary. Such epilepsies are often inherited, age-related, and not associated with structural lesions identified by current neuroradiographic techniques. With partial or focal seizures, the prevalence of identifiable underlying disease or abnormality in the brain is much higher.

History. An effective history requires an exact description of events from both witnesses and the patient. Reports of witnesses are especially useful because the patient's consciousness and recall of the event are likely to have been compromised. Questioning should include inquiry into the presence of an aura, focal onset, loss of consciousness, and observed injury during the convulsion. Such symptoms suggest seizure rather than syncope, although it is not possible to distinguish between them absolutely on the basis of any characteristic features.

Once it has been ascertained that a seizure has occurred, it is essential to check carefully for a history of focal onset, even in patients with a history of generalized seizure. The focal onset of a witnessed seizure that later became generalized may be an important clue to an underlying lesion of the central nervous system.

History is also essential for identifying precipitants and underlying disease. It should include inquiry into drugs (e.g., alcohol, cocaine, amphetamines, antidepressants, sedatives, theophylline, insulin, diuretics), cardiac arrhythmias, valvular disease, previous malignancy, stroke, and head trauma. The examiner should check for symptoms of hyperglycemia and hypoglycemia (see Chapter 102) in addition to those of meningeal irritation (headache, stiff neck). A family history of convulsions should always be sought.

Physical Examination. The physician may have the opportunity to perform the neurologic examination shortly after the seizure. A focal residual abnormality, such as paralysis of one arm (Todd's paralysis), may suggest a focal onset even when the witnessed event was generalized. In addition to a careful neurologic examination, the physical should also include a check for postural hypotension, abnormalities in heart rate and rhythm, head trauma, carotid disease, cardiac disease, systemic infection, and signs of alcohol and drug abuse (see Chapter 228 and Chapter 235).

Laboratory Studies. It is not possible by clinical means to determine definitively whether a transient or persistent neurologic event is a seizure.

Electroencephalography is the most helpful laboratory diagnostic test in the diagnosis of a seizure disorder. An abnormal electroencephalogram (EEG) with epileptiform features such as spikes or sharp waves supports the diagnosis of seizures and may provide information about the type of seizure disorder. However, an abnormal EEG pattern is not adequate for the diagnosis of seizures, and a normal interictal EEG pattern can be found in up to 20% of patients with purely generalized seizures. The likelihood of detecting an abnormality in partial complex seizures (temporal lobe epilepsy) is increased by obtaining a *sleep EEG*. However, because the EEG concentrates on cortical disturbances, abnormalities of deep temporal lobe or diencephalic structures may not be evident on a surface EEG. Specialized units provide in-hospital telemetric monitoring of patients with suspected epilepsy. A Digitrace device allows for ambulatory EEG recording for periods of up to 72 hours. The patient records clinical events with a push-button, and the patient's experiences then can be correlated with the EEG findings.

Neuroimaging. Most neurologists would agree that *magnetic resonance imaging* (MRI) of the brain without and then with *gadolinium* contrast enhancement is an important part of the workup of a patient with a first seizure. This procedure is more sensitive than *computed tomography* (CT) and may be particularly useful in demonstrating abnormalities in the medial temporal region. *Positron emission tomography* (PET) and *single-photon emission computed tomography* (SPECT) are new methods of examining cerebral function in patients with seizures. They may confirm the presence of an organic abnormality and provide an outline of the abnormal region for which surgical treatment of epilepsy might be considered. It is unlikely that a primary physician would refer a patient for one of these studies, but the primary physician should be aware that newer methods to differentiate generalized from localization-related seizures and select patients for epilepsy surgery are available in epilepsy centers.

Other Testing. Additional laboratory studies should include blood chemistries; measurement of electrolyte, calcium, and alcohol levels and a toxic screen are important. All patients with risk factors for HIV should undergo *HIV testing* (see Chapter 7). Unless evidence of infection is found or the patient presents in status epilepticus, it is no longer common practice to perform a *lumbar puncture* for a patient with a first seizure. If fever is present or the history is compatible with systemic infection, lumbar puncture remains an essential part of the neurologic evaluation.

PRINCIPLES OF MANAGEMENT

As precise a diagnosis as possible must be made before treatment is begun. This includes both the phenotype of the seizure, the EEG findings, and the identification of any underlying cause or precipitating factors. The distinction between a single seizure and epilepsy is important. During the past 20 years, important advances have been made in the treatment of all seizure types. Monotherapy with one of the standard antiepileptic drugs (AEDs) (Table 170.3) provides adequate control in 70% of adult patients. In another 15% to 20%, seizures can be controlled with a combination regimen including one or two additional AEDs. Unsatisfactory control of the seizures of the remaining patients makes them candidates for surgery or experimental drug therapy.

Table 170.3. Pharmacokinetic Summary of Antiepileptic Drugs

The Isolated Seizure

As noted earlier, an isolated convulsion does not constitute epilepsy. When a single convulsion has occurred because of a transient metabolic disturbance or drug overdose or withdrawal, it is best treated by attending to the factors that led to the disturbance. The long-term use of drugs for seizure prophylaxis in such patients is not indicated, although a short-termcourse may be used in the setting of alcohol or drug withdrawal (see Chapter 228 and Chapter 236). When no obvious, self-limited cause can be determined in a patient who presents with a single seizure, then prophylaxis must be considered. Social variables, such as loss of driving privileges, will influence the decision to treat. The most critical issue is to determine risk factors for recurrence. Recurrence is most common within the first 6 months after the first seizure, and more than 50% of patients who have a recurrence will have it within this period. The recurrence rate after a first unprovoked seizure varies from 36% to 77%. Risk factors for recurrence include known prior neurologic lesions, history of epilepsy in a sibling, prolonged Todd's paralysis, and EEG with generalized epileptiform discharges. The risk for recurrence after two seizures is 70%, and after a third nearly 80%.

Recurrent Epileptic Seizures

Overview of Basic Approach to Pharmacologic Treatment. The treatment of choice for recurrent epileptic seizures is the administration of a *single anticonvulsant drug* appropriate for the seizure type diagnosed (Table 170.1). Most available AEDs are used to prevent the recurrence of seizures rather than to produce any specific effect on the course of established epilepsy or to prevent the development of seizures after trauma. As a group, generalized seizures respond best to treatment, and full seizure control is possible with monotherapy for as many as 80% of patients with idiopathic epilepsy.

The drug should be used in doses sufficient to control the seizures as completely as possible. If side effects become intolerable, the drug should be replaced with another one, also used as monotherapy, until it is clear that the patient's seizures cannot be controlled with a single drug. In general, it is better initially to add rather than to substitute a second drug, and thereby provide seizure protection while the serum concentration of the second drug is rising. The first drug should then be tapered and discontinued in an attempt to continue monotherapy.

Carbamazepine and *phenytoin* remain the first-line treatments for adult patients with localization-related epilepsy. The rates for complete control of tonic–clonic seizures are similar for carbamazepine, primidone, phenobarbital, and phenytoin; carbamazepine offers better efficacy than phenobarbital and primidone for localization-related seizures and is also better tolerated. Phenytoin is approximately equally as effective as carbamazepine for localization-related epilepsy. Valproate is the first-choice drug of some neurologists for generalized epilepsy. Several studies have found no significant difference in seizure control among patients with localization-related seizures treated with phenytoin, valproate, or carbamazepine.

Side effects severe enough to necessitate a change in therapy occur in about 30% of patients treated with AEDs. Side effects and interactions of drugs may become intolerable if more than one drug is required. A second drug should not be added until it has been documented that control cannot be achieved with the first drug at a high therapeutic concentration or that the dose required to achieve control produces toxic effects.

When an AED is begun or the dosage of the drug is altered, one must wait for five drug-elimination half-lives to elapse before the effect of the change can be assessed. To achieve immediately a steady-state concentration equal to the usual maintenance concentration, it is usually necessary to give a loading dose of drug. Levels should be checked frequently while doses are adjusted (see Table 170.3 for appropriate intervals for level checks, maintenance doses, loading doses, and therapeutic levels of AEDs).

Classes of Antiepileptic Agents. Several effective drugs are available for treating each form of epilepsy, the drug of first choice being the one causing the least toxicity in any individual patient. Three types of antiepileptic drugs are available. *Type 1 drugs,* which include *carbamazepine* and *phenytoin*, block sustained repetitive firing, the rapid firing of action potentials that is produced by an applied depolarizing current and is dependent on the opening of increased numbers of sodium channels. *Type 2 drugs,* including *phenobarbital, valproate,* and *benzodiazepines*, have the dual actions of enhancing g-aminobutyric acid (GABA) inhibitory transmission and blocking sustained repetitive firing. *Type 3* is represented by *ethosuximide*, an AED that has no effect on either postsynaptic GABA-ergic inhibition or sustained repetitive firing but that blocks T-calcium currents, which appear to be important in the generation of normal rhythmic activity.

Important Drug–Drug Interactions. Carbamazepine, phenobarbital, and phenytoin are *inducers* of the *hepatic microsomal cytochrome P-450 enzymes*. The production of endogenous compounds such as steroids is generally regulated by intrinsic homeostatic feedback mechanisms, but increases in dosage may be necessary for medications containing steroids, used in immunosuppression, the treatment of cerebral edema, and oral contraception. Valproate is an inhibitor of this enzyme system. Table 170.4 lists selected, clinically significant drug interactions for phenytoin that may be of relevance in primary care practice. A useful pamphlet by James Fischer summarizing many drug interactions with AEDs is published by the McMahon Publishing Group in New York and is a handy reference in the primary care office practice setting.

Table 170.4. Phenytoin: Side Effects and Drug Interactions

Phenytoin. For most seizure types occurring in adults, phenytoin is an appropriate drug choice. The proprietary formulation, Dilantin, is preferable to the generic formulation. Phenytoin is well absorbed orally and has a serum half-life of 22 to 30 hours. An initial loading dose must be administered. Dose-related side effects include nystagmus, ataxia, dysarthria, and blurred vision. The presence of nystagmus can be used as a crude guide to the adequacy of dose. Duration-related side effects include osteomalacia, peripheral neuropathy, a folate-deficiency anemia, and cerebellar degeneration. Idiosyncratic reactions include gingival hypertrophy, hypertrichosis, spiking fevers, exfoliative dermatitis, bone marrow depression, liver abnormalities, teratogenesis during the first trimester of gestation, and neonatal coagulation defects.

Carbamazepine (Tegretol) is also an excellent first-line drug for adult-onset generalized tonic–clonic seizures and for complex partial seizures. Many patients report less fatigue and better performance while on this medication than on phenytoin, but a controlled study failed to confirm that carbamazepine is clearly superior. The major disadvantages of this medication include the necessity of multiple daily dosing and the requirement for frequent blood testing during initiation of the medication to monitor for uncommon instances of *bone marrow depression*.

Valproate. For patients allergic to phenytoin or carbamazepine, valproate (Depakote) is a good choice of medication. Many neurologists would choose this as a first-line drug for spike-and-wave or generalized tonic–clonic epilepsy, even in the absence of EEG abnormalities. This drug also has to be given in multiple daily doses (Table 170.3). Major side effectsof valproate are nausea, weight gain, hair loss, platelet dysfunction, fetal anomalies (neural tube defects), and liver dysfunction.

Phenobarbital is no longer a first-line drug for generalized tonic–clonic seizures, although for patients allergic to the three medications described above, it provides good control, usually with acceptable side effects.

New Antiepileptic Drugs. Several new AEDs have been introduced in the past decade. These are summarized in <u>Table 170.5</u>. Felbamate, gabapentin, lamotrigine, topiramate, and oxazepine are effective as add-on therapy for patients with partial and secondarily generalized tonic–clonic seizures. Lamotrigine is acquiring a role as monotherapy for patients with newly diagnosed epilepsy. Felbamate carries a risk for aplastic anemia and acute hepatic failure and is reserved for selected patients in whom the benefits outweigh the risks and in whom other AEDs have failed. Gabapentin has an excellent side effect profile and for this reason is used as add-on therapy. As a single agent, it is not sufficiently effective to control most adult forms of epilepsy.

Table 170.5. New Antiepileptic Drugs

Optimizing therapy requires selection of the AED that is most effective for the patient's epileptic syndrome and that has the most favorable safety profile. However, the tolerability and therapeutic efficacy of each AED can differ considerably among patients. Therapeutic monitoring of blood levels provides a standard for each individual patient's seizure control. Some patients require treatment with more than one agent, but alternative monotherapy should be tried first. The overall efficacy and safety of the new AEDs promises alternatives for many patients with refractory seizures. However, additional clinical trials and more widespread clinical use are at present needed to determine the exact role these drugs will play as first-line choices in epilepsy management. The older drugs remain the most cost-effective first-line drugs against localization-related and generalized epilepsy in adults.

Surgery for Epilepsy. With the advent of sophisticated monitoring techniques for the localization of epileptic foci, surgery has begun to play an increasing role in seizure management. Many neurologists would consider referral to a center specializing in epilepsy surgery for patients who have failed several standard drugs or who require more than one drug for seizure control and experience intolerable side effects of the medical regimen.

Prognosis and Duration of Therapy

The prognosis is a function of the underlying condition. The prognosis of *idiopathic epilepsy* depends on both the age at onset and type of convulsion. Patients with primary generalized seizures have the best overall prognosis. Childhood-onset seizures cease by age 20 in more than half of cases. Although statistics vary according to age at onset and type of seizure, on average, more than half of patients are seizure-free with or without medication at 10 years after diagnosis. The probability of remaining seizure-free is highest for those patients whose seizures were generalized at the outset and were diagnosed before age 10. Eighty percent of recurrences develop within 5 years of discontinuation of medication. The major cause of failure to control seizures is *noncompliance*, and it has been shown that as many as one third of patients do not take their medication as prescribed.

The early identification of patients with refractory epilepsy has been studied. Among patients who fail to become seizure-free with medications, those who have had many seizures before the initiation of therapy or who show an inadequate response to initial treatment with AEDs are the most likely to have refractory epilepsy. For patients with correctable structural abnormalities, surgery should be considered as soon as treatment with two first-line drugs fails. In selected groups, this approach can yield an 80% seizure-free success rate.

Discontinuing Antiepileptic Drugs. Most neurologists require a seizure-free interval of at least 2 years before considering discontinuation of medication. The EEG is of only modest help in predicting which patients may be weaned successfully from their medications; persistent EEG abnormalities would make discontinuation of medication inadvisable, but the documentation of a normal EEG does not eliminate the risk for seizure recurrence. In a large prospective study, the risk for relapse was greatest in patients who had complex partial seizures with secondary generalization, EEG abnormalities before treatment that did not change during treatment, or a requirement for valproate. According to current American Academy of Neurology recommendations, discontinuation of AEDs can be considered for a patient who has has been seizure-free for 2 to 5 years on AEDs if the patient has a single type of partial seizure, the neurologic examination findings and intelligence quotient are normal, and the EEG has normalized with treatment. For patients not meeting this profile, the risk for recurrence may be almost 40%.

INDICATIONS FOR REFERRAL AND ADMISSION

The workup of a patient with a first seizure can be accomplished by the primary care physician with a sleep-deprived EEG and MRI. Antiepileptic medication usually can be initiated in the outpatient setting, and appropriate monitoring of therapeutic levels can be planned (<u>Table 170.3</u>).

For the patient who fails to respond to the first-choice medication or for whom side effects are intolerable, a second drug should be tried. If it appears that the patient may require two drugs for seizure control or if the organic nature of all the witnessed spells is questionable, it is appropriate to refer the patient to a neurologic specialist experienced in drug management and the techniques of EEG and telemetry. Such a referral will also provide the patient with access to centers in which epilepsy surgery is performed and through which newer anticonvulsant medications can be obtained.

Differentiating between an epileptic attack and other systemic disorders or psychiatric conditions can be difficult. Nonepileptic attacks and epileptic seizures can coexist in patients with seizure disorders. Monitoring with telemetry for several days in the hospital may be necessary to clarify the diagnosis. However, hospitalization after a typical generalized seizure is not necessary for a patient with a known seizure disorder, unless significant trauma has occurred or it is necessary to adjust the medication program under careful monitoring.

PATIENT EDUCATION

Perhaps the most important role a physician can play in caring for an epileptic patient is that of counselor, educator, and sometimes legal advocate. A long-standing relationship must be maintained with a patient whose chronic disease is surrounded by an enormous amount of superstition, prejudice, and misunderstanding. The diagnosis of epilepsy clearly imposes certain restrictions on the patient's life, so that the certainty of the diagnosis in a healthy young person is imperative (see above).

Work. In addition to reviewing the prognosis with the patient, it is important for the physician to emphasize that even if seizures are not entirely controlled, most epileptics are able to lead productive lives. Of the nation's 4 million epileptics, 15% to 25% are unemployed, a figure higher than the national average. However, people known to have seizures are barred absolutely only from those professions that require a chauffeur's or pilot's license.

Driving. Driving laws vary from state to state, but in general, states require a *seizure-free interval* of *6 months to 1 year* before reapplication for a driver's license may be made. Continued supervision by a physician is mandatory. These laws apply both to patients with generalized epilepsy and those with localization-related seizures.

Alcohol and Caffeine. The diagnosis of epilepsy does not make absolute abstention from alcohol mandatory, although the patient should be counseled that alcohol can lower the seizure threshold and that binge drinking is contraindicated. The relationship of seizures to the ingestion of large amounts of caffeine is less clear, but

the patient should be counseled to use substances containing caffeine in moderation.

Pregnancy and Contraception. Women with epilepsy face several special issues. The American Academy of Neurology recommends that during the reproductive years, monotherapy with an AED should be the aim of treatment, and that the decreased effectiveness of hormonal contraception caused by enzyme-inducing AEDs be discussed with the patient. For an epileptic woman considering *pregnancy*, folic acid supplementation should be instituted at a dosage of no less than 0.4 mg daily. The teratogenic potential of AEDs should be discussed, as should options for considering AED discontinuation before pregnancy. Women with epilepsy who take carbamazepine or valproate should be offered prenatal testing with a-fetoprotein levels at 14 to 16 weeks' gestation. Non–protein-bound AED levels should be monitored during pregnancy. The effect of pregnancy on the severity of a seizure disorder is nil in about half of women. Of the remainder, half experience a slight worsening of seizures. Ideally, with well-controlled seizures, it would be possible to taper and discontinue the patient's medication before conception. However, one does not always have such luxury, and a patient may worry about teratogenesis. The risk for fetal malformations in an epileptic woman not on medication is still roughly double that of the general population, and teratogenesis has clearly been established for phenytoin (digital and craniofacial abnormalities and some cardiac defects), valproate (neural tube defects), and carbamazepine (facial anomalies and neural tube defects). Nonetheless, women taking phenytoin still have a 94% chance of having a completely normal pregnancy outcome.

Thus, the risks of continuing AEDs must be weighed against the benefits of preventing a sustained convulsion (fetal hypoxia, mechanical injury if the mother falls). For the patient who needs to remain on AEDs during pregnancy, monthly monitoring of her drug levels is important because the combination of decreased protein binding, decreased absorption, and increased metabolism and plasma volume result in lower drug levels. Vitamin K at a dosage of 10 mg/d should be prescribed in the last trimester of pregnancy for women taking enzyme-inducing AEDs. Postpartum adjustment of the AED will be necessary for women whose dosage has been increased during pregnancy. AED dosages usually can be reduced to those given before pregnancy by 8 weeks after delivery.

Surgery. *Surgical procedures* pose no special threat to the epileptic patient as long as medications are not discontinued. Parenteral forms of phenytoin, phenobarbital, and valproate are available. Although no parenteral form of carbamazepine is available, a rectal suppository can be prepared in many hospital pharmacies.

Breast-feeding. Should the mother taking anticonvulsant therapy elect to nurse her infant, breast-feeding usually poses little problem. Some sedation in the infant is occasionally seen with phenytoin, carbamazepine, or phenobarbital. One case has been reported of an infant with thrombocytopenia and anemia, presumed to have been induced by valproate ingested through breast milk. Breast-feeding appears to be safe, without any risk for hepatic or hematologic toxicity to the infant.

Heredity of Seizures. Patients may worry considerably about the inheritance of seizures. Epilepsy is hereditary, although the precise genetics are not clear for all types. One fourth to one third of patients with idiopathic epilepsy have a family history of seizures. Seizures develop in 3% of the children of patients with idiopathic epilepsy. Febrile convulsions also appear to be more common in children who have afflicted relatives, as are posttraumatic seizures.

Teaching First Aid. Families of patients with epilepsy should know the fundamentals of emergency management of seizures. They should be instructed in the positioning that protects the airway and cautioned against use of the time-honored tongue blade. It should be emphasized to the patient's family that few seizures last long enough to impair cardiopulmonary function.

THERAPEUTIC RECOMMENDATIONS

- Establish an etiologic diagnosis and treat the underlying cause if possible. Symptomatic therapy can begin while evaluation is in progress.
- To prevent further convulsions, begin with a loading dose of a drug of choice appropriate to the seizure type identified. This can often be accomplished on an outpatient basis. A maintenance dose is then begun, and the dose is adjusted to achieve a therapeutic level, with the level checked at an interval appropriate for the drug half-life.
- If seizures persist, check the serum levels of the AED and inquire into alcohol and other drug use. Add a second drug and then taper and discontinue the first drug if the seizures cannot be controlled with the drug of first choice.
- If the seizures are controlled, have the patient continue the medication for at least 2 years. If the patient remains seizure-free, a cautious attempt to taper the medication can be made according to the guidelines explained in the preceding text.
- Teach the patient how to recognize the warning signals of a seizure and what to do to minimize injury. Instruct the patient about the role of alcohol in precipitating seizures.
- Educate the patient and family about prognosis, activity, and job precautions.

CHAPTER 171 MANAGEMENT OF TRANSIENT ISCHEMIC ATTACK AND ASYMPTOMATIC CAROTID BRUIT

AMY A. PRUITT

INTRODUCTION

Stroke is the third leading cause of death in the United States and is the leading cause of long-term disability in the older population. Although medical and surgical therapies for stroke are improving, prevention is still the most effective strategy and a major responsibility of the primary care physician. Stroke prevention through risk factor management may be a major contributor to the rapid decline during the past two decades in death rates from stroke. The cornerstone of the preventive effort is the early identification and vigorous treatment of stroke risk factors (e.g., hypertension, diabetes, coronary artery disease, smoking; see Chapter 26, Chapter 30, Chapter 54, and Chapter 102). Atrial fibrillation, a major risk factor for embolic stroke, also requires serious attention (see Chapter 28 and Chapter 83).

Patients who present with a transient ischemic attack (TIA) or an asymptomatic carotid bruit pose the problem of stroke prevention at a more advanced stage of cerebrovascular disease. Approximately 50,000 patients with TIAs present for evaluation annually, and it is estimated that 2 million people have some degree of asymptomatic carotid stenosis. The primary physician should be able to recognize these conditions by history and physical examination, use appropriate noninvasive imaging and flow studies cost-effectively, and know when to initiate more aggressive measures, such as anticoagulant therapy or surgical intervention.

PATHOPHYSIOLOGY, CLINICAL PRESENTATION, AND COURSE

Transient Ischemic Attack

Transient ischemic attacks are defined as episodes of temporary, focal cerebral dysfunction resulting from vascular disease that last *less than 24 hours* and *usually less than 10 minutes*. TIAs are part of a spectrum that includes ischemic events lasting more than 24 hours and partially reversible, nondisabling strokes. The distinction between TIAs, cerebral infarction with transient signs (CITS), and stroke has become less clear with the advent of computed tomography (CT) and magnetic resonance imaging (MRI) because many patients whose deficits appear to resolve completely are found to have radiographic changes suggesting infarction. However, all these patients fall into a group that may be at risk for further ischemic damage.

Pathogenesis. TIAs can develop through any of several mechanisms. In the majority of cases, *emboli* of platelets and fibrin or of atheromatous material that breaks off from a vessel wall (usually the carotid) transiently occlude a cerebral or ophthalmic artery or one of its branches. Thrombus formation distal to an atherosclerotic plaque is common in tightly stenosed arteries (>75% stenosis, residual lumen <2 mm) or even in totally occluded carotid arteries, and the thrombus often serves as a source of emboli. The heart is the other important source of emboli. Cardiac lesions predisposing to cerebral embolism include mitral valve stenosis, mitral valve prolapse, calcified mitral annulus, ventricular aneurysm or dyskinesia, atrial or ventricular clot, valvular vegetation, and interatrial shunt. Atrial fibrillation greatly exacerbates the risk for cardiac embolization. Occasionally, the intracranial arteries are the source of emboli. This phenomenon occurs most frequently among male African-Americans and should be considered in patients with no extracranial vascular or cardiac source of emboli. The aortic arch may also be a source of atheromatous emboli.

Transient ischemic attacks may also develop when *transient hypotension* occurs in conjunction with a hemodynamically *significant carotid stenosis* (>75% occlusion). The resulting reduction in collateral flow to the ipsilateral carotid territory can lead to transient neurologic symptoms. The reduced blood pressure rarely results in focal symptoms unless a severely stenotic lesion is already present.

Small-vessel thrombotic or lacunar stroke may be preceded by transient, focal neurologic deficits in as many as a third of patients who go on to have a completed stroke. The clinician must be aware that the distinction between stroke mechanisms, particularly distal emboli or large-vessel origin and small-vessel thrombotic disease, may be difficult. Because management of the two types of conditions differs considerably, it is important to be aware of syndromes that commonly are associated with small-vessel disease (pure motor hemiparesis, ataxic hemiparesis, clumsy hand dysarthria syndrome).

In certain rare instances, TIAs may be attributable to one of the following: steal phenomena (e.g., subclavian steal); hyperviscosity states (e.g., polycythemia); vasculitis; coagulopathies (e.g., antiphospholipid antibody syndrome, deficiency of factor V Leiden, protein C, protein S, or antithrombin III); dissection of the carotid or vertebral artery. These underlying causes of stroke and TIA are more common in younger patients (under age 45).

Clinical Presentation. TIAs can be divided into those caused by disease in the carotid circulation and those that are a consequence of disease in the vertebrobasilar territory. Symptoms of TIA associated with *carotid disease* include transient monocular blindness; clumsiness, weakness, or numbness of the hand; and disturbed speech. Transient monocular blindness is caused by occlusion of the ophthalmic artery or branches ipsilateral to the carotid stenosis and classically is described by the patient as a "shade" or "curtain" that descends over the affected eye. In patients with symptoms suggestive of carotid disease, the detection of a carotid bruit on the same side as the symptomatic eye or cerebral hemisphere is suggestive but not diagnostic of high-grade carotid stenosis.

Symptoms of *vertebrobasilar disease* include binocular visual disturbance, vertigo, paresthesias, diplopia, ataxia, dysarthria, light-headedness, generalized weakness, loss of consciousness, and transient global amnesia. Each of these may be an isolated symptom of disease of the posterior circulation, although isolated vertigo without other brainstem symptoms is rarely caused by vertebrobasilar occlusive disease (see Chapter 166).

Certain clinical features are likely to be associated with carotid or vertebrobasilar disease, but no single feature is a consistently reliable sign. Two clinical features were found in an angiographic study to correlate with the arteriographic findings: (a) A *hemispheric attack lasting longer than 60 minutes*, whether single or multiple, was significantly associated with a *normal carotid* (attacks were most likely to be caused by emboli from the heart); (b) the *nonsimultaneous occurrence of transient hemispheric episodes* and *transient monocular blindness* correlated with an 80% incidence of carotid disease. No difference between groups with normal or diseased carotid arteries was found when the cumulative number of attacks per patient was considered. Similarly, the presence of purely ocular or purely hemispheric symptoms could not be used to distinguish between the two groups.

Clinical Course and Risk for Stroke. The interval since the most recent TIA appears to be the single most important factor in predicting the risk for stroke. Of those patients in whom stroke will develop, approximately one half will have a stroke within 1 year after the first TIA, and approximately one fifth will have a stroke during the first month after the episode. The risk for stroke cannot be predicted by the number of TIAs, duration of symptoms, or clinical phenomena. All patients with any type of TIA should be considered at risk for stroke, and those with TIA of recent onset (<1 month) should be evaluated urgently (see below). About 50% to 75% of patients with occlusive carotid disease who have a stroke have preceding TIAs.

Cardioembolic Stroke with Transient Symptoms

In patients with cardioembolic stroke who have transient symptoms, the symptoms tend to last several hours. The neurologic disorder associated with cardioembolic infarction is maximal at onset in 80% of patients, and about 75% of emboli lodge in one of the middle cerebral arteries and cause symptoms similar to those of carotid occlusive disease.

Asymptomatic Carotid Bruits

Incidental discovery on physical examination of an asymptomatic carotid bruit suggests the presence of an atherosclerotic lesion that has narrowed the lumen by at

least 50%, to less than 3 mm. The pitch of the bruit increases with the severity of stenosis. Prolonged, very high-pitched bruits suggest a residual lumen of less than 1.5 mm (>75% stenosis). Most atherosclerotic lesions causing bruits tend to be located on the posterior wall of the common carotid artery at the bifurcation, compromising flow at the origin of the internal carotid. When stenosis is tight and flow is reduced, a mural thrombus may form distally in the proximal internal carotid artery, worsening occlusion and serving as a source of emboli. Plaque ulceration may also provide a nidus for mural thrombus formation.

Epidemiologic studies indicate that asymptomatic bruits are associated with an increased risk for stroke, coronary disease, and death, but not necessarily with an increased risk for stroke on the side of the bruit. In a large, prospective study of 500 patients with asymptomatic bruit followed for an average of 2 years by clinical and Doppler examination, the overall risk for stroke in patients who remained asymptomatic was 1% at 1 year and 1.7% when those in whom TIAs developed were included. A major predictor of stroke was the severity of carotid stenosis, as was progression to high-grade stenosis (>75% stenosis, residual lumen <2 mm). Other risk factors included hypertension, preexisting heart disease, male sex, and a positive family history.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of a TIA-like episode includes any condition that causes transient symptoms in a focal distribution and is not limited to those of vascular origin. Vascular mechanisms include carotid or vertebrobasilar occlusive disease, small-vessel ischemic stroke, and occlusion by emboli originating in the heart or aortic arch. *Focal seizures* (see Chapter 170) can produce symptoms similar to those of a TIA, as can the focal aura of *migraine*, which is not always followed by headache (see Chapter 165). *Hyperventilation* can produce distal tingling and numbness. *Carpal tunnel syndrome* may present with intermittent (often nocturnal) paresthesias in a median nerve distribution. Even a protruding *cervical disk* or osteophyte may produce transient focal motor or sensory symptoms (as during manipulation of the head or neck; see Chapter 167).

WORKUP

The goals in evaluating a TIA or an asymptomatic bruit are the detection of significant vascular disease and the assessment of stroke risk. One needs to identify those patients who require aggressive intervention. In addition, if cerebrovascular disease can be ruled out as the cause, a search for other causes is required. The patient with a new onset of TIAs (<30 days) has an increased risk for stroke and should be evaluated promptly.

History. For the patient with a suspected TIA, questioning should first confirm that the transient episode was indeed a TIA, based on onset and duration. Symptoms lasting longer than 24 hours exclude TIA; cessation within 10 minutes increases the probability. An episode that lasts hours might be the consequence of an embolic event. The onset of headache during resolution of the neurologic deficit is more suggestive of a migrainous episode (see Chapter 165). A careful description of symptoms may be helpful in distinguishing vertebrobasilar involvement from carotid disease (see above). In addition, the frequency of episodes, date of first onset, and presence of underlying heart disease and cardiovascular risk factors are important to ascertain because they can help predict the clinical course. If the patient has hypertension or cardiac disease or is older (>65 years), the risk for subsequent stroke is increased. A disabling stroke is more likely to develop in patients with carotid symptoms than in those with vertebrobasilar dysfunction. The patient is at greatest risk for stroke in the first few months after the onset of TIAs.

When an apparently asymptomatic carotid bruit is found on physical examination, it is worthwhile to go back to the patient's history and check carefully for overlooked transient neurologic events. Their presence would greatly increase the significance of the physical examination finding and indicate a heightened risk for stroke.

Inquiry into a history of hypertension or heart disease and any family history of stroke further helps to determine stroke risk. Risk factors for stroke include advanced age, elevated systolic blood pressure, current smoking, and the presence of diabetes, atrial fibrillation, or coronary heart disease.

Physical Examination. Physical examination should be directed to the cardiovascular and nervous systems. One checks for hypertension, atrial fibrillation, and heart murmurs (see Chapter 21 and Chapter 33). Funduscopic examination at the time visual symptoms occur may reveal an embolus in one of the retinal artery branches. Neurologic examination findings are likely to be normal if the examination is conducted after the TIA has passed.

Gentle palpation and auscultation of the carotid arteries should be performed to note upstroke, volume, and the presence of a bruit. As stated above, the presence of a bruit does not invariably herald significant stenosis (a bruit can be present with hemodynamically insignificant lesions), but in as many as 70% to 80% of cases, the bruit does indicate important ipsilateral carotid disease. The pitch of the bruit and its duration should be noted because they tend to correlate with severity of stenosis.

Palpation of the facial and superficial temporal pulses with simultaneous assessment of the supratrochlear and supraorbital pulses may confirm collateral flow to the latter two vessels by way of the external carotid artery, which suggests occlusion of the internal carotid artery. Unfortunately, the vertebrobasilar circulation is not accessible to accurate physical examination.

Laboratory Studies. Initial laboratory studies should include a complete blood cell count and a determination of glucose, cholesterol, triglyceride, and electrolyte levels. Homocysteine has been independently associated with stroke risk and should be measured, along with serum folate and vitamin B$_{12}$. It appears that most people with low serum folate or vitamin B$_{12}$ levels also have high homocysteine levels.

No entirely reliable noninvasive test for carotid or vertebrobasilar disease is available. In the past two decades, great strides have been made in the noninvasive evaluation of the carotid arteries and vessels of the posterior circulation. For the assessment of suspected *carotid lesions*, the combination of *Doppler* and *B-mode ultrasonography* allows a determination of lumen size and visualization of the carotid arterial lesion. In studies comparing arteriography and duplex carotid ultrasonography, a reduction in the diameter of the carotid artery of more than 60% was associated with a residual lumen at arteriography of less than 2 mm. However, in some instances, one cannot tell if the carotid artery is completely occluded or only tightly stenosed.

Magnetic resonance angiography (MRA) increasingly is being used in lieu of standard arteriography in the preoperative assessment of symptomatic carotid disease. However, most clinical studies still require the gold standard of arteriography. The use of *transcranial Doppler* techniques helps to measure flow in the ophthalmic system, assess the hemodynamic significance of the carotid stenosis, and detect any major stenosis of the intracranial vessels.

For the study of the *posterior circulation, transcranial Doppler* ultrasonography provides a relatively inexpensive means of noninvasively surveying large intracranial vessels. The test measures the velocity of flow, which increases in the setting of stenosis. However, it does not provide direct anatomic information. *MRA* provides noninvasive visualization of the vertebrobasilar system.

To detect silent or prior infarction, unsuspected hemorrhage, or nonvascular disease, such as tumor, *CT* or *MRI* of the brain should be performed.

No entirely reliable noninvasive test for occlusive disease is available, and *arteriography* remains the definitive diagnostic procedure. Arteriography with the use of selective transfemoral catheterization or digital subtraction techniques should be performed only if the physician would proceed to endarterectomy in the instance of carotid disease or to anticoagulation in the case of vertebrobasilar disease. Thus, the procedure should lead to a critical management decision. The dye load involved in cerebrovascular angiography can be substantial and necessitates adequate hydration, particularly in patients with underlying renal disease or diabetes.

Transthoracic echocardiography makes it possible to identify cardiac lesions that predispose to embolization, but the yield is low in patients over the age of 50 without evidence of cardiac disease on physical examination (see Chapter 33). *Transesophageal echocardiography* is more sensitive and specific for detecting intracardiac and aortic sources of embolization, such as left atrial thrombus and atherosclerosis of the ascending aortic arch. It should be considered when standard echocardiography is unrevealing but clinical suspicion of embolization is strong. Ambulatory *Holter monitoring* is useful when atrial fibrillation as a precipitant of embolization is a concern and results of the *resting electrocardiogram* are normal (see Chapter 25 and Chapter 29).

Abnormalities of blood coagulation may contribute to 4% of strokes in young persons. Some authorities recommend a *coagulopathy workup* for stroke patients whose age is below 50, who have prior venous disease or a family history of abnormal clotting and no other explanation for their stroke, or whose hematocrit, platelets, prothrombin time, or partial thromboplastin time is abnormal. A full workup in the young stroke patient would require a test for anticardiolipin antibodies; measurement of protein C and protein S, antithrombin III, factor V Leiden, and homocysteine levels; an antinuclear antibody test; determination of the erythrocyte sedimentation rate; and syphilis serology.

PRINCIPLES OF MANAGEMENT

Transient Ischemic Attack

The literature on therapeutic options in TIAs is complex and often confusing. Until recently, many studies were not well controlled, and study populations were often not well defined or characterized. Recent demographic data have clarified those patients at greatest risk for stroke. As noted earlier, the interval since the most recent TIA appears to be the most important single factor in predicting the risk for stroke. Therefore, all patients with any type of TIA should be considered at risk for stroke, and those with a recent onset (<1 month) of TIA should be evaluated urgently. The physician should remember that although TIAs are predictors of stroke, myocardial infarction is still the most common cause of death in this group (annual mortality rate of 5%) and that the patient's cardiovascular status and cardiac risk factors must also be considered (see Chapter 30).

With the caveat that optimal therapy for TIAs is an evolving area and that new information is forthcoming regularly, the following guidelines for management are recommended:

Symptomatic Patients with Tight Carotid Stenosis. Patients with *more than 70% carotid stenosis*, especially those who have had recurrent TIAs or a TIA within 4 months of the current visit, require prompt attention and should be considered for *carotid endarterectomy*. If adequate radiologic support is available, these patients should undergo arteriography as soon as possible in addition to a careful cardiovascular evaluation (see Chapter 30). Because the risk for cardiovascular mortality and morbidity associated with noncardiac surgery is very high in this population, a careful cardiac assessment is an essential component of the determination of surgical candidacy. (Some physicians directly admit such patients to the hospital and immediately place them on IV heparin until arteriography can be performed—a practice that has been the subject of several small trials; see Annotated Bibliography).

The role of surgery has recently been clarified by the North American Symptomatic Carotid Endarterectomy Trial, published in 1991. This trial involved more than 600 *symptomatic patients* with *high-grade* (*70% to 99%*) *stenosis* of a carotid artery in the appropriate territory for their TIA. The trial was terminated early when it became clear that endarterectomy (when performed by a skilled surgical team) was significantly superior to medical management (aspirin) for patients with recent hemispheric or retinal TIA or nondisabling stroke and *ipsilateral* high-grade stenosis of the *internal carotid artery*.

Symptomatic Patients with Less Severe Carotid Stenosis. The North American Symptomatic Carotid Endarterectomy Trial also addressed the role of surgery in patients with *less severe carotid stenosis* (*50% to 69%*). For those who recently have had a TIA or a stroke, endarterectomy lowers the risk for stroke to a greater degree than does medical management. Patients with *less than 50% stenosis* do not benefit from surgery. These patients have a cardiovascular mortality risk from noncardiac surgery equal to that of patients with critical carotid stenosis, but a lower stroke risk. The reader is urged to watch the literature for reports from both of these multicenter trials for guidance on the best approach to the management of such patients.

All patients should have their blood pressure well controlled (systolic blood pressure <140 mm Hg and a diastolic blood pressure <90 mm Hg). In patients with a history of stroke or TIA, blood pressure-lowering is not only safe, but appears to reduce the risk of recurrent events (HOPE and PROGRESS trials). ACE inhibitors should be considered as first-line anti-hypertensive agents for patients with known cerebrovascular disease. Combination therapy with a low dose diuretic (e.g., indapamide 2.5 mg/d or hydrochlorothiazide 12.5 mg/d) appears to offer the greatest benefit and may be instituted at the physician's discretion. Low-dose ACE inihibitor therapy should be considered for all patients with cerebrovascular disease regardless of blood pressure.
Updated: 12/20/01

Smoking and excessive alcohol consumption should be stopped, coronary artery disease treated, fasting blood glucose maintained below 126 mg/dL, and a regular exercise program of 30 to 60 minutes three times per week instituted. Estrogen replacement should be maintained in postmenopausal women. Lipid-lowering therapy should be instituted in patients with elevated cholesterol.

A daily *antiplatelet agent* should be prescribed. Options include *aspirin*, *clopidogrel*, *ticlopidine*, and a combination of aspirin and extended-release dipyridamole. Aspirin (50 to 325 mg/d) is recommended as initial therapy. Ticlopidine is effective in reducing the risk for recurrent TIA or stroke in both men and women, but it may increase serum cholesterol levels and has been associated with neutropenia. Clopidogrel has a better safety profile and is a good alternative to aspirin or ticlopidine. Dipyridamole combined with aspirin (Aggrenox) is at least as effective as clopidogrel. Anticoagulant therapy with warfarin is not routinely recommended for patients with atherothrombotic TIAs. Long-term oral anticoagulation with warfarin is advised for patients with atrial fibrillation, but aspirin confers some benefit in these patients if oral anticoagulation is contraindicated (see Chapter 28 and Chapter 83).

Candidates for Medical Therapy. Medical therapy may be elected for TIA patients who are *elderly*, *cannot tolerate surgery*, have a *single remote TIA*, or are seen in settings where angiographic and surgical services are unavailable. The optimal medical management for TIA begins with *aspirin*. In the Canadian Cooperative Study Group evaluation of 585 patients with TIA, aspirin therapy achieved a 19% overall reduced incidence of TIA, stroke, and death in male patients. The results of a U.K. study were similar, and the Dutch TIA trial found that 30 mg of aspirin/day was no less effective than higher doses in preventing vascular events and caused fewer gastrointestinal side effects. As noted earlier, patients with a history of stroke or TIA require blood pressure lowering (systolic BP <140 mm Hg, diastolic BP <90 mm Hg), which reduces the risk of recurrent events. In patients with known cerebrovascular disease, ACE inhibitors are the drug class of first choice for this task. Adding a low dose of mild diuretic (e.g., indapamide 2.5 mg/d or hydrochlorothiazide 12.5 mg/d) appears to enhance the protective effect of ACE inhibition (PROGRESS trial). The addition of an ACEI at low dose should be considered for all patients with cerebrovascular disease regardless of blood pressure.
Updated: 12/20/01

Patients with Transient Ischemic Attack and Normal Carotid Vessels. Patients with transient ischemic attack and normal carotid vessels should undergo a thorough cardiac evaluation to rule out an embolic source in the heart. In the absence of atrial fibrillation, valvular heart disease, or carotid disease, the proper preventive treatment for future stroke is not clear. It is common practice to place such patients on *aspirin* prophylactically (325 mg/d), and some evidence is available to recommend this practice. Although aspirin may reduce the morbidity from myocardial infarction, it is unclear whether it reduces stroke with noncarotid sources. Aspirin and warfarin have yet to be compared in a well-designed, randomized study.

Warfarin therapy is indicated for patients having TIA-like episodes believed to be caused by cardioembolic disease. Several controlled multicenter studies have demonstrated that the incidence of thromboembolic complications of *nonrheumatic atrial fibrillation* can be significantly reduced by oral anticoagulant therapy in comparison with aspirin or placebo. Warfarin anticoagulation is currently recommended, and low-intensity therapy (prothrombin time 1.2 to 1.4 times control) has proved equally efficacious and safer than standard-intensity therapy for patients with nonrheumatic atrial fibrillation (see Chapter 28 and Chapter 83).

Asymptomatic Carotid Bruit

A carotid bruit detected in an asymptomatic patient need not be considered an invariable harbinger of stroke, but it does suggest atherosclerotic carotid disease. The risk for stroke increases significantly with severity of stenosis, onset of TIAs, and progression of the lesion. The patient should undergo a thorough, noninvasive carotid evaluation (see above) to confirm the carotid origin of the bruit, the severity of stenosis, and its hemodynamic effects. Regardless of the severity of stenosis, the recognition and *prompt reporting of any TIA symptoms* should be emphasized. Previously asymptomatic patients with high-grade stenosis (70% to 99%) who subsequently experience a TIA are at markedly enhanced risk for stroke and should be referred promptly for consideration of *surgical intervention* (see above).

Medical Therapy. Antiplatelet therapy with low-dose aspirin (60 to 325 mg/d) is recommended; higher doses are associated with an increased risk for subarachnoid hemorrhage, especially in elderly patients with hypertension. Aggressive treatment of *cardiovascular risk factors* (i.e., *hypertension, lipids, smoking, diabetes*; see Chapter 26, Chapter 27, Chapter 54, and Chapter 102) is essential, not only because the risk for coronary events is high and can be significantly reduced (see Chapter 30), but also because the risk for stroke can be lessened. For example, clinically significant reductions in the risk for stroke and stroke mortality (12% to 23%) are associated with aggressive lipid-lowering therapy with statins, reductions in risk similar to those associated with the use of antiplatelet agents. The benefit of identifying and treating elevated *homocysteine* levels remains to be ascertained, even though such elevations appear to be associated with an increased risk for stroke.

Endarterectomy. The role of carotid endarterectomy in the asymptomatic patient with a high-grade stenosis is unresolved. The use of carotid endarterectomy is on the rise; after a 6-year decline, the number of operations rose by 94% between 1991 and 1996. The cost-effectiveness of this practice needs to be questioned in view of data from randomized trials. In the Asymptomatic Carotid Atherosclerosis Study, a 53% reduction in *relative risk* was noted, but the *absolute risk* declined by only 1% annually in a comparison with medical therapy. Sixty-seven patients would have to undergo surgery to prevent one stroke, at an additional cost of more than $1.5

million. Moreover, because patients were a select, low-risk surgical group and the surgeons and hospitals were screened for a perioperative complication rate of only 2.3%, it is difficult to extrapolate these results to practice at large. Reported perioperative complication rates in most settings are considerably higher (e.g., 6.5% for perioperative stroke and death, including a 1.8% rate of disabling stroke). Asymptomatic patients with an occluded carotid artery and asymptomatic stenosis on the other side experience a reported perioperative complication rate after endarterectomy of 12.6%. Such levels of perioperative risk appear to outweigh any benefit obtained from elective endarterectomy. To date, trials of asymptomatic persons have failed to identify a subgroup in whom prophylactic benefit clearly outweighs such operative risk. Thus, despite the temptation to conclude that these patients are at particular risk for stroke, surgery cannot yet be recommended in this asymptomatic population.

Pending definitive data on medical versus surgical therapy in the truly asymptomatic patient, some authorities recommend that endarterectomy be considered for those who demonstrate a rapid progression to hemodynamically and anatomically critical stenosis (e.g., lumen <1 mm), provided that they have no active coronary disease, are not diabetic, and have an anticipated life expectancy of more than 5 years. In support of this view is the high risk for stroke; against it is the high cardiac risk associated with surgery and the absence of proven benefit. If surgery is going to be recommended, one must have access to a skilled surgical team with a proven record of low perioperative morbidity and mortality (<2%) and be sure that a careful preoperative cardiac risk assessment is carried out (see Chapter 30 and Chapter 36).

CHAPTER 172 MANAGEMENT OF MULTIPLE SCLEROSIS

AMY A. PRUITT

Multiple sclerosis (MS) is the most common demyelinating disease of the central nervous system (CNS), affecting approximately 2.5 million young adults worldwide. Severe disability develops in approximately 30% of patients. The manifestations of the disease are protean, and its clinical course is highly variable from patient to patient. Although most patients with MS will be under the care of the neurologist during periods of marked exacerbation, they often depend on the primary physician for close monitoring, interpretation of symptoms, treatment of intercurrent infections, and decisions regarding the need for referral. Consequently, the primary physician must be familiar with the range of clinical presentations for MS, its natural history, and the available therapeutic options. Such knowledge facilitates the provision of proper primary care and ensures the optimal timing of referrals.

PATHOPHYSIOLOGY, CLINICAL PRESENTATION, AND COURSE

The etiology of multiple sclerosis remains unknown, but available research suggests an interplay of genetic susceptibility, environmental exposure(s), and defective regulation of the immune response. These factors result in a series of discrete episodes of myelin-specific *autoimmune injury* to the CNS, separated both in time and space. Acutely, an infiltrate of lymphocytes, macrophages, and plasma cells forms in areas of involvement. T cells are thought to initiate the process, and activated macrophages to damage the myelin. Localized edema and transient breakdown of the blood–brain barrier occur. The chronicity of the inflammatory process results in the formation of a plaque or glial scar, made up of proliferated astrocytes that cluster in response to inflammatory injury of the myelin sheath. Lesions occur predominantly in the white matter of the brain and spinal cord; occasionally, gray matter is involved to a minor degree.

Demyelination is characteristically focal, but axonal injury can occur early in the course of the disease. Brain atrophy also has been documented during early, clinically silent phases of the illness. Plaques are most commonly found in the optic nerves, spinal cord, brainstem, cerebellum, and periventricular areas. After an attack, some remyelination occurs, which accounts for a partial resolution of symptoms. However, partially demyelinated axons are susceptible to dysfunction, particularly under conditions of heat stress but also spontaneously. Even a hot shower may cause a temporary exacerbation.

Clinical Presentation is a function of the site of the inflammatory process. Attacks are by definition those that produce symptoms that last more than 24 hours. They average up to one per year and decrease in frequency over time. Transient *sensory deficits* are the most common initial presentation, affecting about 40% to 50% of patients. They include *paresthesias* or diminution of sensation in the upper or lower extremities. The sensory disturbance may be bilateral and symmetric, extending to involve the adjacent trunk. About 15% to 20% experience *acute monocular visual loss* because of *optic neuritis*. A central scotoma, transient pain on eye movement, and decreased pupillary reaction to light (Marcus-Gunn pupil) are characteristic features. *Diplopia* resulting from *internuclear ophthalmoplegia* or an oculomotor defect is another common symptom heralding MS. Bilateral internuclear ophthalmoplegia is very characteristic of MS and strongly suggests the diagnosis. A failure of adduction and coarse nystagmus in the abducting eye are noted. Other oculomotor functions remain intact. *Ataxia* and *intention tremor* are manifestations of cerebellar involvement. *Motor deficits* may occur acutely or insidiously, with the insidious variety particularly common in older patients. Legs are more likely to be involved than arms, initially asymmetrically. However, upturned toes are common bilaterally, even in patients with unilateral problems. *Urinary difficulties* (frequency, urgency, incontinence) are consequences of upper motor nerve injury in the spinal cord. The external sphincter fails to relax adequately, causing incomplete emptying. Such autonomic injury may also produce *constipation* and *impotence*.

Later in the course of illness, *cerebral involvement* may produce memory loss, personality change, and emotional lability. More than 60% of MS patients demonstrate abnormalities on formal neuropsychiatric testing, even if asymptomatic. *Paroxysmal symptoms* may result from dysfunction of partially demyelinated axons and simulate a transient ischemic attack or focal seizure, or produce an attack of tic douloureux (see Chapter 176).*Fatigue* may be prominent and even predate exacerbations.

Clinical Course and Prognosis. The clinical course tends to follow one of three basic patterns. Younger patients manifest a *relapsing–remitting* course, characterized by attacks followed by complete or nearly complete remission. In later years, a *secondary progressive* course, with steady gradual worsening, develops in more than 50% of patients. About 10% of patients who present with MS in later life (40 to 60 years of age at onset) have a steadily progressive course; this pattern is called *primary progressive* and tends to be associated with prominent spinal cord involvement. An uncommon form of MS, *relapsing progressive*, is diagnosed when patients have largely progressive disease exacerbated by acute attacks and little remission.

After 15 years of clinical disease, about 50% of patients are still capable of walking and 30% are able to continue working. Frequent attacks early in the course of the disease increase the chances of disability, as does late onset, a progressive course, or early cerebellar or pyramidal involvement. In about 5% to 10% of patients, the disease seems to pursue a very "benign" course, but it is difficult to predict in advance which patients safely can forego any disease-modifying therapy.

DIAGNOSIS

The diagnosis is suggested clinically by the development of symptoms and signs suggesting CNS disease separated both anatomically and in time (>1 month). At times, the symptoms suggest only a single lesion, but a careful physical examination reveals evidence of multiple lesions (upturned toes bilaterally, subtle internuclear ophthalmoplegia, mild afferent pupillary defect).

Laboratory findings help support the diagnosis, although no single test is diagnostic and clinical evidence for at least two separate neurologic lesions is still required. The most sensitive test is *magnetic resonance imaging* (MRI). Multiple periventricular plaques, presenting as areas of increased signal intensity on long TR-weighted and proton density-weighted images, are characteristic and found in more than 90% of patients with known MS. Patients with chronic progressive disease have more confluent periventricular and infratentorial lesions, but they are often most disabled by spinal cord lesions. However, the hyperintense white matter lesions seen on long TR-weighted images on MRI are nonspecific, and similar white matter lesions also occur in normal elderly persons and patients with chronic uncontrolled hypertension, advanced Lyme disease, and CNS vasculitis. The *cerebrospinal fluid* examination reveals abnormalities in 95% of MS patients. Modest increases in cell count and protein are common but nonspecific; increases in *immunoglobulin* G (IgG) and *oligoclonal IgG bands* on electrophoresis are more specific and suggest an increased risk for disseminated disease. Visual or auditory *evoked potentials* are abnormal in demyelinated tracts and may serve as additional evidence of MS when MRI results require supporting data. Exclusionary blood work in all patients suspected of having MS should include Lyme disease serology, determination of vitamin B$_{12}$ levels and antinuclear antibody, and possibly HIV testing.

PRINCIPLES OF MANAGEMENT

The twofold goal of therapy for patients with MS is to prevent relapses and retard progressive worsening of the disease. There is no cure for MS, but much can be done to reduce the symptoms of an acute exacerbation. A more difficult task is to improve the long-term course of the illness. Efforts to treat MS have focused on suppressing the immunologically induced inflammatory response that characterizes the condition. Disease-modifying therapy should be considered early in the course for patients with unfavorable prognostic markers, such as progressive disease from the onset, a short interval between the first two relapses, poor recovery from relapse, the presence of motor and cerebellar signs at onset, and multiple cranial lesions on long TR-weighted MRI. Since 1993, several new agents have become available to modify the course of MS. Therapeutic advances in MS depend on the conduct of clinical trials, and problems encountered in the design of such trials include the highly variable and unpredictable course of the disease and the difficulty of establishing measurements of disability.

Treatment of an Acute Attack. High-dose parenteral corticosteroids appear capable of shortening an acute attack. The best available data come from the Optic Neuritis Treatment Trial, a randomized, controlled study of patients presenting with isolated neuritis, in which 3 days of high-dose *IV methylprednisolone* followed by several weeks of oral prednisone was compared with oral prednisone alone or placebo. Patients given high-dose IV therapy demonstrated the best restoration of vision, but at 12 months, their vision was no different from that of patients given placebo. However, at 3 years, they showed a 66% reduction in relative risk for the

development of definite MS. The potential significance of this finding is great, but it requires confirmation. Patients treated with oral prednisone alone did worse at 6 months than those given placebo. The worsening on oral prednisone alone is hard to explain, but oral steroids alone should not be used until more data are forthcoming. For now, a course of high-dose IV therapy is preferred. Whether it should be followed by a more prolonged course of oral prednisone remains unclear because the study did not examine such a program.

Disease-modifying Therapy. The U.S. Food and Drug Administration has approved three drugs for patients with relapsing–remitting MS. These drugs are recombinant *interferon beta-1b (Betaseron)*, recombinant *interferon beta-1a (Avonex)*, and *glatiramer acetate (Copaxone)*. They have all been tested in separate placebo-controlled, double-blinded multicenter trials. Reductions in relapse rates of 33%, 37%, and 29%, respectively, were demonstrated. The interferons have also been shown to reduce the numbers of new lesions on MRI. The further indication of primary prevention has recently been added for Avonex. When Avonex was given after a single episode secondary to demyelination, fewer patients progressed to clinically definite MS. The drugs currently are available only by injection. The interferons have been associated with flulike symptoms, at times severe and persistent. Patients taking Copaxone have experienced uncommonly a systemic reaction of flushing, sweating, and palpitations.

A consensus is growing that disease-modifying therapy should be initiated early in the course of MS, before irreversible disability has developed. This opinion is supported by increased clinical and MRI evidence that the inflammatory process is active in many patients during periods of clinical remission and that irreversible axonal injury accumulates with time, even during the phase of relapsing–remitting disease. Theserum of patients who continue to have clinical disease activity despite interferon therapy should be tested for neutralizing antibodies.

Treatment of Progressive Disease is more problematic. A multicenter study of interferon beta-1b was completed in Europe recently. The study found a significant delay in time to sustained progression in patients who received interferon therapy. Most neurologists offer the disease-modifying drugs to patients with secondary progressive disease. These drugs are extremely expensive and may cause several weeks of unpleasant side effects as they are started; furthermore, the patient and family must be taught how to administer them. The long-term benefits must be inferred from the results of existing studies, which have lasted only 3 to 5 years.

Patients whose disease continues to progress despite interferon or copolymer therapy may benefit from other strategies. IV immune globulin has been used monthly for 2 years in a small study that demonstrated less worsening of disability in the active treatment group. Immunosuppressive agents such as methotrexate and azathioprine have been used, but their efficacy in progressive disability is unclear. Patients with rapidly progressive disease given a course of IV *cyclophosphamide* with or without subsequent booster injections have demonstrated stabilization over 1 year. Such nonspecific immunosuppressive treatment is fraught with significant morbidity and should be reserved for patients with rapidly progressive disease who do not respond to less toxic alternatives. *Plasmapheresis*, the subject of one small, uncontrolled study, showed some benefit for patients with rapidly progressive disease. Approved in January 2000, *mitoxantrone* (*Novantrone*) has been shown to relieve disability significantly, improve ambulation, and reduce the relapse rate in patients with relapsing–progressive or secondary progressive disease. Data also suggest a decrease in lesions visible on gadolinium-enhanced MRI in comparison with the placebo group.

Treatment of Complications. *Paroxysmal symptoms*, such as lancinating pain or limb spasms, respond to *carbamazepine* (200 mg twice daily). Tricyclic antidepressants may help control *emotional lability* and relieve neuropathic pain. Low doses of *amitriptyline* (25 to 75 mg/d) often suffice. Higher doses of tricyclic agents are indicated for overt *depression* (see Chapter 227). *Spasticity* lessens with the use of *baclofen* in low doses (started at 5 to 10 mg three times daily), but confusion, sedation, and increased muscle weakness are limiting side effects. Diazepam and dantrolene are alternatives. When *incontinence* is problematic, an anticholinergic (e.g., 15 mg of proprantheline up to four times daily as needed) or oxybutynin (Ditropan; 5 to 10 mg two or three times per day) will help if the cause is bladder spasm (frequency, urge incontinence); a cholinergic agent is best in cases of bladder atony (see Chapter 134). No specific therapy has been very useful for the debilitating fatigue accompanying this condition, but amantadine (Symmetrel; 100 mg two or three times per day) has been successful in some patients.

PATIENT EDUCATION

One of the most difficult aspects of MS is the uncertainty that accompanies the disease. If the diagnosis is in question, every effort should be made to confirm it or rule it out. Patients with MS fear becoming disabled. Providing them with as much information as possible helps them to maintain a sense of control. Even advice on handling the affairs of everyday life is greatly appreciated, such as avoiding a very hot shower that may transiently exacerbate symptoms. Although it is hard to predict a patient's future clinical course, reasonable estimates can be made based on the clinical course to date.

Patients need to know that progression to disabling disease is not inevitable, that the prognosis is highly variable, and that in many cases the disease never becomes incapacitating. Patient morale appears to be an important determinant of outcome. In randomized studies, the high frequency of remission and outright clinical improvement noted among patients randomized to placebo underscores this point. It should not be surprising that a disease of immune dysfunction such as MS might be influenced by the patient's state of mind, given the well-documented finding that the psychological state can affect T-cell function. Maintaining a hopeful perspective may have a remarkably positive effect and should not be overlooked. The value of establishing a close, supportive relationship cannot be overemphasized.

INDICATIONS FOR REFERRAL AND ADMISSION

When a diagnosis of MS is suspected on clinical grounds, a neurologic consultation can be helpful in determining the need for further diagnostic studies (MRI, lumbar puncture with immunoelectrophoresis, evoked potentials) and in selecting a treatment modality. In addition, patients experiencing an acute exacerbation of functional significance should be referred to a neurologist promptly for consideration of a course of high-dose IV glucocorticoid therapy. Neurologic consultation about the timing or appropriateness of interferon beta or copolymer treatments is important. Referral to an occupational and physical therapist can greatly facilitate the maintenance of daily functioning in patients with significant motor or sensory deficits.

CHAPTER 173 MANAGEMENT OF ALZHEIMER'S DISEASE AND RELATED DEMENTIAS

M. CORNELIA CREMENS

INTRODUCTION

Approximately 4 million Americans suffer from Alzheimer's disease. With the aging of the U.S. population and a doubling of the prevalence of dementia for every 5 years over the age of 65 years, the problem of caring for such patients is becoming an increasingly important medical and societal challenge. Medical care for the majority of patients with Alzheimer's disease and other dementias is usually the responsibility of the primary care physician. This role requires knowledge of the course of the illness, the best approaches to managing concomitant medical and psychiatric conditions (psychosis, anxiety, depression, behavioral disturbances), and the social services available. Skill is required in family education and counseling, appropriate application of new therapies, and cessation of life-prolonging therapy at the end of life.

CLINICAL PRESENTATION AND COURSE

Alzheimer's Disease

Early Stages. Most patients are *mildly forgetful* and complain of such memory deficits as forgetting names or where they placed household items. The patient may seem concerned but has no social or employment problems and shows no evidence of memory deficit during a clinical interview. The next stage is characterized by decreased performance in demanding work or social situations. Patients complain of *poor concentration*, difficulty in remembering words and names, more prominent memory loss, and confusion, and they may report that co-workers have noticed their relatively poor performance. Some patients present initially with *visual–spatial deficits*, whereas others may have difficulty with *speech* early in the course of the illness. Later, patients are easily disoriented and get lost when traveling to an unfamiliar location. Anxiety and depression are common, and many patients begin to deny symptoms. Changes in personality and judgment can begin to cause problems with family and co-workers.

Intermediate Stages. As the illness progresses, patients become unable to travel alone and are unable to handle their personal finances. *Memory for recent events* is drastically impaired, and patients display a decreased knowledge of current events. Complex tasks are impossible, but patients remain fairly well oriented to time and person and can travel to *very* familiar places, like the corner drugstore. Many patients are aware of their deficits and are capable of understanding what is happening to them. Patients instinctively withdraw from previously challenging situations and may even have trouble with the activities of daily living. Difficulty with speech is more pronounced. *Denial* may become pronounced. Anxiety increases, along with suspiciousness and agitation. The most difficult behavior at this point is wandering and pacing, which makes it important that patients begin to wear an identification bracelet available through the Alzheimer's Association.

Late-Stage Disease. Patients can no longer survive without some assistance. They are unable to recall major relevant aspects of their current lives or even the names of close friends and family members. *Delusions* and *hallucinations* are common. For example, the spouse is accused of being an impostor, or patients talk to imaginary persons or their own reflection in the mirror. *Depression*, *agitation*, and *violent behavior* may occur. Frequently, patients are disoriented to time or place. However, they generally remain able to eat and use the toilet without assistance, but they may have difficulty in properly choosing and putting on clothing.

Advanced Disease. In the last stages of the disease, patients become totally *incapacitated* and *disoriented*. They eventually forget their own name and may not recognize their spouse. *Incontinence* is common, with loss of bladder and bowel control. *Personality* and *emotional changes* become very pronounced, although these occasionally occur even in the earliest stages. Eventually, all verbal abilities are lost, motor skills deteriorate, and patients require total care. Total dependence on the caregiver ensues, and it is important to monitor for caregiver stress, or "burnout." Generalized cortical and focal neurologic signs and symptoms are frequently present. Death usually occurs from total debilitation or infection.

Clinical Course. The course of Alzheimer's disease from onset to death varies from 2 to 20 years. The average is about 6 to 8 years. Typically, the illness progresses at a fairly constant rate. If it has rapidly developed during the past year, it is likely to continue at that rate. A slowly progressive illness during the past 5 to 10 years suggests that the patient may survive for a number of years, especially if the patient is in otherwise good physical health. Other clinical features found to be independent predictors of more rapid progression to incapacity and death include hallucinations, paranoia, delusions, misidentification syndromes, extrapyramidal signs, and a low score on initial psychometric testing.

Dementia with Lewy Bodies

This newly identified condition has features that distinguish it from Alzheimer's disease. Accurate diagnosis is essential because of the increased sensitivity of these patients to neuroleptic agents. Because they often present initially with psychosis (usually visual hallucinations), before the onset of other characteristic features, patients who have dementia with Lewy bodies are at great risk for adverse side effects from the use of neuroleptics. Patients may present with psychiatric cognitive or parkinsonian motor symptoms, which leads to a variety of initially mistaken diagnoses. A progressive decline in cognition interferes with social or occupational functioning. Memory impairment may not be prominent in the earlier stages, but deficits in attention and visual–spatial and frontal–subcortical skills are often prominent. Core features of dementia with Lewy bodies include recurrent visual hallucinations that are well formed and detailed, fluctuating consciousness, and spontaneous motor features of parkinsonism and extrapyramidal disease. Other supportive features include falls resulting from difficulty with movement, syncope and transient loss of consciousness resulting from suspected autonomic dysfunction, hallucinations in other domains, systematized delusions, and sensitivity to neuroleptic medications. The pace of the clinical decline may be more rapid than that of Alzheimer's disease.

PRINCIPLES OF MANAGEMENT

Once treatable causes of dementia have been ruled out (see Chapter 169), the physician faces the challenge of caring for the patient with Alzheimer's disease or dementia with Lewy bodies, a person with a chronic, progressively disabling illness. Management involves the skillful interplay of medication to improve the cognitive state and functional status, psychopharmacologic therapy, and supportive care by family members (who often choose to maintain the patient at home) and community agencies. In addition to these challenges, the management of Lewy body disease requires a few unique pharmacologic considerations.

Alzheimer's Disease

Prevention. The development of an effective preventive program for Alzheimer's disease awaits a more definitive understanding of the condition's underlying pathophysiology. At present, most preventive measures are based on etiologic hypotheses. One popular hypothesis is that "oxidative stress" from free radical formation damages neurons and contributes to the characteristic neurofibrillatory histologic changes. On the basis of this hypothesis, increased intake of "antioxidants" has been proposed as a possible preventive measure. Common dietary substances with purported antioxidant activity include *vitamins C* and *E*, *beta carotene*, and the *flavonoids*.

Updated: 7/10/02

Drugs for Memory Enhancement and Improvement of Cognitive Function. To date, no treatment has proved capable of markedly slowing or significantly improving the cognitive defects of Alzheimer's disease. Drugs that *enhance cholinergic transmission* have been the subject of intense study because cholinergic neuronal degeneration and a depletion of acetylcholine-synthesizing enzyme (choline acetyltransferase) have been noted in Alzheimer's disease. Acetylcholinesterase inhibitors and cholinergic receptor agonists are being studied.

Tacrine. The first cholinesterase inhibitor on the market was tacrine (tetrahydroaminoacridine), which effected a modest but statistically significant reduction in the rate of cognitive decline. However, the improvement was not clinically meaningful (no difference in scores of global functioning), and it had to be given four times a day with monitoring of liver function, which limited its usefulness. Few patients are treated with tacrine now, and it is not recognized as an important advance in treatment.

Donepezil (Aricept) and Rivastigmine (Exelon). These newer cholinesterase inhibitors have several advantages over tacrine: less frequent dosing, improvement in behavioral as well as cognitive domains, and reasonably well-tolerated side effects (e.g., mild nausea, rare emesis, mild diarrhea, mild somnolence, occasional insomnia). Donepezil is started at 5 mg/d and increased if necessary to 10 mg/d in once-daily dosing. The drug appears safer and more effective than tacrine. Rivastigmine is started at 1.5 mg twice daily, with the dose increased to 6 to 12 mg/d. Long-term experience with rivastigmine is still limited.

Dietary Supplements (Ginkgo, Lecithin). Many dietary supplements are available and heavily promoted, but they have not proved beneficial. Ginkgo biloba demonstrated an extremely modest effect in only one study. Metaanalysis of the available data suggests modest benefit at best. Many patients and family members ask about taking herbal supplements in addition to the prescribed medications. Because the herbal agents have active ingredients, they should be used cautiously, if at all. No evidence has been found that *lecithin* has any effect or that avoidance of aluminum-containing preparations (e.g., antacids) is of any benefit, despite concerns derived from the increased deposition of aluminum in the central nervous system of patients with Alzheimer's disease.

Estrogen. Estrogen was in the news when epidemiologic studies suggested it as a possible link to reduced rates of Alzheimer's disease in postmenopausal women on hormone replacement. Additional studies are under way, but preliminary data are not promising. Because of speculation that *nerve growth factor* and estrogen may interact to prevent cholinergic neurons from degenerating, additional studies of such growth factors are underway.
