Selegiline and Vitamin E. "Protective" therapy with antioxidants and "preventive" therapy with drugs that inhibit b-amyloid formation are under study. These approaches attempt to address the purported pathophysiologic features of Alzheimer's disease. For example, *selegiline*, a monoamine oxidase inhibitor used in Parkinson's disease, is thought to reduce neuronal oxidative injury and enhance cerebral catecholamine levels. Early evidence suggests that the administration of 10 mg/d may slow functional deterioration in persons with moderately severe disease. a-Tocopherol (vitamin E) traps free radicals and reduces cell death *in vitro* caused by exposure to b-amyloid, the protein found in Alzheimer's disease. In a recently completed randomized, controlled study, megadoses of vitamin E (2,000 IU/d) slowed disease progression and preserved function in persons with moderately severe Alzheimer's disease. However, the combination of selegiline and vitamin E was no better than the use of either agent alone. Many prescribe vitamin E routinely; full benefit remains to be fully defined.

Unhelpful Treatments. Drugs found not to be helpful include cerebral vasodilators (*dihydroergotoxine*), ergoloid mesylates (*Hydergine*), central nervous system stimulants (*amphetamines*), opiate antagonists (*naloxone*), neuropeptides (*vasopressin*), and, believed to act as cerebral vasodilators, probably have some metabolic enhancer activity.

Drugs for Confusion, Agitation, and Disturbed Sleep. (See also Table 173-1 and Table 173-2 and Appendix.)

POTENCY	SEDATION	ANTICHOLINERGIC EFFECT	EXTRAPYRAMIDAL EFFECT	HYPOTENSION
Low				
Thioridazine (10–50 mg)	high	high	low	high
Intermediate				
Perphenazine (0.5–5 mg)	medium	medium	medium	medium
High				
Haloperidol (0.25–2 mg)	low	low	high	low
Thiothixene (0.5–4 mg)	low	low	high	low
Atypical Antipsychotics				
Clozapine (6.25–100 mg)	high	high	low	high
Olanzapine (2.5–10 mg)	medium	medium	low	low
Quetiapine (12.5–300 mg)	medium	low	low	high
Risperidone (0.25–3 mg)	low	low	medium	medium

Table 173-1. Commonly Used Neuroleptics in the Elderly

DRUG	EXTRAPYRAMIDAL EFFECT	HYPOTENSION	SEDATION	ANTICHOLINERGIC EFFECT
Clozapine	low	high	high	high
Olanzapine	low	low	high	med
Quetiapine	low	high	med	low
Risperidone	med	med	low	low

Table 173-2. Comparison of Atypical Neuroleptics

In severe or unresponsive cases, psychotropic pharmacotherapy may be necessary. For the safe and effective use of psychotropic medication in patients with Alzheimer's disease, adjustments in drug selection, dose, and frequency are necessary to compensate for the alterations in drug uptake and metabolism that occur in

the elderly (see Appendix). Such adjustments are particularly important when neuroleptics, benzodiazepines, and sedative-hypnotics are given. In a recent study of nursing home patients, a substantial improvement was noted in many of them when psychotropic drugs, prescribed on a long-term basis, were discontinued or reduced in dose.

The long-term use of sedatives and psychoactive agents in the confused patient should be avoided unless persistent, extreme agitation hampers care. Also problematic is the regular use of sedative-hypnotic agents for sleep (see Chapter 226), as they can cause confusion and disorientation and prolong sedation. If such therapy is contemplated, the lowest possible doses should be given for the shortest time possible. The newer atypical neuroleptics (e.g., *quetiapine* or *clozapine*) are often given first because of their low side effect profile (Table 173-1 and Table 173-2). Quetiapine is easier to prescribe because marrow suppression does not occur; weekly white cell counts are indicated with clozapine use. Patients not responsive to the atypical neuroleptics may respond to a small dose of *thioridazine* (10 to 25 mg daily at bed time). *Haloperidol* is often a first choice in the setting of delusions and hallucinations. Doses in the range of 0.5 to 1 mg two or three times a day usually suffice, but one must be careful to avoid long-term use because of the risk for inducing tardive dyskinesia. b-Blockers and anticholinergics may exacerbate confusion.

Drugs for Depression. Depression is best treated with a *selective serotonin reuptake inhibitor* (SSRI), such as citalopram, sertraline, paroxetine, or fluoxetine. Patients with depression who do not respond to the SSRIs may improve on one of the older tricyclic compounds with few anticholinergic side effects, such as *desipramine* (10 to 50 mg at bedtime) or *nortriptyline* (10 to 75 mg at bedtime), but drugs with marked anticholinergic activity (e.g., amitriptyline) may worsen memory (see Chapter 227).

Management of Behavioral Disorders. Certain behaviors are particularly troublesome to family members. Among those cited most frequently are catastrophic reactions (including violent behavior), wakefulness, suspiciousness, and incontinence.

Catastrophic Reactions. Catastrophic reactions are massive emotional overresponses that are typically precipitated by task failure or minor stress. Hitting and violent resistance to care are extreme forms of such reactions. Most excessive emotional responses can be minimized by teaching the family to avoid or remove the precipitating task or stress, to remain quiet and calm, and to change the focus of attention gently. Neuroleptic drugs, anticonvulsant drugs (e.g., valproic acid, carbamazepine, or gabapentin), or buspirone are sometimes helpful in difficult cases, but only as an adjunct to behavioral techniques (see Appendix).

Wakefulness and Night Walking. Wakefulness and night walking often deprive the caregiver of much-needed rest. Helpful environmental interventions include placing locks on each door so that the patient will not wander out of the house at night, keeping the patient physically active during the day, and not allowing a nap. Sedative-hypnotics, such as a short-acting benzodiazepine or chloral hydrate, may be helpful (see Chapter 228). Occasionally, low doses of a neuroleptic or anticonvulsant may be needed.

Suspiciousness. Suspiciousness and accusatory behaviors are believed to result from the brain-injured person's efforts to explain misplaced possessions or misinterpreted events. If the family understands this, their frustration, hurt, and anger may be reduced. Simple interventions, such as keeping an orderly house or making a sign pointing to where an object is kept, may help. Neuroleptics may be used as a last resort.

Incontinence. Incontinence is typically a late manifestation of Alzheimer's disease, but when present early, it warrants a careful search for other causes, such as urinary tract infection (see Chapter 133) and other causes of dementia, such as normal-pressure hydrocephalus (see Chapter 169).

Inappropriate Sexual Behavior. Inappropriate sexual behavior is very uncommon. Family members can be reassured. In the rare instances in which it occurs, self-stimulation is the usual form; Alzheimer's patients are not child molesters.

Treatment of Deterioration Caused by Concurrent Medical Illness. Patients with Alzheimer's disease deteriorate rapidly both cognitively and behaviorally when they experience a *superimposed illness*. Coexistent medical problems, such as asthma, diabetes, and congestive heart failure, should be carefully controlled. Even a minor upper respiratory tract or urinary tract infection can worsen behavior. Patients are susceptible to *medication-induced delirium*; close supervision of drug regimens is imperative.

Home Environment. As mentioned earlier, families need to be encouraged to maintain a *structured*, predictable environment for the patient. Any change can be devastating and stressful to a patient and may produce a massive emotional overresponse. A schedule in which activities such as arising, eating, taking medication, and exercise occur at the same time each day maximizes the patient's familiarity with the personal environment. At times, the use of an *orientation center* in the home, with pertinent information such as the date, time, schedule of household events, and pictures of relevant people, is very helpful.

Preventing Falls. Of particular importance to survival and quality of life is the need to reduce the risk for *falls* in the home. It has been clearly demonstrated that falls are one of the major predictors of reduced survival. Installing hand rails, encouraging the use of a walker, and eliminating throw rugs and other obstacles can be extremely important to maximizing survival and minimizing disability. In the nursing home environment, the use of both *tricyclic antidepressants* and the SSRIs has been found to increase the risk for falls. The tricyclics may decrease blood pressure and cause postural hypotension. The SSRIs do not cause orthostasis, but they may cause dizziness and increase a patient's mobility. The risk for falls is dose-related, which suggests that physicians should start some patients with doses less than the usual starting dose (see Appendix).

Driving. Frequently, patients will want to *drive* when it is clear that they are no longer safe on the roads. The family members at times will resist stopping the patient from driving, stating that the patient is a good driver. This may be true, but the patient is at great risk for becoming lost or getting into a dangerous situation. Therefore, family education is essential. If possible, it is best to avoid direct confrontation with the patient. Simple techniques such as hiding the keys, disconnecting distributor wires, or giving the patient a nonfunctional set of keys have usually been successful in discouraging patients from driving.

Firearms. Any firearms should be removed from the home for obvious reasons. In addition, smoking and cooking become potentially dangerous activities. Environmental modifications, such as removing stove knobs, having a stove cut-off switch placed in an inconspicuous place, locking rooms or closets, and locking up matches, are important for safety.

Management of the Family. Some family members may well react with dread and depression to the fact that their relative has Alzheimer's disease. Those members who have a preexisting psychiatric illness may decompensate. Others will have suspected the diagnosis and are relieved to find an understanding physician who will be available and helpful during the course of the illness. Family members who are initially stunned and ask few questions should not have information forced on them. Careful explanation of any further tests should be provided and a follow-up appointment arranged within a week. Common questions include the following: How long will the patient live? How rapidly will the patient deteriorate? What are the chances that other family members will be affected by the disease—is it hereditary? Is there a treatment?

Family members concerned about risk can now be more accurately informed than previously with the availability of data from large-scale epidemiologic studies. Being a first-degree relative does confer significant risk [relative risk (RR) about 2.5], as does being African-American (RR, 1.6) and female RR, 1.5). Apo E genotype also is an important risk factor. Although cumulative risk of dementia by age 85 years among first-degree relatives is high (just over 25% for whites and 43.7% for African-Americans), the cumulative risk does not approach these levels until later in life. Graphs of cumulative risk from major epidemiologic studies can be used to help determine an individual family member's degree of risk. Establishing degree of risk can be helpful in determining who should be followed closely, especially as advances are made in prevention of Alzheimer's disease, so that timely intervention can be assured.

Updated: 3/4/02

Most helpful for coping are the services of a social worker skilled in management of Alzheimer's disease. Within the first few weeks after the diagnosis has been made, family members should see a *social worker* who is familiar with community resources, such as visiting nurse services, delivery of meals, financial aid, and nursing homes. For the patient with very early Alzheimer's disease, this may seem premature, but family members will be reassured by the knowledge that help will be available when needed in the future. Most families read about the illness and become acutely aware of its devastating course.

Guilt, unrealistic expectations, and assumption of *excessive responsibility* are common responses of families. In discussing these and similar issues, the physician should focus on both physical realities and the family's emotional response to the patient. One frequently encountered source of difficulty is the reversal of parent–child roles that the care of an elderly person often represents. There is no one way to handle this issue; however, in the overwhelming majority of such cases,

just allowing family members to discuss these and other issues will be therapeutic.

A lack of personal time for caregivers and *sleep disturbances* in patients are the least tolerable aspects of home care. Families do best when relatives and friends visit frequently and when provisions are made for the primary caregiver to take breaks from the responsibilities. Visiting nurses and centers that provide day care can be invaluable. Family support is the major variable in keeping the cognitively impaired elderly patient at home.

Support groups can be very helpful. Even with a compassionate and empathic physician, many families feel alone with this illness and are unable to find friends who understand. Embarrassment may make them withdraw from previous social contacts. To meet the need for communication and information, families in many areas have established *volunteer organizations* that are involved in helping each other, sharing solutions to management problems, exchanging information, supporting needed legislation and research, and educating the community. These organizations welcome members who are concerned about any of the dementing illnesses, of which Alzheimer's disease is the most common. The number of such support groups is growing rapidly, and families consistently report how helpful they are. Local volunteer organizations have established a national organization, the *Alzheimer's Association*, whose goals are family support, education, advocacy, and encouragement of research. The address of the Alzheimer's Association is 919 North Michigan Avenue, Suite 1000, Chicago, IL 60611-1672; the web address is www.alz.org; the telephone number is 800-272-3900. The national organization will give family members the addresses of local groups. Each family member should be encouraged to read one of the available lay books on Alzheimer's disease. *The 36-Hour Day* is required reading for anyone (including the physician) who is dealing with a person with a progressive dementing illness.

Nursing Home Placement and Care. It is always a difficult moment when the family considers nursing home placement. Placement represents an irrevocable loss of autonomy for the patient. The decision must be approached with careful deliberation and respect for the patient. Although the family's needs are important to consider, the physician has a special obligation to the patient. If the patient created an advance directive before becoming mentally incapacitated (see Appendix, Chapter 1.1), the choices set forth can be respected and followed. In the absence of such a directive, the physician needs to act as it appears the patient would have wanted. If a surrogate has been designated, this person can help in the decision making. The goal, first and foremost, is to help the patient.

Before any action is taken regarding nursing home placement, it is worth carefully reexamining the home situation to be sure all alternatives to placement have been explored. Have home health aides, senior day care, and similar supports been used to relieve the family's burden?

Only after all home care resources have been exhausted or found to be insufficient is it proper to proceed with placement. An appropriate site is one that can provide emotional support, reassurance, and security. One seeks a nursing home that preserves a sense of connection and closeness to others. The primary physician plays a critical role in ensuring that the placement is carried out well and serves the best interests of the patient.

As noted earlier, the use of psychoactive drugs in the nursing home environment can adversely affect alertness, mobility, and blood pressure. The risk of falls and the decline in overall functional status correlate with number and doses of drugs prescribed. Use should be kept to a minimum (see Appendix).

Often during advanced phases of the illness, when nutrition begins to decline because of difficulty in feeding, the question arises of the value of a *feeding tube*. The best available data show no benefit from tube feeding in regard to pressure sores, infections, cognitive function, pain, or risk for aspiration pneumonia. Moreover, survival does not appear to be prolonged. The practice of placing a feeding tube is discouraged by most authorities.

Dementia with Lewy Bodies

Although the basic principals and much of the care for this condition are identical to that for Alzheimer's disease, important exceptions exist. The most important one is the need for caution in the administration of *neuroleptics*. Because patients who have dementia with Lewy bodies may present with psychotic features (e.g., vivid visual hallucinations), physicians tend to expose them early to standard neuroleptic medications (e.g., haloperidol), often before the diagnosis is recognized. The net result is a worsening or precipitation of extrapyramidal symptoms and little improvement in mental status. Because patients with Lewy body disease are very sensitive to these medications, it is best to begin with one of the atypical neuroleptics (e.g., *quetiapine* or *clozapine*; see Table 173-2) when treatment of hallucinosis or other psychotic features is required. As noted, quetiapine is easier to prescribe because a weekly white blood cell count is not required. However, it is important to recognize that both agents cause hypotension and sedation, even at low doses. *Selegiline* (5 mg twice daily) has demonstrated some ability to slow disease progression in patients with Lewy body disease.

THERAPEUTIC RECOMMENDATIONS

- Once a progressive dementing illness has been diagnosed, the primary care physician becomes the main coordinator of the patient's care and advisor to the family. The physician should consciously decide whether to take on this responsibility or to refer the patient and family for care by a group specializing in the management of such patients.
- Family members should be apprised of the patient's diagnosis, and an open discussion should be part of the initial management.
- Early in the course of the illness, a social worker should meet with the family to help plan for care and provide emotional support.
- A predictable, well-structured home environment should be established, especially one that limits the risk for falls.
- All unnecessary medications, especially those that may cause cognitive impairment, should be stopped, or the dosage should be reduced.
- When a concomitant psychiatric problem (e.g., depression, anxiety, behavioral disorder, psychosis) develops, psychopharmacologic intervention should be considered.
- For depression, begin with a low dose of an SSRI or a well-tolerated tricyclic agent (see Table 173-3 and Chapter 227). For anxiety or difficulty with sleeping, consider a low dose of a short-acting benzodiazepine (e.g., 1.0 mg of lorazepam; see Chapter 226). For psychotic behavior or catastrophic reactions, a low dose of a neuroleptic may prove useful, with an atypical neuroleptic preferred for patients with Lewy body disease (see Table 173-1 and Table 173-2). Drug treatment should be brief (except in depression), and the smallest dose possible should be given.

DRUG	EXTRAPYRAMIDAL EFFECT	HYPOTENSION	SEDATION	ANTICHOLINERGIC EFFECT
Clozapine	low	high	high	high
Olanzapine	low	low	high	med
Quetiapine	low	high	med	low
Risperidone	med	med	low	low

Table 173-3. Antidepressants for Depression in the Elderly (see also Chapter 227)

- Although a number of drugs are available to treat cognitive impairment, none is consistently effective, and results are modest at best. *Donepezil* (5 to 10 mg daily) or *rivastigmine* (1.5 mg twice daily) effects some improvement in cognitive function, although results are modest. These cholinesterase inhibitors may also improve behavioral problems. *Hydergine*, although widely used, is not recommended.
- Consider a trial of *selegiline* (5 mg twice daily) for patients with Lewy body disease. Every patient with memory loss or cognitive impairment should be on *vitamin E* (2,000 IU/d) to slow functional deterioration in persons with moderately severe disease.
- Family members should be advised to join the local chapter of the Alzheimer's Association and to become knowledgeable about the disease and its course by reading one of the currently available books. (*The 36-Hour Day* is an excellent resource.)
- The need for nursing home placement should be approached carefully and only after home care resources have been fully utilized. Many day care programs have been established that specialize in the care of patients with Alzheimer's disease. Emphasis is on providing for the emotional and physical needs of the patient, although family preferences also deserve consideration. The specialized care units for patients with Alzheimer's disease provide a comfortable,

stimulating, and safe environment for the patient who can no longer remain at home.

CHAPTER 174 APPROACH TO THE PATIENT WITH PARKINSON'S DISEASE

AMY A. PRUITT

Of the movement disorders, the most common is Parkinson's disease, an adult-onset, neurodegenerative disease characterized by tremor at rest, rigidity, and bradykinesia. Parkinson's disease affects more than 1 million people in North America. The refinement of drug therapy for Parkinson's disease has brought relief to thousands of patients with this immobilizing condition. The recent development of therapy that may slow disease progression makes the early diagnosis and treatment of Parkinson's disease particularly critical. Proper treatment requires careful timing and skillful utilization of drugs because important difficulties are associated with pharmacologic therapy. Moreover, drug efficacy declines with time, and the therapeutic response may be blunted by improper timing or inappropriate selection of antiparkinsonian agents.

Although the "fine tuning" of Parkinson's disease is largely in the province of the neurologist, the primary care physician is in the best position to make the diagnosis, institute therapy, and monitor the often substantial side effects associated with antiparkinsonian agents.

PATHOPHYSIOLOGY, CLINICAL PRESENTATION, AND COURSE

Pathophysiology. Parkinson's disease is a *neurodegenerative* condition. Its most characteristic pathologic feature is a loss of *dopamine-containing* neurons; the nuclei of these neurons reside in the pars compacta of the *substantia nigra*, and the axons terminate in the *caudate nucleus* and *putamen* (the striatum). Other pigmented and nonpigmented nuclei in the brainstem and elsewhere are also affected. Associated with neuronal loss is the development of concentric hyalin inclusions in the cytoplasm of affected neurons, called *Lewy bodies.* Symptoms are believed related to the imbalance between dopaminergic and cholinergic influences on striatal tissue created by the loss of dopamine-containing neurons. Proper striatal function depends on this balance.

Although parkinsonism may result from substance exposures, infection, and a host of other conditions (Table 174.1), idiopathic disease remains the most common form. A possible mechanism for idiopathic disease has been suggested by the observation that symptoms of parkinsonism develop in IV drug abusers who inject MPTP (an analogue of meperidine). MPTP causes neuronal degeneration of the substantia nigra through its effects on monoamine oxidase B. Its metabolite concentrates in dopaminergic neurons, where it is bound to neuromelanin and inhibits complex 1 of the mitochondrial respiratory chain. The substantia nigra of patients with Parkinson's disease seems particularly vulnerable to *oxidative insults.* The demonstration that a toxin can produce parkinsonism has led to a thus far unfruitful search for causative environmental precipitants. A rural environment has been reported to be associated with an increased risk for Parkinson's disease, as has exposure to pesticides. Conversely, smoking has been associated with a decreased risk for the development of Parkinson's disease.

Table 174.1. Differential Diagnosis of Parkinsonism

Clinical Presentation. Parkinson's disease is an affliction of middle to late adult life, although 30% of patients report recognizable symptoms before the age of 50. In another 40%, the disease develops between the ages of 50 and 60, and the remainder are more than 60 years old at the time of diagnosis. The classic syndrome of parkinsonism includes *tremor at rest*, *rigidity*, *bradykinesia*, *masked face*, *stooped posture*, and a *shuffling gait.* Although tremor is the most obvious initial finding, it is absent in 20% of patients. Parkinson's disease may begin insidiously with vague, *aching pain* in the limbs, neck, or back and with *decreased axial dexterity* before tremor is noted. *Dysarthria* may be an early feature; *dysphagia* usually occurs later. Significant *orthostatic symptoms* may predominate in some patients. Other early subtle symptoms include decreases in the caliber of *handwriting* and volume of the voice and anosmia. *Depression* is a significant component in many patients and may be a feature of the early disease. The estimated frequency of *dementia* (which usually develops late) varies widely, but cognitive impairment, including hallucinations and psychosis, develops in at least 15% to 20% of patients. However, dementia and psychosis are not inevitable, and remediable causes of changes in mental status always need to be sought.

Clinical Course. Before the introduction of levodopa, Parkinson's disease had a fairly predictable course. At 5 years after onset, 60% of patients were severely disabled, and at 10 years, nearly 80% were. The rate of progression varied widely. Death rarely was a direct consequence of parkinsonism; rather, it was a consequence of immobility (aspiration pneumonia, urinary tract infections) or of trauma. Patients with Parkinson's disease comprise several different subgroups manifesting specific clinical patterns. It is thought that patients who present primarily with tremor have a slower course than do those for whom bradykinesia is the primary symptom. Patients who present with significant instability of posture and gait are largely an older group who are more likely to have cognitive impairment and a more rapid progression of disease.

The advent of dopaminergic agents has changed the natural history of the disease significantly. The initial benefit of levodopa therapy, as mentioned above, is one of the diagnostic criteria for the disease. Although patients with idiopathic Parkinson's disease usually respond to levodopa, the initial benefits of therapy decline for as many as half of all treated patients after 2 or more years. Delay in onset of disability has been enhanced by the use of the monoamine oxidase B inhibitor deprenyl (see below).

DIAGNOSIS

The classic presentation of Parkinson's disease usually poses few diagnostic problems. However, several other presentations may be more problematic. These include isolated tremor at presentation, symptoms confined to half of the body (hemiparkinsonism), and the presence of these symptoms in younger patients. Symptomatic parkinsonism can be seen in several other disorders, such as progressive supranuclear palsy and multisystem atrophy, or as a side effect of numerous medications (Table 174.1). An extrapyramidal syndrome resembling that of parkinsonism also occurs in Alzheimer's disease and many other conditions.

The clinical diagnosis of Parkinson's disease is based on a careful examination in which the clinician looks for physical signs other than those associated with the basal ganglia, elicits a careful drug and family history, and most likely performs at least one neuroimaging study, probably magnetic resonance imaging, to exclude significant small-vessel vascular disease, which may produce a parkinsonian-like state. Table 174.2 provides a summary of inclusion and exclusion criteria, which should help the physician in this clinical diagnosis. Among the inclusion criteria is a sustained responsiveness to levodopa therapy, with improvement lasting for 1 year or more. Many parkinsonian syndromes with other causes may show a transient response to dopaminergic agents.

INCLUSION CRITERIA	EXCLUSION CRITERIA
Presence for 1 year or more of two of the three cardinal motor signs: Resting or postural tremor Bradykinesia Rigidity	Abrupt onset of symptoms Remitting or stepwise progression Neuroleptic therapy within year Exposure to drugs or toxins associated with parkinsonism History of encephalitis Oculogyric crises
Responsiveness to levodopa therapy with moderate to marked improvement and duration of improvement for 1 year or more	Supranuclear downward or lateral gaze palsy Cerebellar signs Unexplained upper motor neuron or lower motor neuron signs More than one affected relative Dementia from the onset of disease Severe autonomic symptoms

Table 174.2. Criteria for the Diagnosis of Parkinson's Disease

PRINCIPLES OF MANAGEMENT

Parkinson's disease cannot be cured, but advances in treatment have improved prospects for patients. The goals of therapy are to delay disease progression, relieve symptoms, and preserve functional capacity. Restoring the striatal balance between dopaminergic and cholinergic activity is at the core of efforts to achieve symptomatic relief. Inhibiting oxidative injury appears helpful in retarding disease progression. The patient may be able to tolerate many of the early signs of parkinsonism, which are sufficient to prompt medical consultation but, aside from provoking psychological discomfort, are not disabling. The goal of therapy is to maintain the patient at maximum function with minimal medication.

The three categories of management strategies are preventive treatment, symptomatic relief, and regenerative therapy.

Delay of Disease Progression: Preventive Treatment

If the degeneration of dopaminergic neurons in the substantia nigra and striatum is a consequence of oxidative injury, then might it be possible to interrupt the degenerative process and slow or halt disease progression with agents that inhibit oxidative activity in the central nervous system? This hypothesis has led to the study of the monoamine oxidase B inhibitors.

Selegiline (Deprenyl). Although not universally accepted, evidence from several double-blinded, placebo-controlled studies of this monoamine oxidase B inhibitor indicates that monotherapy early in the course of disease delays the onset of disability and the need to initiate levodopa therapy. It is suspected that the mechanism of benefit is protection of striatal tissue from oxidative injury, but this theory has yet to be proved,and the major benefit may be some direct effect of relieving symptoms. Nonetheless, it seems reasonable to recommend this drug as initial treatment when Parkinson's disease is first diagnosed because it delays the requirement for levodopa therapy. It may also increase the time during which patients remain functional on levodopa and, for some patients, may decrease the levodopa requirement. This drug is given in the standard dose found to inhibit monoamine oxidase B in most patients: 5 mg given in the morning and 5 mg at noon. Side effects of tremor and dyskinesia are common when deprenyl is used in conjunction with levodopa. These are attributable to increased dopaminergic activity, which can be controlled by lowering the levodopa dose.

Other Antioxidants. In the largest and best-designed of the deprenyl studies, *tocopherol, a vitamin E analogue* with antioxidant properties, was tested. Tocopherol showed no benefit, either alone or as an enhancer of deprenyl activity. Further study of antioxidants and their prolonged effects is ongoing.

Symptomatic Relief

To restore the balance between cholinergic and dopaminergic influences requires either inhibition of cholinergic activity or enhancement of dopaminergic output. One strategy for early symptoms is to use amantadine (Symmetrel), a gluatamine antagonist that may enhance dopaminergic transmission and relieve bradykinesia; however, its effects are transient.

Anticholinergic Therapy. Anticholinergic agents were the mainstay of parkinsonian therapy for more than a century, and they have remained important. Commonly used drugs are *trihexyphenidyl* (Artane) and *benztropine* (Cogentin). These agents may be particularly beneficial for patients with tremor as a prominent symptom. Both are muscarinic blocking agents with typical anticholinergic side effects of urine retention, dry mouth, increased intraocular pressure in patients with glaucoma, and confusion (Table 174.3).

Table 174.3. Drugs Used for Parkinson's Disease

Enhancing Dopaminergic Activity: Dopamine Agonists. Treatment with one of the dopamine agonists—bromocriptine, pergolide, pramipexole, and ropinirole—is increasingly recommended as the first line of therapy for patients with mild to moderate parkinsonian symptoms. These medicines may suffice to control symptoms and delay for several years the need to prescribe levodopa. The side effects of the dopamine agonists are similar to those of levodopa, but dyskinesias and motor fluctuations tend not to occur with these medicines. Since its introduction to the U.S. market, pramipexole has become the most widely prescribed drug for early parkinsonism. Recent reports of several motor vehicle accidents in patients on pramipexole or ropinirole, as a consequence of paroxysmal attacks of sleep, have led to the recommendation that patients taking these medicines refrain from driving.

Levodopa. Eventually, most patients experience a worsening of symptoms that requires the introduction of *levodopa* (in combination with a peripheral dopa decarboxylase inhibitor). Levodopa is recommended for patients who become too symptomatic to function satisfactorily despite anticholinergic therapy with deprenyl plus a dopamine agonist. By prescribing levodopa, the physician is able to offer most parkinsonian patients much benefit, although the drug has a number of important limitations and side effects.

One limitation is the duration of action, which makes it necessary to consider carefully when to begin levodopa therapy. Weighing against early initiation of levodopa treatment is the phenomenon of a decline in its effectiveness in as many as 50% of patients after 2 years of use. This observation is the basis for the traditional view that onset of therapy should be delayed as long as possible. However, some data indicate a reduction in mortality when levodopa is started within 1 to 3 years of onset of symptoms rather than after 4 years. Clinical judgment that takes into account both of these findings is required.

Levodopa is the naturally occurring precursor of dopamine. It crosses the blood–brain barrier and enhances dopaminergic activity. However, because much of the drug is converted peripherally by a decarboxylase into dopamine (which cannot cross the blood–brain barrier), levodopa is best given in combination with a peripheral

decarboxylase inhibitor, such as *carbidopa*. Combination preparations containing both agents in various strengths are commonly used. In a typical starting program, the combination preparation of 25 mg of carbidopa and 100 mg of levodopa is given (e.g., Sinemet 25-100 two or three times daily; see Table 174.3). Levodopa is rapidly absorbed after oral administration, reaches its peak effect after 30 minutes to 2 hours, and has a half-life of 1 to 3 hours. The rate of absorption is decreased by the ingestion of a protein-rich meal.

Adverse Effects. Significant adverse reactions develop in many patients; *nausea*, *vomiting*, *anorexia*, *hypertension*, *dyskinesias*, and *hallucinations* can be disturbing. The nausea can be partly overcome by taking the drug with small meals. Dyskinesias include chorea, athetosis, and dystonia. They usually occur simultaneously with peak concentrations of levodopa and are best managed by having the patient take small doses of medication at frequent intervals.

Problems in Late-stage Therapy. With disease progression, the threshold for the development of adverse central side effects appears to decline. " *Wearing off*" is the recurrence of severe symptoms hours after the most recent dose of medication and is often followed by a recurrence of rigidity and bradykinesia. A *controlled-release preparation* (Sinemet CR) relieves this problem for some patients.

As drug efficacy declines, patients may experience the "*on-off*" *phenomenon*, with a severe fluctuation of dose–response relations and rapid onset and termination of therapeutic and adverse effects. A study of the underlying pathophysiology has revealed impaired absorption of levodopa with meals and inhibition of levodopa transport into the brain by dietary amino acids. Treatment entails taking levodopa 1 hour before meals, adding an ergot preparation (see below), and reducing the protein content of the diet. Use of a controlled-release formulation may also help, but the development of the "on-off" state represents an advanced form of disease and a difficult one to treat. Drug "holidays" have been proposed to restore sensitivity to levodopa, but results are not impressive.

The development of a sustained-release preparation, Sinemet CR (50 mg/200 mg) has been a major therapeutic advance for patients afflicted with motor fluctuations. The controlled-release form can almost double the duration of effect to 5 to 6 hours. To match the effects of conventional levodopa preparations, a program of up to 25% more daily levodopa in the controlled-release form may be required. Doses administered after 6:00 p.m. can be given in the rapidly absorbed formto eliminate nocturnal side effects of the medication. Other ways to manage wearing-off symptoms include administering drugs that reduce the metabolism of dopamine or levodopa. The catechol- *O*-methyltransferase (COMT) inhibitors tolcapone and entacapone have been introduced for this purpose. Tolcapone must be used with caution, as cases of fulminant hepatic failure have been reported. The physician should refer a patient requiring this therapy to a neurologist with expertise in the treatment of late-stage Parkinson's disease.

Other Dopaminergic Agents in Late-stage Disease. *Bromocriptine* and *pergolide* are direct *dopamine-receptor agonists*. These agents are used to enhance the therapeutic effects of levodopa and may be particularly helpful in late stages of the disease, when the conversion of levodopa to dopamine is inefficient in the degenerating substantia nigra. They are less likely than levodopa to cause dyskinesias and the on-off phenomenon. In addition, they may allow the use of lower doses of levodopa when given early on with levodopa as combined therapy. A small trial of gabapentin (Neurontin) has shown some efficacy for patients with advanced disease, and this drug has the advantage of causing very few side effects. Both the direct dopamine agonists and the levodopa controlled-release preparations are likely to be prescribed by neurologists, although recognition of the necessity to move to these sorts of therapies will be in the province of the primary physician, who sees the patient most frequently.

Treatment of Psychiatric Symptoms. Nightmares, hallucinations, and increased sexual drive are disturbing psychiatric features of late-stage disease. Hallucinations and psychosis are best treated with the atypical neuroleptic clozapine. Severe depression is managed with the same medications given to patients without Parkinson's disease. However, because most of these patients are elderly, the physician must be careful of side effects of the tricyclic antidepressants. Theoretically, the combination of selegiline (deprenyl) and a selective serotonin reuptake inhibitor is problematic, and indications for this class of drug should be carefully weighed against the possibility of inducing the *serotonin syndrome* (hypertension, tachycardia, other autonomic dysfunction, and hallucinations). *Electroconvulsive therapy* may be used in depressed patients who are not confused.

Supportive Measures

Because maintaining function is a central goal of therapy, one should not forget the value of such important adjunctive measures as *physical therapy* and *psychological support*. Physical therapy can improve functioning by helping to preserve muscle strength and flexibility. Although a central componentof the supportive psychological effort involves close follow-up and detailed patient education (see below), one must also be watchful for the development of depression and the need to treat it promptly and effectively (see Chapter 227).

Regenerative Therapies

As the pathophysiology of parkinsonism has become better understood, the role of functional neurosurgical procedures has grown. Surgery is reserved for disabling, medically refractory problems. In carefully selected cases, thalamotomy and deep-brain stimulation of the thalamus can control tremor. They do not help bradykinesia. When the problem is severe dyskinesia and on-off fluctuations, unilateral pallidotomy has been demonstrated to be effective. Pallidal deep-brain stimulation may be a good alternative. For the treatment of bradykinesia, *transplantation* of fetal substantia nigra tissue into the striatum relieves the signs of parkinsonism in animals with experimental lesions of the substantia nigra. Early attempts to treat humans who had Parkinson's disease with grafts of tissue, either autografts of the adrenal medulla or grafts of human fetal tissue, were disappointing, although the results with fetal tissue were better than those with the adrenal medullary grafts. Adrenal medullary grafting has been abandoned, but work on fetal tissue transplantation has continued and is producing increasingly beneficial results. Nonetheless, this method of therapy remains investigational at this time.

Other methods of therapy under development include new drugs to inhibit dopamine breakdown, synthesis of new dopamine-receptor agonists, and blockade of excitotoxic neurotransmitter receptors in the subthalamic nucleus. Small-scale, short-term study of *gabapentin,* which stimulates the striatal release of g-aminobutyric acid (GABA), has produced promising results in patients with advanced disease. It is theorized that GABA stimulation may help overcome the loss of dopaminergic stimulation. Finally, jejunal infusion of levodopa and carbidopa has been tried in an attempt to improve levodopa absorption.

PATIENT EDUCATION

Patient and family education is essential to the success of therapy. The need for trial and error to obtain maximal benefit with minimal side effects must be explained. Frequent visits will be needed in the initiation period and later in the course of the disease. Although therapy can be proposed optimistically, the inevitable diminution in efficacy of therapy must be anticipated and discussed with patient and family so that they can be adequately prepared, both psychologically and practically. Patients are obviously concerned about their prognosis, and a frank discussion of what is known is usually appreciated. A number of helpful guidebooks are available for patients and their families.

THERAPEUTIC RECOMMENDATIONS

- After other potential causes of parkinsonism have been excluded, it is appropriate to start deprenyl (selegiline) in the early stages of disease. The daily dose is 10 mg (5 mg in the morning and 5 mg at noon). This drug may also be started in patients already taking levodopa/carbidopa (Sinemet) in an attempt to lower the amount of levodopa needed.
- If symptoms progress to impair daily functioning despite the use of deprenyl, then starting one of the dopamine agonists is appropriate. The most frequently prescribed is pramipexole (Mirapex). The initial starting dose is 0.125 mg three times daily. The dose is doubled at weekly intervals until a maintenance dose of about 1 mg three times daily is reached. As symptoms progress, the combination preparation levodopa/ carbidopa (Sinemet) is indicated. Sinemet is usually begun at a dose of 25 mg/100 mg three times daily, after which the dose is adjusted according to the individual response.
- Combination treatment with anticholinergics, amantadine, and direct dopamine agonists (bromocriptine, pergolide, ropinirole) may be used to maximize effect (Table 174.3). Anticholinergics are particularly helpful for the treatment of tremor.
- Problems of long-term management and loss of efficacy include end-dose wearing off, on-off effect, drug-induced confusion, and loss of dopamine response. COMT inhibitors may be used to lessen these later problems with dopamine therapy. Appropriate consultation for adjunctive therapies can be initiated for such patients.
- The important roles of physical therapy, psychological support, and recognition and treatment of depression should not be neglected in the day-to-day management of patients with Parkinson's disease.

CHAPTER 175 MANAGEMENT OF BELL'S PALSY (IDIOPATHIC FACIAL MONONEUROPATHY)

AMY A. PRUITT

Bell's palsy is an idiopathic paralysis of the facial muscles innervated by the seventh cranial nerve. The condition encompasses 80% of all facial mononeuropathies. Satisfactory explanations for the condition are lacking, although serologic and DNA evidence implicates herpesvirus infection in some patients. Ischemia with subsequent edema of the facial nerve and adjacent structures has been invoked to explain facial palsy in patients with vascular risk factors. The condition shows an increasing incidence with age, is slightly more common in the winter, and is associated with pregnancy, diabetes, and hypothyroidism. In patients under the age of 50, it is more common among women, but this gender distribution reverses in patients over the age of 50.

The primary physician should be able to distinguish Bell's palsy from other, more ominous causes of facial palsy and balance therapeutic intervention against the self-limited course and favorable prognosis of the disease.

CLINICAL PRESENTATION AND COURSE

Clinical Presentation. The distinction between Bell's palsy and other facial paralyses is usually not difficult. The onset is usually acute, with maximal deficit developing within a few hours. The motor deficit is almost always unilateral and in two thirds of cases may be accompanied by pain in or behind the ear. Fever, tinnitus, and mild hearing diminution may be present during the first few hours. Symptoms may fluctuate during the first few days after onset. Voluntary and involuntary motor responses are lost. Both upper and lower parts of the face are affected, a feature that distinguishes this peripheral facial nerve lesion from a central supranuclear lesion, in which only lower facial muscles are affected. Patient symptoms include facial muscle paresis, facial asymmetry, and drooling. The palpebral fissure appears widened, the forehead is smooth, and the nasolabial fold is flattened. Bell's phenomenon (the normal upward deviation of the eye with lid closure) is exaggerated because of weakness of the orbicularis oculi. The corneal reflex may be decreased on the involved side. Lacrimation is only rarely defective, and depending on the level of the injury, loss or perversion of taste on the anterior two thirds of the tongue or hyperacusis may occur, causing altered taste, decreased tearing, decreased salivation, or altered sensitivity to sound.

Clinical Course. In 75% to 90% of cases, patients recover to a cosmetically acceptable level without treatment. Most do so within 3 weeks. Recovery is best in children; a poor prognosis has been associated with increasing age, hyperacusis, diminished taste, and severity of the initial motor deficit. The prognosis can be assessed by electromyographic testing of the involved muscles at least 72 hours after the clinical nadir. Patients with evidence of extensive axonal degeneration have a poorer prognosis. Those with partial or complete preservation of the compound muscle action potential amplitude have anatomic continuity of the facial nerve, partial axonal preservation, and a better prognosis. Electromyography is indicated only for patients with severe clinical involvement that has not improved by 7 to 10 days after onset.

Other poor outcomes in Bell's palsy result from abnormal regeneration of damaged nerve fibers. Lacrimation during eating or "crocodile tears" appear when fibers regrow and connect with lacrimal ducts instead of salivary glands. Abnormal movements (facial synkinesis) may occur if regenerating motor fibers innervate inappropriate muscles. Contracture of the involved site may be noted during voluntary movement. Seven percent of patients experience recurrent facial paralysis.

DIFFERENTIAL DIAGNOSIS

Other causes of facial paralysis involve injury to the facial nerve and include bacterial infection (from a source in the ear), herpes zoster, diabetes mellitus, sarcoidosis, Guillain-Barré syndrome, tumor (acoustic neuroma, pontine glioma, neurofibroma, cholesteatoma, parotid gland tumor, meningeal carcinomatosis), trauma (fracture of the temporal bone), and Lyme disease. Bilateral facial paralysis raises a different set of diagnostic possibilities, including Guillain-Barré syndrome (with or without HIV infection), sarcoidosis, and Lyme disease. Diseases of the neuromuscular junction such as myasthenia gravis or botulism must also be considered in the presence of bilateral facial nerve dysfunction.

WORKUP

The patient found to have a mononeuropathy of the seventh cranial nerve should be examined for evidence of an underlying cause. One checks for zosteriform lesions (see Chapter 193) on the tympanic membrane, in the external auditory canal, and behind the ear. The skin is examined for the characteristic truncal erythematous lesion of early Lyme disease (see Chapter 160) and for neurofibromas. The tympanic membrane is also checked for cholesteatoma and evidence of otitis media (see Chapter 218). The jaw is noted for tenderness and trauma to the temporal bone. The lymph nodes are palpated for enlargement, and the chest is auscultated for signs of interstitial involvement suggestive of sarcoidosis (see Chapter 51). A careful neurologic examination completes the assessment, with a focus on the detection of additional neurologic deficits.

Laboratory studies are of limited value in the assessment of this facial mononeuropathy in a patient with a characteristic history and physical findings, although they may reveal diabetes or some other medical condition associated with an increased risk for Bell's palsy. Testing for Lyme disease (see Chapter 160) may be appropriate in highly endemic areas, as suggested by a recent study in which one fourth of summertime cases of Bell's palsy demonstrated evidence of infection with the tick-borne spirochete of Lyme disease, *Borrelia burgdorferi*. The identification of Lyme disease has important consequences for management (see below and Chapter 160).

Computed tomography or magnetic resonance *imaging studies* are necessary only when a posterior fossa mass is suspected as the cause of the seventh nerve palsy. Lumbar puncture is indicated if inflammation, granuloma, or malignancy is a consideration. A mild pleocytosis of the cerebrospinal fluid has been reported in typical cases of Bell's palsy. In patients with atypical or persistent facial palsy, gadolinium-enhanced magnetic resonance imaging can help differentiate Bell's palsy from other causes. Electromyography may be used to predict recovery but is not needed for diagnosis and is most informative when at least 3 weeks have elapsed after the onset of facial paralysis.

PRINCIPLES OF MANAGEMENT

Of greatest practical importance during the acute stage of the illness is the prevention of injury to the *cornea*, which is left exposed by weakness of the orbicularis muscle. When the lid is weak, *methylcellulose drops* should be prescribed for use twice a day and at bedtime; in addition, the lid may need to be taped shut at night. If corneal abrasion is suspected because of pain, visual impairment, or other ocular symptoms (see Chapter 201), then prompt referral for ophthalmic consultation and slit-lamp examination with fluorescein is indicated.

Corticosteroids. Because the prognosis for most cases of Bell's palsy is good, little or no treatment is necessary in most instances. However, if paralysis is severe and the patient is seen within a few days of onset, a short course of *corticosteroid therapy* will increase the chances for maximal recovery. One study reported full facial recovery in 88% of a group treated with prednisone and in 64% of an untreated control group. Another study found a decrease in the frequency of chronic autonomic dysfunction (from 10% to 1%) when prednisone was administered early in the course of illness. Associated ear pain diminished more quickly when steroids were used. Nevertheless, the benefits of steroid treatment are often difficult to demonstrate because the disease has such a good prognosis. Steroid therapy seems to make a difference only in cases with poor prognostic signs. Patients with Lyme disease as the underlying cause should not receive steroids, which can worsen the situation by compromising immune function.

Therapy for Herpesvirus Infection. Based on serologic and DNA evidence that herpesvirus infection is the cause of many cases of facial paralysis, some authorities now recommend institution of appropriate therapy (e.g., 200 mg of *acyclovir* five times daily or 1,000 mg of *valacyclovir* twice daily for 7 to 10 days; see Chapter 192). Initial studies comparing prednisone therapy with and without antiviral therapy show a modest benefit from the addition of antiviral therapy. More data are needed to

define the role of antiviral treatment better.

Other Treatments have been used. Based on the theory that nerve swelling contributes to the deficit, surgical decompression has been tried, but without much success. Some patients have been followed with electromyographic stimulation of the muscles to hasten particularly stubborn paralyses. The possible role of electromyographic stimulation in management is unclear; it has not been subjected to controlled study.

THERAPEUTIC RECOMMENDATIONS AND INDICATIONS FOR REFERRAL

- Ascertain that the condition is indeed Bell's palsy. Check for involvement of other cranial nerves and ear infection. Examine for zosteriform lesions on the tympanic membrane, in the external auditory canal, and behind the ear.
- In areas endemic for Lyme disease, examine the patient carefully for characteristic features and consider serologic testing (see Chapter 160).
- Explain the benign nature and good prognosis of the condition and caution the patient about corneal abrasion. Mention that altered taste, decreased tearing, decreased salivation, or altered sensitivity to sound may be experienced.
- Prescribe methylcellulose eye drops, to be used twice a day and at sleep, with taping of an especially weak lid. Tarsorrhaphy may be considered when severe lid weakness exists.
- If the patient is seen within 1 week of onset of facial weakness and if no important contraindications to corticosteroid use are found (Lyme disease would be a contraindication), then a short course of prednisone may be prescribed.
- Begin with 60 mg of prednisone every morning for 5 days. If improvement occurs or weakness does not progress during these 5 days, then taper and terminate over 10 more days. If improvement does not occur during the first 5 days, then continue the 60 mg of prednisone each morning for a total of 10 days and taper over another 10 days. If postauricular pain recurs when the dose is tapered, then reinstitute the preceding dose.
- If viral infection is suspected clinically or initial symptoms are severe, consider adding to the prednisone therapy an early course of therapy for herpesvirus infection (e.g., 200 mg of acyclovir five times daily or 100 mg of valacyclovir twice daily for 7 to 10 days; see Chapter 192).
- In the 10% of patients who do not achieve an acceptable recovery, autografting with a hypoglossal to facial anastomosis may provide reasonable cosmetic results and afford lasting protection of the eye. Patients in this category should be referred to an otolaryngologist or a neurosurgeon.

CHAPTER 176 MANAGEMENT OF TIC DOULOUREUX (TRIGEMINAL NEURALGIA)

AMY A. PRUITT

Tic douloureux is among the most excruciating of pain syndromes seen in office practice. Fifteen thousand new cases occur annually in the United States; most patients are middle-aged or elderly. Some have found the pain so intolerable that they consider suicide. The primary physician needs to know how to use available medical therapies and when to send the patient for a neurosurgical consultation.

CLINICAL PRESENTATION AND NATURAL HISTORY

The illness is characterized by paroxysms of unilateral lancinating facial pain involving the jaw, gums, lips, or maxillary region (areas corresponding to branches of the trigeminal nerve). The maxillary and mandibular divisions are affected more frequently than the ophthalmic division. Minor, repeated contact with a trigger zone often precipitates an attack, setting off fierce pain that usually lasts up to a few minutes. Repeated paroxysms may continue day and night for several weeks. The disease is unilateral and unaccompanied by demonstrable sensory or motor deficits, features that distinguish it from trigeminal pain with other causes, such as tumor.

The condition can be chronic, although spontaneous remissions are not uncommon. Women are more often affected than men, and the incidence rises with age. The etiology of the condition remains unknown. Despite much speculation, no definitive evidence links it to herpes simplex virus. The pathologic lesion found in some electron micrographs appears to be a breakdown of myelin.

Although trigeminal neuralgia may be a symptom of multiple sclerosis, which should be considered in a young adult with trigeminal neuralgia, it is infrequently the initial or sole manifestation of this disease. Similarly, trigeminal neuralgia is uncommonly the isolated symptom of a cerebellopontine angle tumor. Both diseases can be demonstrated by magnetic resonance imaging (MRI), and some authors recommend MRI for all patients with trigeminal neuralgia, although the cost–benefit ratio remains to be determined.

DIFFERENTIAL DIAGNOSIS

Although few conditions absolutely mimic the lancinating pain of trigeminal neuralgia, pain referable to structures of the face may be similar. Conditions that should be excluded include dental disease, temporomandibular joint dysfunction, temporal arteritis, sphenoid sinusitis, and cluster headache. The pre-eruption pain of herpes zoster, which occurs in the distribution of the ophthalmic division of the trigeminal more frequently than in the distribution of the other two divisions, and post-herpetic neuralgia, which follows the skin eruption by a few weeks, are two other entities to be considered.

PRINCIPLES OF MANAGEMENT

Treatment is symptomatic. Because the condition may be self-limited and agents that give temporary relief are available, drug therapy should be tried before surgery is contemplated.

Carbamazepine (Tegretol) is the drug of choice; it was initially tried because anticonvulsants were believed to be helpful in causalgia. Studies have shown impressive short-term effects; most patients report marked relief of pain within 24 to 72 hours. The drug is so effective that some argue that failure to respond places the diagnosis in doubt. The starting dose is 100 to 200 mg twice daily. The maintenance dosage ranges from 400 mg to 800 mg/d and is adjusted according to serum drug levels; the therapeutic range is 5 to 12 μg/mL. An extended-release preparation of carbamazepine allows for the same total daily dose with convenient twice-daily dosing. The most common side effect is sedation.

Unfortunately, by 3 years, 30% of patients no longer obtain relief by taking carbamazepine; alternative therapy is needed. Moreover, the incidence of serious side effects (bone marrow suppression, rash, liver injury) is high (5% to 19%), so that therapy may have to be discontinued. Marrow suppression is often reversible if the drug is stopped early. Skin rash often precedes other serious side effects; it may be erythematous and pruritic. The onset of a skin rash is an early indication to halt therapy. Annoying side effects include nausea, diarrhea, ataxia, dizziness, and confusion. Neurologic reactions are reported most commonly and affect about 15% of patients. Starting carbamazepine at a dose of 200 mg daily helps to avoid many of the annoying minor side effects. During the first 2 months of therapy, a complete blood cell count and platelet count should be obtained weekly to biweekly; later, the frequency of monitoring can be reduced to monthly. It is advisable to attempt a reduction or cessation of carbamazepine therapy at least once every 2 to 3 months.

Baclofen, an agent that enhances synaptic transmission of g-aminobutyric acid, has been used with success in a high percentage of cases. Some now consider it the drug of choice for trigeminal neuralgia. The initial dosage of 10 mg twice daily is increased slowly. The usual maintenance dosage is 50 to 60 mg/d. Sedation and nausea are the most common limiting side effects. Abrupt cessation of therapy can lead to hallucinations and seizures; therefore, discontinuation must be gradual.

Combination Therapy may be necessary because trigeminal neuralgia tends to increase in severity. Carbamazepine and baclofen in *combination* or either in conjunction with *phenytoin* can provide additional relief. The usual daily dose of phenytoin that achieves therapeutic serum levels is 300 to 400 mg (see Chapter 170). Parenteral phenytoin is sometimes used emergently for patients who are having a flurry of severe attacks and cannot take medicine orally. *Gabapentin* (Neurontin) may be prescribed if other medicines are unsuccessful, but sedation can be a limiting side effect if high doses are needed. *Narcotics* should be avoided because they are unlikely to be helpful for long-term control of pain and may lead to drug dependency.

Surgical Approaches can be considered when drug therapy proves inadequate. *Microvascular decompression* affords the best chance of long-term pain relief without sensory deficit, but because it entails more complicated surgery, it is often reserved for younger patients. The least invasive procedure producing acceptable deficits with the greatest relief of symptoms is percutaneous radio frequency rhizotomy. The small pain fibers are destroyed, whereas the more heavily myelinated touch fibers that supply the relevant zone are spared. The procedure has produced lasting relief in 90% of those treated once; only 5% have experienced an undesirable loss of sensation. The late recurrence rate is 10%, and pain relief is achieved with a repeated procedure in these patients; few need further treatment.

Formerly Used Treatment Methods include *alcohol injection* or partial section of the sensory root of the fifth cranial nerve. These techniques provided pain relief, but often only for 1 to 2 years, and at the price of unacceptable permanent sensory deficits. Total *tooth extraction* is an ineffective and erroneous treatment method.

PATIENT EDUCATION

The patient needs to be told that the condition can be controlled and is often self-limited. This knowledge can prevent a distraught sufferer from attempting suicide. The physician must keep in mind the anguish these patients may experience; they require close support. Obvious ways to prevent attacks, such as avoiding repetitive contact with the trigger zone, have usually been discovered by the patient, but they are worth mentioning. Patients treated with carbamazepine must be informed of the risk for marrow suppression and the importance of regular monitoring of the complete blood cell count.

THERAPEUTIC RECOMMENDATIONS AND INDICATIONS FOR REFERRAL

- Teach the patient to avoid repetitive contact with the trigger zone.
- Begin drug therapy for disabling and frequent episodes of pain with *carbamazepine* (100 mg twice daily, preferably in the extended-release preparation); increase the dosage by 200 mg/d until control of symptoms is achieved or a dosage of 800 to 1,000 mg/d is reached.
- During the first 2 months of carbamazepine therapy, monitor the complete blood cell and platelet counts weekly to biweekly; thereafter, monthly checks will

suffice.

- Stop carbamazepine immediately if the white blood cell count falls below 3,000/mm^3 or if skin rash, easy bruising, fever, mouth sores, or petechiae develop.
- An alternative to carbamazepine is *baclofen* at a dosage of 10 mg twice daily. Increase the dosage by 10 mg/d every 3 days until a response is achieved or a maximum of 60 mg/d is reached. Discontinue the medication gradually; do not withdraw it abruptly.
- If carbamazepine or baclofen alone is not sufficient to control symptoms, add *phenytoin* at a dosage of 300 mg/d.
- If the above medicines are unsuccessful, gabapentin (Neurontin) may be started at a dose of 300 mg at bedtime and then increased by 300 mg every 4 days until a total of 1,800 mg is being taken divided into three doses daily. Sedation may be a limiting side effect.
- Avoid narcotics because they are unlikely to be helpful for the long-term control of pain and may lead to drug dependency.
- Refer the patient who cannot be managed by pharmacologic measures to a neurosurgeon skilled in selective radio frequency rhizotomy or microvascular decompression.

PART 12 DERMATOLOGIC PROBLEMS

CHAPTER 177 SCREENING FOR SKIN CANCERS

ARTHUR J. SOBER

INTRODUCTION

Neoplasms of the skin are among the most common cancers in humans. It has been estimated that more than 1 million new tumors occur annually in the United States. The majority are basal cell carcinomas—relatively benign, locally mutilating tumors associated with few deaths. Squamous cell carcinoma, the second most common cutaneous malignancy, causes approximately 2,000 deaths annually. Melanoma, of which there are more than 47,000 cases annually, is responsible for approximately 7,700 deaths per year. The first two types of skin cancers derive from the epidermal keratinocytes; the third type develops from the melanocytes along the basal layer of the epidermis.

Screening for these tumors is important because they are relatively easy to diagnose in early stages, when cure is possible by simple measures. This is particularly true for melanoma, because we are in the midst of a striking, unexplained increase in its incidence. In the past decade, the incidence of melanoma in the United States has approximately doubled. Since 1960, the incidence of melanoma in the United States has increased more rapidly than that of any other cancer.

EPIDEMIOLOGY AND RISK FACTORS

Basal Cell Carcinomas. Basal cell carcinomas are probably the most common malignancy in humans. They are distinctly sun-related, with risk proportional to total accumulated sun exposure and frequency increased in people who work outdoors (e.g., farmers, sailors). Approximately 90% occur on the head or neck. Best available epidemiologic data from a study of nomelanomatous skins cancers suggest that use of tanning devices, especially before age 20, may contribute to risk. Other etiologic factors include a genetically transmitted autosomal dominant disorder, the basal cell nevus syndrome, in which multiple basal cell carcinomas occur in relatively young persons in association with palmar pits, bone cysts, and frontal bossing. Basal cell lesions can develop in persons exposed to arsenic. Scars from radiation dermatitis and thermal burns can also provide sites favorable to the development of basal cell tumors. Previously identified disease is also a risk factor. **Updated: 3/4/02**

Once a single basal cell carcinoma has developed, the chance that a second one will ensue within 1 year is 20%. After two have developed, there is a 40% likelihood that a third or more will occur within 1 year. This observation forms the basis of annual follow-up examinations after basal cell carcinoma has been detected.

Squamous Cell Carcinomas. Squamous cell carcinomas may develop from *actinic keratoses* and may also occur following arsenic ingestion or in areas of scarring from radiation dermatitis or thermal burns. Two thirds of squamous cell carcinomas occur on sun-exposed surfaces, with risk again proportional to total accumulated sun exposure. Those arising in sun-damaged skin usually behave in a less biologically aggressive fashion than do those that occur on unexposed surfaces. It is the latter group that appear to metastasize more frequently. Data from a recent epidemiologic study suggest that use of tanning devices, especially before age 20, may contribute to risk. **Updated: 3/4/02**

Melanoma. Melanoma, although far less common than basal cell and squamous cell cancers, accounts for 75% of skin cancer deaths. The incidence has been increasing rapidly during the past few decades and currently exceeds that for Hodgkin's disease, leukemia, pancreatic cancer, carcinoma of the thyroid, and carcinoma of the pharynx and larynx. The sex ratio for melanoma in the United States is approximately 1:1. A second primary tumor develops in up to 10% of patients; 10% have affected relatives.

Risk Factors and Precursors. Because of the rapid rise in melanoma incidence, attention has focused on melanoma risk factors and precursors. Persons with *fair skin* who tan poorly and burn easily are at greatest risk, especially those with a history of episodic, *intense sun exposure*. Blacks, Asians, and dark-skinned whites have a much lower risk.

Precursor lesions include *congenital nevi* and *dysplastic nevi* (i.e., clinically atypical moles). Although congenital nevi occur in approximately 1% of all newborns, most of these are small (£1.5 cm in diameter). Melanoma risk has been most clearly associated with large (>20 cm) nevi. *Giant hairy nevus* (Fig. 177-1) is a form of congenital nevus associated with malignant degeneration; the overall risk for malignancy is about 6%. Melanomas may arise in these lesions at any time throughout life, but most often by age 10. Melanoma occasionally arises in smaller pigmented congenital nevi, but the exact risk is unknown.

Figure 177-1. Giant hairy melanocytic nevus.

Dysplastic nevi occur in 2% to 10% of light-skinned whites and usually are recognizable early in adolescence. Lifetime risk for melanoma is approximately 6%, or five times that of all whites in the United States. An inherited predisposition to dysplastic nevi may contribute to the 8- to 12-fold increase in melanoma risk among first-degree relatives. In patients with dysplastic nevi and two or more first-degree relatives with cutaneous melanoma, the lifetime risk exceeds 50%. Patients with a large number of benign-appearing nevi may also be at increased risk.

NATURAL HISTORY OF SKIN CANCERS AND EFFECTIVENESS OF THERAPY

Basal Cell Carcinomas. Basal cell carcinomas rarely metastasize or cause death, but they can be locally invasive and disfiguring. Metastasis is an extremely infrequent event that usually occurs in patients who have delayed therapy for many years and who have large, locally invasive, eroded lesions. The risk for other skin cancers is increased because of their shared risk factors. Population-based study raises the queston of a small but significant increase in the risk for nondermatologic cancers (e.g., testicular cancer, breast cancer, non-Hodgkin's lymphoma) in persons with basal cell cancer if basal cell disease is diagnosed before age 60. The

significance of this finding remains to be elucidated.

Several effective forms of therapy exist, all yielding a cure rate of approximately 95%: *surgical excision*, *radiation* therapy, *electrodesiccation and curettage*, and cryotherapy with *liquid nitrogen* applied by special spray apparatus.

Treatment of the 5% of basal cell carcinomas that recur presents a greater challenge. The cure rate of a *recurrent basal cell carcinoma* is about 66% when the four modalities listed above are applied. A special form of surgery, *Mohs' micrographic surgery*, is used for difficult, recurrent, or infiltrative basal cell carcinomas. In Mohs' surgery, the excised tissue is examined directly under the microscope to determine whether the tumor has been completely removed. Additional sections of skin are removed until all the borders are histopathologically clear of tumor. With Mohs' technique, cure rates of recurrent tumors exceed 90%, and those for primary tumors are better than 98%.

The use of *5-fluorouracil* (5-FU) topically and *interferon alfa* within lesions has been advocated by some physicians for the treatment of *superficial basal cell carcinoma*. Experience has not been sufficient to permit a definition of the role of these modalities in relation to the forms of therapy that have a clearly established track record, but they may have some role in patients with multiple lesions in whom other techniques cannot be employed.

Squamous Cell Carcinomas. Squamous cell carcinomas may begin as *actinic keratoses*, of which perhaps 1 in 1,000 annually undergoes malignant change. *Bowen's disease* represents carcinoma *in situ*, which may progress to a more advanced lesion if untreated.

Actinic Keratoses. Application of *5-FU* cream or solution twice daily for 2 to 4 weeks usually results in the destruction of these lesions. Some clinically inapparent lesions will also be destroyed by this therapy. The patient must be warned about the impressive inflammation that occurs when 5-FU is used. Because 5-FU is also a photosensitizing agent, treatment in late fall or winter, when solar exposure is diminished, is preferred. Other effective modalities include cryotherapy with *liquid nitrogen* and *light desiccation*. If a cutaneous horn is present, *excisional biopsy* of the lesion may be warranted to rule out the presence of a squamous cell carcinoma. Actinic keratoses are extremely common and usually present no great threat to life.

Bowen's Disease. Bowen's disease (squamous cell carcinoma in situ) represents the next grade of neoplasia in the keratinocytic line; it is substantially less common than actinic keratoses. *Surgical removal* of the lesions of Bowen's disease is probably the most effective treatment. Alternatively, this tumor can be treated satisfactorily by cryotherapy with *liquid nitrogen*. A preparation of 5% 5-FU, applied two to three times daily for 6 weeks and covered by a plastic occlusive dressing, may also be used to treat Bowen's disease.

More Advanced Squamous Cell Carcinomas. More advanced squamous cell carcinomas are treated with surgical excision or radiation; the latter is reserved for people older than 60 years.

Melanomas. Melanomas can be divided into four histopathologic categories, each with a characteristic natural history and clinical course.

Superficial Spreading Melanoma. Superficial spreading melanoma is the most common type in the United States, representing 70% of all melanomas diagnosed. The early lesion exists 1 to 7 years before a nodule develops, which indicates that deep penetration has occurred. Before penetration, the lesion grows superficially, and its removal during this time is associated with a 5-year survival rate approaching 100%.

Nodular Melanoma. Nodular melanoma has a poorer prognosis. It may arise de novo or within a nevus as an invasive tumor from the onset. Even with early recognition, metastasis will already have occurred in a substantial proportion of patients. This type of tumor can occur on any cutaneous surface, as can superficial spreading melanoma. Nodular melanoma represents about 15% of all melanomas.

Lentigo Maligna Melanoma. Lentigo maligna melanoma, the third type, accounts for about 5% of melanomas and occurs on sun-damaged skin of elderly patients. It is the least aggressive of the melanomas and may be present for 5 or more years before dermal invasion develops. Before dermal invasion, the lesion is termed *lentigo maligna*. Local excision is satisfactory in the treatment of lentigo maligna. In lentigo maligna melanoma, excision with wider margins is advocated. Surgical outcome in this type of tumor is almost uniformly favorable, although recurrence is sometimes seen. It is unusual for a patient to die of disseminated lentigo maligna melanoma.

Acral Lentiginous Melanoma. Acral lentiginous melanoma occurs on palms, soles, subungual areas, and mucous membranes. This is the most common type to affect blacks and east Asians, but it may also occur in whites. The lesion begins as a flat, pigmented lesion that may be irregular in its border and pigment pattern. Early biopsy is essential to achieve cure before metastasis has occurred.

Prognosis. The most widely used system for estimating the prognosis of a patient with melanoma is that of Breslow, which utilizes *thickness* of the primary tumor as the principal determinant. Tumor thickness is measured with an ocular micrometer on a standard microscope from the granular cell layer down to the deepest tumor cell. Lesions *with a thickness of less than 0.85 mm* have a nearly uniformly favorable prognosis (5-year survival of 99%), whereas those with a thickness of more than 3.65 mm have a fairly poor prognosis (5-year survival of 42%). In between these extremes are lesions of 0.85 to 1.69 mm (5-year survival of 94%) and 1.70 to 3.64 mm (5-year survival of 78%). Ten-year survival figures follow a similar prognostic pattern according to lesion thickness (96%, 83%, 59%, and 29%, respectively).

A prognostic model that adds consideration of *age* (£60 years vs. >60 years), *sex*, and *tumor site* (limb vs. extremity) to lesion thickness appears to improve prediction by nearly 50%, particularly for persons with lesions of intermediate thickness. The relative risk for mortality associated with a lesion on an extremity is reduced by 20% in comparison with that of a lesion on the trunk. Age below 60 years confers a 30% reduction in relative risk, and female sex lowers the relative risk by about 10%. When skin thickness alone is considered, a person with a lesion between 1.70 and 3.60 mm in thickness has a 10-year survival of 59%, but the four-variable model provides a series of predictions ranging from 89% survival (younger woman with an extremity lesion) to 24% survival (older man with a truncal lesion).

Treatment. Systems for determining prognosis are used to match treatment extent with seriousness of the lesion.

Primary Melanoma. At present, *wide local excision* is the treatment recommended for primary melanoma. The width of excision in our institution is based on primary tumor thickness. For tumors up to 1.0 mm thick, 1.0-cm margins are recommended; 2-cm margins are recommended for tumors from 1.0 to 4.0 mm thick. The therapeutic usefulness of elective regional lymph node dissection and removal is still being debated. *Sentinal lymph node biopsy* is useful as a staging procedure in high-risk patients, enabling meaningful stratification for adjuvant therapy. There is little evidence to suggest that prophylactic removal of nodes confers any more benefit than removal after the nodes have become clinically apparent.

Disseminated Melanoma. Currently, treatment remains difficult and unrewarding. With the most effective and widely used single agent, dacarbazine (dimethyl triazenoimidazole carboxamide, or DTIC), the response rate is approximately 20%. The nitrosoureas have also been utilized, with approximately the same response rate. Even patients who respond usually relapse and die after a few months. Combinations of chemotherapy are currently being evaluated, as are new forms of immunotherapy.

Because the prognosis in disseminated melanoma is poor, attempts are being made to use *adjuvant therapy* postoperatively in patients who are at high risk for recurrence. At present, only *interferon alfa 2b* has proved beneficial in increasing disease free–survival in patients with stage III disease (nodal involvement), but increased overall survival remains to be established.

The management of giant congenital nevi is controversial. Early surgical removal is necessary to prevent malignancy. Because the risk is modest and the cosmetic consequences of surgery can be substantial, some advocate a wait-and-see approach with regular follow-up.

CLINICAL SCREENING AND DIAGNOSIS

Skin cancers are unique among cancers in their accessibility and the relative ease with which a tissue diagnosis can be made.

Basal Cell Carcinomas. Basal cell carcinomas may take several forms. The typical appearance is that of a translucent *papule* with *telangiectases* over the surface (Fig. 177-2) that slowly enlarges, with subsequent development of a *central ulceration* (Fig. 177-3). This lesion has been termed the "rodent" ulcer. Basal cell

carcinoma may also become pigmented in darker-skinned persons and be confused with melanoma of the nodular or superficial spreading type. Superficial forms of basal cell carcinoma exist, most commonly on the back, that have the appearance of an *erythematous plaque*. Superficial basal cell carcinomas are also becoming more common on the legs of women. The usual presence of papular elements at the border facilitates the diagnosis. In the sclerotic form of basal cell carcinoma (morpheaform basal cell carcinoma), nests of tumor cells are interspersed within thick fibrotic bundles. This tumor is more resistant to treatment.

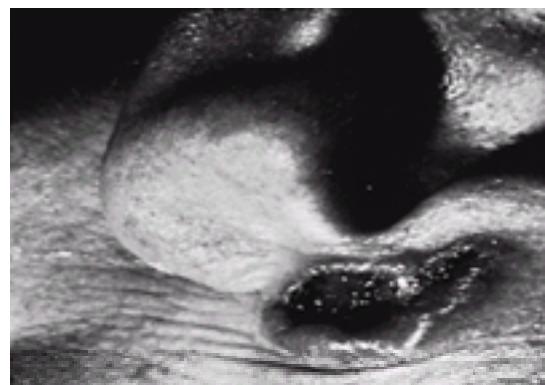
Figure 177-2. Nodular basal cell carcinoma. Note telangiectasia.


**Figure 177-3.** Basal cell carcinoma—"rodent" ulcer.

The differential diagnosis of basal cell carcinoma includes dermal nevi and other appendage tumors, such as *trichoepithelioma*, which can look just like a basal cell carcinoma. On histopathologic examination of a basal cell carcinoma, proliferation of basophilic cells is seen, usually in nests surrounded by discrete lacunae located in the upper dermis. This tumor is relatively easy for the pathologist to diagnose microscopically. Because basal cell carcinomas are more common in persons who have already had one, patients should be followed on an annual basis for early detection of new lesions.

Squamous Cell Carcinoma. The precursor *actinic keratosis* appears as a scaly erythematous patch that is flat to slightly raised; it may be single or multiple and occurs in sun-exposed areas (Fig. 177-4). Often, this lesion is more easily felt (a sandpaper-like texture) than observed. It appears to evolve through cycles from a macular erythematous lesion to a raised scaly lesion. In the later stages, a crusted surface, and sometimes even a horn of keratin, develop. Histopathologic examination of these lesions reveals atypical keratinocytes in the basal cell layer of the epidermis.

Figure 177-4. Actinic keratosis on the upper lip.

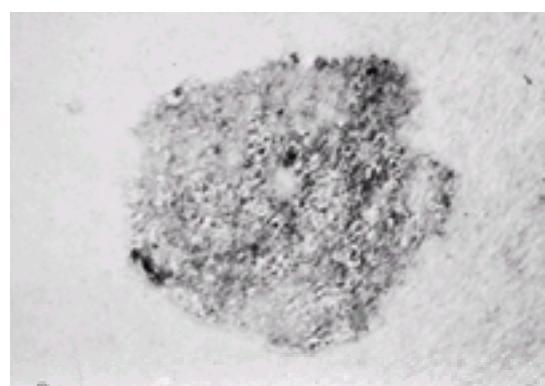
Bowen's Disease. Bowen's disease, the carcinoma *in situ* stage, usually presents as a chronic, asymptomatic, nonhealing, slowly enlarging erythematous patch that generally has a sharp but irregular outline. It may resemble eczematous dermatitis but does not respond to topical steroid therapy (Fig. 177-5). Within the patch, areas of crusting are generally found. The sharp borders, chronicity, and lack of symptoms are clues that suggest the necessity of performing a biopsy. In dark-skinned patients, such as those of Mediterranean descent, these lesions may have a brown to blue-gray coloration. Bowen's disease can occur on any part of the skin and on mucocutaneous sites, such as the vulva. In the vulvar area, the differential diagnosis includes lichen sclerosis et atrophicus, lichen simplex chronicus, squamous cell carcinoma, and, when the lesion is pigmented, melanoma. On histopathologic examination, atypical keratinocytes are noted throughout the epidermis but do not invade the dermis.


Figure 177-5. Bowen's disease—squamous cell carcinoma in situ.

Invasive Squamous Cell Carcinoma. Invasive squamous cell carcinoma presents as a flesh-colored, asymptomatic nodule that enlarges and often undergoes

ulceration and crusting (Fig. 177-6). The lesion may become keratotic and have a thickened surface. A cutaneous horn may be present. Excisional biopsy with close margins is the procedure of choice for the diagnosis of this lesion. Microscopically, the squamous cell carcinoma has fingers of atypical keratinocytic cells infiltrating into the dermis. The nuclei are clearly atypical; mitoses are frequently found.

Figure 177-6. Squamous cell carcinoma in typical locations.

Squamous cell carcinoma may sometimes be confused with a benign keratinocytic lesion, *keratoacanthoma*, which is dome-shaped and exhibits a prominent central plug (Fig. 177-7). Histopathologically, keratoacanthoma may be difficult for the pathologist to differentiate from squamous cell carcinoma. The keratoacanthoma usually exhibits more rapid growth and often regresses spontaneously.

Figure 177-7. Keratoacanthoma. Note the central keratotic plug.

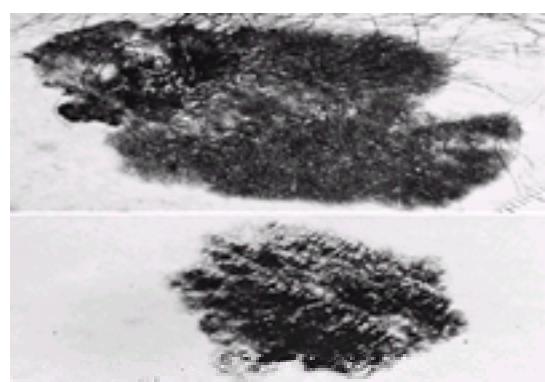
Melanoma. The hallmarks include *asymmetry* (one half is not identical to the other) and *irregularity of the border* (sometimes a notch is present; Fig. 177-8), *variegation in the color* and *pigmentation pattern* (notably red, white, blue, and admixtures of these colors, such as grays and pinks), and *increased size* (>6 mm). The recognition of suspected pigmented lesions that may represent early disease is facilitated by use of the mnemonic *ABCD*:


Figure 177-8. Melanoma of the superficial spreading type. Note the irregularity of the border and prominent notch.

A, *asymmetry* of lesion shape

B, *border irregularity*

C, *color variegation*

D, *diameter greater than 6.0 mm* (the size of a pencil eraser tip)

Use of the ABCD system has been associated with sensitivities as high as 92% and a specificity of 98%. Additional features seen in intermediate and advanced lesions include an *irregular raised surface* and *ulceration* or *bleeding* of the surface. Regardless of appearance, any pigmented lesion that undergoes change should be considered for excisional biopsy. Each type of melanoma has distinguishing features.

Superficial Spreading Melanomas. Superficial spreading melanomas have some irregularity in the border and some alteration in the regularity of pigment pattern and coloration (Fig. 177-8).

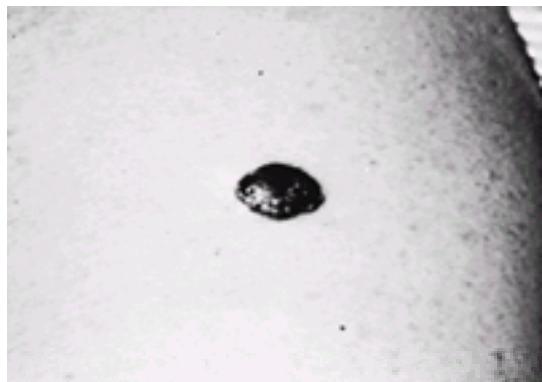
Nodular Melanoma. Nodular melanoma, which arises de novo or within nevi as an invasive tumor from the onset, has no radial growth component. It appears as a blue, blue-black, or gray nodule of varying size (Fig. 177-9). These lesions may be symmetric or have an irregular perimeter. Their borders are characteristically discrete and sharp. Most of these lesions are deeply invasive at the time of diagnosis. About 5% of nodular melanomas lack pigment (*amelanotic melanoma*).


Figure 177-9. Melanoma, nodular type.

**Lentigo Maligna.** Lentigo maligna begins as a freckle-like lesion that slowly expands. It has a markedly irregular pigmentation pattern and usually an extremely irregular border. Spontaneous regression may occur; the border may advance on one side while regressing on another, so that the lesion appears to march across the skin surface.

Acral Lentiginous. Acral lentiginous melanoma occurs on palms, soles, subungual areas, and mucous membranes, beginning as a flat pigmented lesion that may be irregular in its border and pigment pattern. Early biopsy is essential to achieve cure before metastasis has occurred.

The Distribution. The distribution of melanoma across the body surface is not uniform. In both sexes, lesions aggregate on the back. In female patients, the lower extremities are heavily affected, but they are spared in male patients, in whom the anterior torso is more likely to be involved. The bra and swim trunk areas are spared in females, and the swim trunk area and thighs are spared in males.

Because a *second primary tumor* develops in up to 10% of patients with melanoma, it is worthwhile to examine the entire skin surface to look for a second tumor on each encounter. In familial melanoma, a second primary tumor may develop in as many as 30% of patients. Because a trait favoring the development of melanoma appears to occur in families, family members of patients who have had melanoma should be examined.

DIFFERENTIAL DIAGNOSIS

The preceding characteristics are sometimes found in *pigmented basal cell carcinoma* and pigmented lesions of Bowen's disease. In addition, odd dermal or compound nevi, irritated seborrheic keratoses, and occasionally vascular lesions can be clinically confused with melanoma. The benign blue nevus also shares similar clinical features. Biopsy and histopathologic evaluation are warranted if a lesion meets the criteria previously noted.

CONCLUSIONS AND RECOMMENDATIONS FOR SCREENING AND PREVENTION

- Screening for skin cancer represents one of the best examples of early detection leading to an improved outcome. For example, the current 5-year survival rate for melanoma is 95% if the thickness of a lesion is less than 0.85 mm. It is estimated that with education of patients and physicians about signs of disease and the importance of early diagnosis, the overall 5-year survival rate for malignant melanoma could approach 90%.
- Every primary physician should be able to recognize the common skin cancers, and patients should be taught to avoid risk factors and report suspect lesions. In particular, the following precautions should be observed:
  1. All fair-skinned persons who sunburn easily and those with evidence of solar damage or skin cancer should be warned about the hazards of continued high-intensity solar exposure. They should be advised to avoid sun exposure between 11:00 a.m. and 2:30 p.m., the period during which 70% of exposure to harmful ultraviolet radiation occurs, and to avoid or minimize use of tanning devices, which are a source of ultraviolet radiation. **Updated: 3/4/02**
  2. All persons at risk for skin cancer should be advised to use a broad-spectrum sunscreen when going out into the sun. The preparation should block some ultraviolet A in addition to most ultraviolet B radiation and have a solar protection factor (SPF) of at least 15.
  3. Patients with a history of exposure to arsenic or previous radiation therapy and radiation dermatitis should be watched closely for the development of cancer.
  4. For nonmelanomatous skin cancer, patients should report to their physician any new, slowly growing, nodular or papular lesions that are flesh-colored or translucent, and particularly the occurrence of any bleeding, ulceration, or horn formation. Areas of maximum solar exposure are at greatest risk.
  5. For malignant melanoma, patients are asked to report to their physician any pigmented lesion with an irregular border or a variation in color, especially blue, gray, or black. Any growth in a pigmented lesion or change in color should also arouse suspicion.
  6. If any doubt exists about whether a skin lesion is benign, the obligation of the primary physician is either to obtain a sample of the lesion for biopsy or to refer the patient to an experienced specialist for an opinion. If patients and physicians work together, the incidence of skin cancer and the deaths associated with it can be greatly reduced.

CHAPTER 178 EVALUATION OF PRURITUS

WILLIAM V. R. SHELLOW

Pruritus is an unpleasant cutaneous sensation that provokes the urge to scratch. It may be localized or generalized and may occur with or without skin lesions. Itching may be caused by a dermatologic condition, systemic illness, or psychological disturbance. The complaint is particularly common among the elderly. It can prove challenging when the cause remains elusive and symptoms interfere with daily functioning. The primary physician should be capable of performing a reasonably detailed evaluation and providing effective symptomatic relief.

PATHOPHYSIOLOGY AND CLINICAL PRESENTATION

Pathophysiology. The sensation of itching arises from free nerve endings of the skin. These fibers are especially concentrated in the flexor aspects of the wrist and ankles. Afferent transmission is through unmyelinated C fibers to the dorsal horn of the spinal cord, ascending to the contralateral spinothalamic tracts and terminating in the cerebral cortex. The scratch response is a spinal reflex. Many chemical mediators and modulators of itch have been suggested, including substance P, opioid and nonopioid peptides, somatostatin, neurokinin A, histamine, serotonin, kinins, and prostaglandins.

Various external stimuli decrease the threshold for itching. These include inflammation, heat, dryness, and vasodilation. Persons vary in their response to itching. The perception of itching can be influenced psychologically, which explains why a physician may experience itching after attending a patient with scabies or pediculosis.

Clinical Presentations. Pruritus may be localized or generalized and can occur with or without skin lesions. Pruritus resulting from a systemic disease can occur with or without a primary skin lesion.

Dermatologic Disease. A host of dermatologic conditions can present with itching, including pediculosis and scabies (see Chapter 195), contact dermatitis (see Chapter 184), urticaria (see Chapter 181), psoriasis (see Chapter 187), lichen planus, and dermatitis herpetiformis. Dry skin (xerosis) (see Chapter 183) is the most frequent precipitant and is particularly common in the elderly. Symptoms are worse in the winter or with use of air conditioning, which lowers indoor humidity. Tangential light reveals fine scaling and cracking. Patients with urticaria usually give a history of wheals and demonstrate dermatographism (urticaria elicited by stroking the skin with a blunt object). Scabies and dermatitis herpetiformis can have a subtle presentation, with few skin manifestations when the patient is initially seen. In dermatitis herpetiformis, vesicles are characteristic, but excoriations may obliterate them. An intense burning sensation often predates the appearance of skin lesions. Scabies is endemic in long-term care facilities. In persons with good hygiene, fewer than 10 of the characteristic burrowing-induced skin lesions (see Chapter 195) may be present. At times, the only finding may be nonspecific papules caused by an immune skin response.

Renal Disease. Pruritus may accompany severe chronic renal failure, especially in patients undergoing hemodialysis. Secondary hyperparathyroidism causing elevated levels of histamine is one suspected mechanism. Other investigations have implicated endopeptidases or kinins as substances that can accumulate in uremia.

Endocrine Disease. Generalized itching occurs among 4% to 11% of patients with Graves' disease, usually when the disease is long-standing. Increased kinin activity and slightly elevated skin temperatures are suggested mechanisms. The mechanisms for other endocrinopathies are poorly understood.

Liver Disease. Among the many disorders of the liver, obstructive cholestatic jaundice produces the greatest degree of pruritus. Itching can be especially prominent and the presenting manifestation in primary biliary cirrhosis. About 20% to 25% of patients with jaundice are plagued by itching, although it is rare in the absence of cholestasis. The pruritus of cholestasis has been linked to the release of proteases in the skin by bile salts. Itching during the last trimester of pregnancy has been reported in 1% to 3% of expectant women and is thought to be cholestatic in origin, although jaundice is uncommon.

Hematologic Disease. The itching of *polycythemia vera* affects 30% to 50% of patients and is exacerbated by a hot shower or bath. In mycosis fungoides, pruritus has been suggested as an adverse prognostic factor. *Lymphoma* and *Hodgkin's disease* may also cause pruritus; its role as a prognostic indicator is less significant than previously thought. Histamine release by an increased number of circulating basophils is postulated as the pathophysiologic mechanism. Pruritus has also been found in association with iron-deficiency anemia and with HIV infection. Mechanisms are unclear.

Psychiatric Disease. Patients with neurotic scratching report that they scratch even in the absence of itching. Itching is reported to occur more often at night, when other stimuli are lacking. Although the excoriations of this "neurodermatitis" may occur anywhere the patient can reach, they tend to be concentrated in the extremities. Depression and dsyphoric mood are particularly common among such patients, as are serious conflict and situational stress preceding the onset of pruritus.

DIFFERENTIAL DIAGNOSIS

The conditions that cause itching may be dermatologic, systemic, or psychological in origin (Table 178.1). Skin disorders account for the vast majority. The pruritus may be localized or generalized. Localized itching is usually a sign of a primary dermatologic condition, dermatophyte infection, infestation, or a psychological disorder. Generalized itching raises the possibility of a systemic condition or a psychogenic cause, although dermatologic disease still predominates. In the elderly, the most common cause of itching is xerosis. Although generalized pruritus may accompany lymphoma and other malignancies, its presence does not increase the risk for underlying or future malignancy in a person who presents with no other manifestations of malignancy.

Table 178.1. Conditions Associated with Pruritus

WORKUP

A search for a primary dermatologic disease or scabies infestation is the first step in the evaluation of the pruritic patient. Often, a careful look at the skin combined with a few clues from the history suggests the diagnosis. Skin diseases associated with recognizable lesions and characteristic distribution usually do not present

significant diagnostic difficulty, unless camouflaged by excoriations, lichenification, secondary eczema, or infection. Systemic illnesses require a more detailed history and a physical examination that extends beyond the skin, followed by selected laboratory studies.

History. Location, associated symptoms, precipitants, clinical course, and severity (including effect on sleep and daily activity) should be carefully elicited. A detailed description of any skin changes or rashes should be included. If the patient reports little in the way of skin findings, clues to an underlying dermatologic condition should still be sought. For example, a history of atopy, asthma, or urticaria raises the probability of an allergic origin, whereas concurrent pruritus in household members is suggestive of scabies, and worsening in winter points to dry skin. Environmental factors such as sunburn, prickly heat, the presence of cats in a household, exposure to fiberglass, and excessive drying of the skin also deserve consideration. Pharmacologic exposure is important to review because a subclinical allergic reaction may occur with almost any drug. One should also check specifically for use of opiates, amphetamines, quinidine, aspirin, B vitamins, and niacinamide.

In the setting of generalized pruritus, one should inquire about symptoms or a history of hyperthyroidism (see Chapter 103), renal failure (see Chapter 142), lymphoma (see Chapter 84), polycythemia (see Chapter 80), cholestatic liver disease (see Chapter 62), and HIV infection (see Chapter 13). Pregnancy should be suspected as the cause if the patient is a woman in her third trimester.

If the cause is not evident from the medical history, it is worth exploring psychosocial aspects of the patient's life and any relation between psychological or situational stresses and the onset of pruritus. Given the high prevalence of depression among patients with idiopathic pruritus, inquiry into symptoms of depression (see Chapter 227) may prove useful.

Physical Examination. A careful and complete inspection of the skin is essential. The presence and distribution of a rash, excoriations, lichenification, and inflammatory changes should be noted, along with any evidence of xerosis (scaling and dryness). Dry skin is especially evident on the legs; tangential lighting can help reveal the scaling.

If the complaint is localized, a more detailed look at the involved area is needed. The scalp is checked for psoriasis and seborrhea; the trunk for urticaria, scabies, and the linear lesions of contact dermatitis; the inguinal area for *Candida* infection, pediculosis, tinea, and scabies; the hands for eczema, contact dermatitis, and the telltale interdigital lesions of scabies; the legs for neurotic excoriations, stasis dermatitis, atopic dermatitis (popliteal fossa), lichen simplex (lateral malleoli), and dermatitis herpetiformis (knees); and the feet for tinea and contact dermatitis.

If the pruritus is generalized and no evidence of primary dermatologic disease can be found, a search for signs of a systemic condition is warranted. The skin is examined for jaundice and findings associated with HIV disease (see Chapter 13), the sclerae are checked for icterus, the lymph nodes for enlargement, the thyroid for goiter, and the liver and spleen for organomegaly.

Laboratory Studies. Test selection should be based on findings from the history and physical examination. Resorting initially to a "panscan" is wasteful and likely to generate false-positive results. Skin scrapings are performed to confirm a clinical diagnosis of scabies or dermatophytosis (see Chapter 195 and Chapter 191). A skin biopsy examination with special stains or direct immunofluorescence may be required to confirm a diagnosis of mastocytosis, mycosis fungoides, or one of the autoimmune bullous diseases. In the setting of suspected cholestasis, one should order a determination of serum bilirubin, alkaline phosphatase, and transaminase levels, and obtain an ultrasonogram of the biliary tree (see Chapter 62). If lymphoma or carcinoid is a concern, chest radiography or abdominal computed tomography may be indicated (see Chapter 44 and Chapter 84). HIV testing is indicated if the patient has a history of high-risk sexual behavior or IV drug use (see Chapter 13).

If the diagnosis continues to be elusive, then a complete blood cell count and measurement of blood urea nitrogen, thyroid-stimulating hormone, calcium, albumin, and globulin levels are worth considering. Pruritus *per se* is not a predictor of malignancy and need not trigger a workup for occult malignancy in the absence of other clinical evidence for cancer.

SYMPTOMATIC THERAPY AND PATIENT EDUCATION

To be most effective, the treatment of pruritus should be based on etiology if possible. However, nonspecific symptomatic measures are sometimes required, especially if the workup is still in progress and the itching is disturbing sleep and interfering with daily life. Symptomatic treatment is also indicated for refractory conditions (e.g., biliary cirrhosis). Even if little can be done for the underlying condition, relief from itching is greatly appreciated. Avoidance of provocative factors is important, complemented by simple empiric therapy of low toxicity. Teaching the patient how to overcome the itch–scratch–itch cycle is most beneficial.

Nonspecific Behavioral and Topical Measures. Patients should be told to trim their fingernails, to keep them clean to prevent excoriation or infection, and to rub with their palms rather than their fingers if they have an uncontrollable urge to scratch. If vasodilators or foods such as coffee, spices, or alcohol precipitate itching, they should be avoided. Changing one sheet at a time helps reduce the static electricity that can precipitate itching. Rough clothing, particularly wool, should be avoided. Cotton clothing that has been doubly rinsed of detergents is preferred. Humidification of the indoor environment should be maintained when an air conditioner is used and during the winter, either with humidifiers or by placing bowls of water near radiators. Frequent and prolonged showering is to be avoided because it eliminates the skin's normal oil protection and contributes to dryness. Mild soaps (Dove, Basis, Neutrogena, Purpose, Aveeno Bar) are preferred to drying, antiperspirant soap products. Use of hot water is discouraged because it worsens itching by increasing cutaneous blood flow.

Such behavioral measures can be helpful regardless of the cause of itching and often reduce or eliminate the itching without further measures. Additional topical approaches include sponging the skin with cool water and using moisturizers before bedtime. However, only lotions and creams recommended by the physician should be used. The use of simple *emollient* preparations (Moisturel, Eucerin, Lubriderm, Aveeno Lotion) is encouraged, especially after bathing. It can be useful to add Alpha-Keri or other lubricating agents to the rinse cycle when sheets are washed.

Preparations containing combinations of *menthol, phenol*, and *camphor* (e.g., Sarna lotion) applied several times daily may provide symptomatic relief. *Calamine* lotion may alleviate itching briefly but is drying; it is most useful on weeping lesions. *Pramoxine*-containing products (PrameGel, Prax, Pramosone) also may reduce itching, but other topical anesthetics and antihistamines should be avoided because they can be potent sensitizers. *Hydrocortisone* cream, lotion, or ointment may provide symptomatic relief of itch; however, treatment with high-potency corticosteroids should be restricted to specific steroid-responsive dermatoses because prolonged use can cause dermal atrophy.

If environmental manipulation and topical agents are not effective, then systemic medications must be considered.

Nonspecific Systemic Measures. The systemic medications most commonly used are antihistamines, sedatives, and aspirin. By occupying the histamine receptors, the *histamine$_1$-blocker antihistamines* are very effective for allergen-mediated itch. In nonallergic itch, antihistamines are no more effective than aspirin but are often worth a try. Their sedative quality makes them useful as a bedtime medication in patients who have sleep difficulties. The choice of an ideal agent is found by trial and error on the basis of the placebo, sedative, and anticholinergic effects of the drug. *Hydroxyzine* (e.g., 25 mg three times daily or 50 mg daily at bedtime) is among the most effective of these agents. It is mildly to moderately sedating and more effective than diphenhydramine or cyproheptadine, other commonly used antihistamines. The nonsedating metabolite of hydroxyzine, cetirizine (Zyrtec), is an excellent antipruritic agent when used at doses of 5 to 10 mg daily. Diphenhydramine is available without prescription and is very sedating. Nonsedating antihistamines such as astemizole (Hismanal), loratadine (Claritin), and fexofenadine (Allegra) are useful for daytime use when histamine plays a primary role, such as in urticaria, but are generally disappointing as antipruritics and do little to help the patient fall asleep.

Mild antiinflammatory agents such as *aspirin* are occasionally useful for symptomatic relief, especially if the suspected mechanism is kinin- or prostaglandin-mediated. Systemic steroids suppress itching but should not be used for symptomatic relief.

Specific Symptomatic Measures. As noted above, the most effective therapy is etiologic. A few symptomatic measures for specific causes are important to consider, especially when treatment of the underlying disease is problematic.

Hepatobiliary Disease. For extrahepatic obstruction, the treatment of choice is relieving the obstruction. For intrahepatic cholestasis, including the pruritus of pregnancy, the chelating agents *cholestyramine* and *colestipol* are used with benefit. *Ursodeoxycholic acid* has also proved useful, particularly in persons with primary biliary cirrhosis, in which pruritus can be very intense and refractory. *Ultraviolet radiation* [ultraviolet B, psoralens with ultraviolet A (PUVA)] is sometimes resorted to

when the pruritus persists despite all other measures.

Psychiatric Illness. Sedatives, especially the *benzodiazepines*, can be useful in acute circumstances associated with anxiety and difficulty falling asleep, but long-term use is to be avoided because of risk for habituation (see Chapter 226). *Antidepressants* are helpful in psychogenic cases with evidence of concurrent depression. Doxepin, an antidepressant with antihistaminic properties, is particularly useful and may be given before bedtime. *Pimozide*, a neuroleptic, is effective for treating delusions of parasitosis.

HIV Infection. Pruritus may be an initial manifestation of underlying HIV infection, which is suggested when it occurs in the absence of rash or jaundice. It responds to antiretroviral therapy. Other treatable causes in HIV-infected patients include scabies (see Chapter 195), dry skin (see above), psoriasis flare (see Chapter 187), sulfa allergy associated with trimethoprim/sulfamethoxazole prophylaxis for *Pneumocystis* pneumonia (holding of drug), staphylococcal folliculitis (antibiotic therapy), and liver failure (see above).

Renal Failure. The best treatment is correction of the underlying disease, but symptomatic measures are often necessary. Recalcitrant uremic pruritus has been treated with ultraviolet photochemotherapy, IV xylocaine, activated charcoal, IV erythropoietin, exchange transfusion, and parathyroidectomy, with varying degrees of success. Topical *capsaicin* is sometimes helpful, as can be cimetidine. The opiate antagonist *naloxone* has been shown in some studies to relieve pruritus, but in others it has appeared to worsen the problem (see also Chapter 142).

INDICATIONS FOR REFERRAL

The patient with refractory or idiopathic pruritus poses a very frustrating problem that often benefits from a dermatologic consultation and consideration of skin biopsy. The consultation lets the patient know that the problem is being taken seriously and that everything is being done to address both its cause and the patient's discomfort. When pruritus represents a somatic response to psychological distress, it may be useful to consider a mental health referral with the patient.

CHAPTER 179 EVALUATION OF PURPURA

Purpura represents bleeding into the skin. In the office setting, patients present with easy bruising, spontaneous ecchymoses, or a petechial rash. Although many cases of purpura are caused by unappreciated trauma, patients who report easy bruising or spontaneous ecchymoses need to be evaluated for an underlying bleeding disorder (see Chapter 81). Those with petechial rashes may have a platelet problem, vasculitis, or a bacteremia. The primary physician should be able to make these distinctions and efficiently initiate the evaluation.

PATHOPHYSIOLOGY AND CLINICAL PRESENTATION

The integrity of small vessels is maintained by quantitatively and qualitatively adequate platelets and by healthy connective tissue. Normally, a break in a vessel triggers prompt formation of a platelet plug followed by a fibrin clot. Purpura occurs when the integrity of the vessel wall or the mechanisms of hemostasis are disturbed.

Purpura is divided in petechial and ecchymotic categories. *Petechiae* are red macules that measure less than 3 mm in diameter; they reflect a defect in platelets or vessel walls. When caused by disturbances of platelets, petechiae appear in dependent areas, such as the ankles and lower legs (see Chapter 81). Immune-mediated inflammation of small vessels may also produce petechial macules, which sometimes progress to palpable lesions (so-called *palpable purpura*; see below).

Ecchymoses are purpuric lesions larger than 3 mm in diameter. They may result from trauma or a clotting factor disorder as well as from a vascular or platelet problem. Clotting factor dysfunction causes delayed but more prolonged blood loss, during which continuous oozing secondary to inadequate fibrin clot formation results in ecchymoses rather than petechiae (see Chapter 81).

The mechanisms of purpura can be divided into the thrombocytopenic, thrombocytopathic, coagulopathic, vascular, connective tissue, and idiopathic varieties. The first three are discussed in detail in Chapter 81. The vascular, connective tissue, and idiopathic varieties require further elaboration here.

Vascular Defects

These range from mild disruption of the endothelium to necrotizing injury. The latter are the more important.

Small-vessel Vasculitis of a *leukocytoclastic* variety is capable of damaging vessel walls and causing palpable purpura. It usually occurs in the context of a *hypersensitivity reaction* or *rheumatoid disease*, but causes range from dysproteinemias to *Wegener's granulomatosis* (Table 179.1). In a hypersensitivity reaction, immunologically mediated, necrotizing neutrophilic infiltration of arterioles, capillaries, and venules occurs. The process can be systemic, but it is often limited to the skin. In rheumatoid disease, the postcapillary venules are the principal site of leukocytoclastic injury; systemic involvement is the rule.

Table 179.1. Important Causes of Leukocytoclastic Small-Vessel Vasculitis

The skin lesions of leukocytoclastic vasculitis typically begin as small macules that become palpable and may turn confluent or nodular. The petechial papules do not blanch; they appear in symmetric fashion and predominate in dependent areas. Urticaria, vesicles, and necrotic ulcerations may also develop. Fever, arthralgias, myalgias, arthritis, pulmonary infiltrates, effusions, pericarditis, peripheral neuropathy, abdominal pain, bleeding, and encephalopathy can occur along with the petechial rash if systemic involvement is present. The skin commonly itches, stings, or burns. Hematuria and proteinuria are often detected.

Bacteremia can lead to vascular injury and the formation of petechiae, which are sometimes palpable. Petechial lesions associated with *subacute bacterial endocarditis* are flat, do not blanch, and appear on the upper chest, neck, and extremities in addition to the mucous membranes. In *gonococcal* and *meningococcal septicemias*, petechiae develop early, become pustular, and then turn hemorrhagic and necrotic. The lower extremities are a common site for the gonococcal lesions, which resolve within 5 to 7 days. The rash of *Rocky Mountain spotted fever* begins as pink macules on the wrists, soles, ankles, and palms. The rash spreads centripetally and by the fourth day becomes petechial and papular. Hemorrhagic, ulcerated lesions may follow.

Other Forms of Vascular Injury include *stasis dermatitis*, in which petechial lesions in the legs result from capillary injury. *Scurvy* compromises the vascular endothelium, and perifollicular purpura develops because of increased capillary fragility. In *amyloidosis*, deposition of amyloid in the skin and subcutaneous tissue causes fragile vessels, with ecchymoses forming when the skin is pinched.

Connective Tissue Defects compromise vessel walls and supportive extravascular structures and lead to easy bruising. When caused by the degeneration of dermal collagen because of *age* or *corticosteroid use*, ecchymoses may develop after trivial injury and be noticed on the face, neck, dorsum of the hands, forearms, or legs. A variant is stasis or *orthostatic purpura*, which usually develops in the lower extremities of an elderly patient following a prolonged period of standing.

Idiopathic Causes include *autoerythrocyte sensitization*, a puzzling form of purpura characterized by spontaneous, painful ecchymoses surrounded by erythema and edema. Headache, nausea, and vomiting sometimes accompany the purpura. Many patients with this condition also have pronounced psychoneurotic complaints. The mechanism is unknown, but intradermal injection of autologous red cells or DNA can reproduce the clinical picture.

Purpura simplex or *easy bruising syndrome* is an idiopathic condition of young women in otherwise good health. All platelet and bleeding parameters are normal, and the risk for hemorrhage during surgery or childbirth is not increased.

Platelet and Clotting Factor Disorders

Platelet and clotting factor disorders are discussed in Chapter 81.

DIFFERENTIAL DIAGNOSIS

The causes of purpura can be divided into thrombocytopenic, thrombocytopathic, clotting factor, vascular, connective tissue, and idiopathic categories (see also Chapter 81). Purpura associated with trauma or drug-induced impairment of platelet function, benign purpura simplex, and senile purpura are the most common forms. Vasculitis is particularly troublesome because of the wide range of potentially important causes (Table 179.1).

WORKUP

The workup of the patient with purpuric lesions must emphasize the history and physical examination to avoid costly, nonproductive laboratory evaluations. The clinical findings are also essential in quickly differentiating serious hematologic, vasculitic, or infectious pathologies from more benign processes. For example, ecchymoses smaller than 6 cm, localized to such areas of trauma as the thighs, are less likely to be of pathologic significance than are larger ones; palpable purpuric lesions indicate a vasculitic process; and petechial macules in dependent areas suggest a problem with platelets.

History. A careful description of the location, size, and clinical course of the purpuric lesions, along with an inquiry into associated symptoms and precipitants, comprises the essence of the history. One should quickly screen for a bleeding diathesis by inquiring about blood loss from other sites; easy bruisability; bleeding into a joint; a history of abnormally heavy bleeding with menstruation, surgery, or dental work; and a family history of a bleeding problem. A review of medications is essential, with a focus on agents that can interfere with platelet function (e.g., aspirin, NSAIDs, dipyridamole, ticlopidine, sulfinpyrazone) and those associated with hypersensitivity reactions that affect platelets (e.g., antibiotics, quinidine, phenothiazines). Any history of renal or hepatocellular failure is important to note.

Patients with an early petechial rash or palpable purpura should be carefully checked for fever, pruritus, joint pain, urticaria, dry mouth/dry eyes, morning stiffness, pleuritic pain, abdominal pain, melena, hematuria, lymphadenopathy, jaundice, symptoms of inflammatory bowel disease, chronic leg edema, and paresthesias. A recent streptococcal or staphylococcal infection may be responsible for a hypersensitivity vasculitis and should be noted. Medications to be reviewed include recent use of a penicillin, a thiazide, aspirin, or amphetamines. If fever is prominent, bacteremia must be considered, and the patient should be asked about recent purulent penile or vaginal discharge, pelvic pain, other recent infection, IV drug abuse, HIV infection, and history of a heart murmur or recent dental work.

Physical Examination begins with inspection of the skin lesions. If they appear petechial, it is useful to press a glass slide over them. Failure to blanch helps differentiate petechiae from nonpurpuric skin lesions. However, blanching lesions must not be dismissed too hastily because telangiectases and spider angiomata are signs of conditions predisposing to purpura (see Chapter 81). Shining a light tangentially to the skin is a sensitive means of detecting elevated lesions, which may be confirmed by careful palpation. The size, number, and location of purpuric lesions should be recorded and note made of whether they are palpable or macular, petechial, or ecchymotic. It is sometimes helpful to circle ecchymoses so that extension or regression can be followed objectively.

If the history suggests a bleeding problem or if the physical examination reveals petechiae in dependent areas or large ecchymoses, then the physical examination should be directed toward hematologic causes (see Chapter 81).

If palpable purpura is present, then the physical examination should include inspection for splinter hemorrhages, rheumatoid nodules, a separate malar rash, dry mucous membranes, jaundice, lymphadenopathy, pleural effusion, heart murmur, pericardial rub, hepatic abnormalities, purulent vaginal or urethral discharge, joint inflammation, and changes of stasis dermatitis.

If the history reveals only easy bruising and no evidence for hematologic or vasculitic pathology can be found, then consideration of connective tissue and idiopathic causes is in order. Does the patient appear cushingoid or have a history of long-term corticosteroid use?Is the patient elderly with multiple small ecchymotic lesions in areas of minor everyday trauma? Are the ecchymoses tender in the absence of trauma? Is the patient an otherwise healthy young woman with easy bruising and relatively small ecchymoses?

Laboratory Studies. There is no standard battery of laboratory tests for the patient with purpura. To obtain meaningful information, the selection of studies must be based on the clinical findings.

Suspected Hematologic Disease. In patients with flat petechial rashes, the presence of platelet-related disease should be checked for with a *platelet count* and a determination of the *bleeding time* (see Chapter 81). Those with large ecchymoses may have a clotting factor problem and are best screened by measuring the *prothrombin time* and *partial thromboplastin time*. Other hematologic testing may also be in order. (See Chapter 81 for more details of the hematologic evaluation.)

Suspected Vasculitis. If palpable purpura is noted, the first priority is to rule out bacteremia. The history and physical examination often provide important clues, but two sets of *blood cultures* should be obtained at the outset, especially if fever or other manifestations of infection are noted. If rheumatoid disease is clinically suspected, one can screen by testing for *antinuclear antibodies* (ANA) and *rheumatoid factor*, although the results may be nonspecific (see Chapter 146). Patients with respiratory tract symptoms and purpura may have Wegener's granulomatosis and should undergo testing for *antineutrophil cytoplasmic autoantibodies* (ANCA) (see below). The finding of red cells on *urinalysis* or a stool positive for occult blood on *guaiac testing* may provide additional evidence for a systemic vasculitis, but the best means of confirming vasculitis is to perform a *skin biopsy* on one of the palpable, purpuric skin lesions. In addition to histologic processing, the biopsy specimen should also be cultured and a Gram's stain performed.

If a *leukocytoclastic vasculitis* is confirmed by skin biopsy, then more specific testing can be conducted if clinically indicated. The otherwise healthy patient with resolving skin lesions and nothing more than a recent history of using a potentially offending drug needs no further evaluation. If the lesions persist, more testing may be in order. Elderly persons are at risk for dysproteinemias; a serum *immunoelectrophoresis* should be considered. *Cryoprotein* and *serum complement* determinations may prove useful diagnostically in a young woman with leukocytoclastic histology. Testing for *ANCA* may help in the etiologic identification of cases presenting pathologically as small-vessel vasculitis. Consultation with a rheumatologist is advised to optimize test selection and interpretation, particularly in persons who are ANCA-positive, because more specific immunochemical testing is required to differentiate among causes.

PATIENT EDUCATION

Detailed reassurance needs to be provided to the patient with no hematologic or systemic abnormality, but only *after* a thorough evaluation has been completed. In the elderly patient with senile purpura, supportive explanation that the condition is a normal concomitant of aging is often helpful. Similarly, the young woman with a syndrome of easy bruising can be reassured. Occasionally, such patients buy and take large doses of vitamins C and K in the hope of lessening easy bruising. Such self-treatment is without any proven efficacy and adds an unnecessary expense. Avoidance of aspirin and NSAIDs is better advice.

For patients who require drugs that impair platelet function or compromise connective tissue integrity, it may be necessary to advise at least a reduction in dose; otherwise, they may have to accept the cosmetic unpleasantness of ecchymoses. It may be helpful to prepare those with palpable purpura for extended testing and the possibility of a skin biopsy.

INDICATIONS FOR ADMISSION AND REFERRAL

Any patient with fever and purpura requires prompt hospital admission because bloodstream infection and systemic vasculitis are possible causes. The person with evidence of bleeding from multiple sites is also best hospitalized, as is the patient with severe thrombocytopenia or marked prolongation of the prothrombin time or partial thromboplastin time.

As noted earlier, consultation with a rheumatologist is worthwhile to guide the evaluation of the vasculitic patient, particularly when the cause is elusive.

CHAPTER 180 EVALUATION OF DISTURBANCES IN PIGMENTATION

WILLIAM V. R. SHELLOW

Disturbances in pigmentation are conspicuous and common. Patients complain about general darkening, brown spots, or depigmented areas. Pigmentary alterations may be manifestations of a genetic, endocrine, metabolic, nutritional, infectious, or neoplastic problem. Physical and chemical factors also can be important because skin color can be altered by exposure to heat, solar and ionizing radiation, trauma, drugs, and heavy metals.

PATHOPHYSIOLOGY AND CLINICAL PRESENTATION

Pigmentary changes are caused by melanin being absent, increased, decreased, or abnormally placed or distributed. Hyperpigmentation may result from an increased rate of melanosome production, an increased number of melanosomes transferred to keratinocytes, or a greater size and melanization of melanosomes. Hyperpigmentation is perceived as blue when melanin is located deeply because of the Tyndall phenomenon. The pathophysiologic mechanisms that produce hyperpigmentation through the melanocyte system include increased levels of adrenocorticotropic hormone (ACTH), which has a melanocyte-stimulating action, ultraviolet radiation, and certain drugs.

Hypomelanosis, or depigmentation, may result from the genetic loss of melanocytes or destruction by inflammation. Inflammation may be secondary to infection or burns or associated with a variety of immunologically mediated diseases.

Hyperpigmentation

Hyperpigmentation may be circumscribed or diffuse.

Circumscribed Hyperpigmentation includes freckles (ephelides), lentigines, café-au-lait spots, and melasma. *Freckles* are small, macular lesions seen on areas exposed to the sun. Freckles may become less dark in adults, but they darken after exposure to long-wave ultraviolet radiation. *Lentigines* are macular, and they are larger and darker than freckles. Histologically, the two are easily distinguishable. Senile lentigines appear on sun-exposed areas in older patients. Patients call them "liver spots" and usually do not realize that "liver" refers to the color of the lesion and not to its cause. Café-au-lait spots are light to dark brown macules ranging in size from 1 to 20 cm. They can be round or oval with smooth or irregular borders. The presence of multiple lesions is associated with neurofibromatosis and Albright's syndrome. Nevocellular nevi are also circumscribed, hyperpigmented lesions, that, if macular, may be difficult to differentiate from lentigines.

Melasma, or *chloasma*, is a blotchy hyperpigmentation that occurs on the forehead, cheeks, and upper lip, usually in women. Pregnancy, use of oral contraceptives, and other hormones contribute to its development, but exposure to sunlight appears to perpetuate the condition. During pregnancy, a physiologic darkening of the linea alba, pigmented nevi, nipples, and genitalia is caused by melanocyte-stimulating hormone (MSH) and by increased levels of estrogen and progesterone.

Diffuse Hyperpigmentation results from increased amounts of melanin in the epidermis. The color may be accentuated in sun-exposed areas, over pressure points or body folds, or in areas of trauma, such as new scars. Hyperpigmentation occurs in *Addison's disease* when the pituitary produces increased amounts of MSH and ACTH because of decreased cortisol levels.

Metabolic diseases such as Wilson's disease, von Gierke's hemochromatosis, alkaptonuria, biliary cirrhosis, and porphyria cutanea tarda may be accompanied by diffuse melanosis. On occasion, rheumatoid arthritis, Still's disease, and scleroderma have been associated with hyperpigmentation.

Drugs such as busulfan, cyclophosphamide, clofazimine, minocycline, and zidovudine can produce diffuse melanosis, as can topical nitrogen mustard. Chronic inorganic arsenic poisoning causes diffuse hyperpigmentation with normal or lighter skin areas scattered throughout, colorfully called "rain drops in the dust." Chlorpromazine, amiodarone, and antimalarial drugs tend to produce a bluish gray hyperpigmentation. Silver (argyria) and gold (chrysiasis) as well as bismuth and mercury can accumulate in the skin and cause hyperpigmentation, depending on the dose given. Bleomycin can produce hyperpigmentation in a linear, flagellate pattern. Berloque dermatitis is the name given to a type of photocontact dermatitis associated with exposure to a photosensitizer, such as oil of bergamot in perfumes and some hair preparations. A similar compound in citrus rinds causes inflammation and pigmentation in areas exposed to both the sensitizing chemical and the sun.

Diffuse melanosis may be seen during starvation, with *hepatic insufficiency*, in *malabsorption syndromes*, and with *lymphomas* and *other malignancies*. *Postinflammatory hyperpigmentation* can be caused by a number of precipitants. For example, in phytophotodermatitis, contact with photosensitizing agents present in meadow grass, citrus fruits, and edible plants is associated with an exaggerated sunburn. Hyperpigmentation follows the acute phase. Skin contact with organic dyes and aromatic compounds can lead to photosensitization followed by hyperpigmentation. Tar, pitch, and oils can induce similar changes.

Physical trauma, friction, and heat may also lead to postinflammatory pigmentary changes, as may inflammatory dermatoses that stimulate melanin formation.

Yellow discoloration is seen in jaundice, which involves the sclerae, and in carotenemia, which does not. Lycopenemia will probably be seen more frequently because lycopene in tomatoproducts has been recommended for preventing prostate cancer. The skin color seen with excessive lycopene intake is more orange-yellow. Quinacrine, an antimalarial drug, can cause a yellowish discoloration of the skin. Other skin-yellowing drugs are phenazopyridine and canthaxanthin.

Hypopigmentation

Hypopigmentation may be hereditary or acquired. A *hereditary* disorder can be associated with a lack of or deficiency of melanin. A deficiency or lack of melanocytes accounts for the depigmented areas of partial albinism (piebaldism). A white forelock may be present. In oculocutaneous albinism, melanocytes are normal in number but unable to produce melanin secondary to defective or absent tyrosinase. Diseases involving abnormal amino acid metabolism, such as phenylketonuria and homocystinuria, are associated with hypopigmentation of the skin and hair. In tuberous sclerosis, elongated hypopigmented patches are seen. Certain cutaneous diseases lead to a loss of melanin into the dermis, which lends a gray appearance to the skin.

Vitiligo is a common, acquired disorder of hypopigmentation with an autoimmune mechanism that includes the formation of antibodies to melanocytes. It may occur in the setting of pernicious anemia, Hashimoto's thyroiditis, and a host of other autoimmune endocrine disorders. Any area of the skin can be affected. Onset is usually early in adult life. Lesions may be symmetric and occur primarily on exposed skin, intertriginous areas, and bony prominences and around orifices. In involved areas, the hair may be white. The border of the lesion is often sharp and hyperpigmented. Occasionally, vitiligo assumes a segmental or zosteriform pattern. Halo nevi—centrifugal areas of depigmentation that surround a pigmented nevus—are present in one third of cases. Premature graying of the hair occurs in about 35% of cases.

Partial repigmentation of vitiligo may occur in sun-exposed areas, but vitiliginous patches may burn because of the lack of protective pigmentation. Vitiligo has been associated with autoimmune diseases and endocrinopathies.

Depigmentation may be caused by a variety of *chemical agents*, most notably phenolic compounds that interfere with tyrosinase activity. Contact with rubber and antioxidants may also cause loss of pigment. Dermatitis may precede the loss of pigment, and areas remote from the inflamed sites may also lose pigment. The use of liquid nitrogen to treat lesions on skin types IV to VI may result in postinflammatory hypopigmentation, as can the intralesional injection of corticosteroids.

Dermatoses and Infections may result in localized areas of pigment loss. Such areas may be more noticeable in dark-skinned persons. Small, hypopigmented areas, termed *idiopathic guttate hypomelanosis*, occur on women's legs and may be related to the trauma of shaving. *Tinea versicolor*, pityriasis alba, erythema ab igne,

sarcoidosis, scleroderma, cutaneous T-cell lymphoma (mycosis fungoides), and various eczematous conditions may present as areas of hypopigmentation.

DIFFERENTIAL DIAGNOSIS

Table 180.1 lists the causes of disturbances in pigmentation.

Table 180.1. Causes of Disturbances in Pigmentation

WORKUP

Hyperpigmentation

Evaluation of the patient with localized hyperpigmentation requires inspection of the lesions and inquiry about previous dermatoses and the use of oral contraceptives that can produce melasma. The majority of localized hyperpigmented areas are postinflammatory and of cosmetic concern only, although they should be distinguished from more worrisome pigmented lesions, such as melanomas (see Chapter 177).

History. Diffuse hyperpigmentation necessitates a careful history that specifies the time of onset and possible sun exposure. A drug history that emphasizes agents known to produce pigmentary changes should be pursued. A general review of systems should be made, and any weakness associated with Addison's disease or any itching and hepatic dysfunction associated with biliary cirrhosis should be noted. The physician should consider the possibility of severe vitamin deficiency or malnutrition.

Physical Examination. One checks for hyperpigmentation in creases and scars (characteristic of Addison's disease) and clues to obvious underlying pathology, as may occur with malignancy, hepatic insufficiency, or malabsorption.

Laboratory Investigation is a function of the clinical findings, with biopsy a consideration if deposition of heavy metal or hemosiderosis is a diagnostic consideration.

Hypopigmentation

History. Hypopigmentation requires a careful history of approximate time of onset and possible exposure to bleaching agents, most notably phenol-containing industrial cleaners such as those used in janitorial work. Patients with vitiligo should be given a careful general review that seeks to identify associated conditions, such as pernicious anemia, thyroid disease, diabetes, or connective tissue disease.

Physical Examination. The total depigmentation of vitiligo should be differentiated from partial postinflammatory hypopigmentation. An ophthalmoscopic examination should be performed to detect retinal pigmentary changes. Persons with vitiligo should be examined for manifestations of pernicious anemia (see Chapter 79), thyroid disease (see Chapter 104), diabetes (see Chapter 102), and collagen vascular disease (see Chapter 146).

Laboratory Studies. Hypopigmented areas should be scraped and a potassium hydroxide wet mount examined microscopically to diagnose tinea versicolor. Laboratory screening to test for concurrent autoimmune disease is best undertaken according to the clinical presentation but might include evaluation for serum vitamin B_{12}, thyroid-stimulating hormone, antithyroid antibodies, random glucose, and antinuclear antibodies.

SYMPTOMATIC THERAPY AND PATIENT EDUCATION

Hyperpigmentation

In treating hyperpigmented areas, the chief symptomatic advice is strict avoidance of sunlight. Topical bleaching with *hydroquinone* cream may be effective. Strong topical cortico-steroid preparations have a pigment-lightening effect, as does *retinoic acid*. A bleaching solution of 0.1% retinoic acid, 5% hydroquinone, and 0.1% dexamethasone in a hydrophilic ointment or alcohol is quite effective. Hydroquinone–sunscreen combinations such as Solaquin and Solaquin Forte are useful in treating melasma. Melanex is an alcoholic solution of hydroquinone that is cosmetically well accepted by patients. Neither agent works well in postinflammatory hyperpigmentation because the melanin is deeper. No matter what is prescribed or recommended, it is important to stress to patients that lightening of pigment that has been accomplished only after months of treatment can be undone in a single day (or less) of unprotected exposure to the sun.

Hypopigmentation

Hypopigmented areas can usually be masked by appropriate cosmetics, by bleaching normal skin, or by repigmentation with *psoralens* and *ultraviolet A radiation* (PUVA). Hundreds of treatments may be required. The primary physician must assess the desire for treatment and inform the patient of the alternatives. Age, sex, or duration of vitiligo does not affect the response. Lesions on the face and abdomen tend to become repigmented more rapidly than those on the hands, feet, and bony prominences. Treatment should probably be supervised by a dermatologist experienced in using these agents to achieve optimal cosmetic results. *PUVA* with both *oral* and *topical psoralens* may be effective. With oral psoralens, many months of treatment are necessary to obtain cosmetic improvements. Topical psoralen plus ultraviolet A has no systemic effects such as nausea, and eye precautions are not required. Titration is very important, however, because severe blistering can result with this method of treatment.

If careful workup reveals no accompanying hematologic or endocrinologic autoimmune disorders, the patient can be reassured that only the skin is affected. Others appreciate knowing that the condition is not contagious. The primary physician should advise the patient about cosmetic alternatives and help the patient decide on an appropriate course of treatment. Because these patients may be unhappy with their body image, psychological support and counseling can be very helpful and should not be overlooked.

CHAPTER 181 EVALUATION OF URTICARIA AND ANGIOEDEMA

Urticaria (hives) is a pruritic, often immune-mediated skin eruption of well-circumscribed wheals on an erythematous base. It is estimated that up to one fifth of the population will experience an urticarial episode, with women more likely to be affected than men (especially with regard to chronic urticaria). Angioedema is a related condition involving the deeper layers of the skin. Approximately half of patients have urticaria with angioedema, 40% have pure urticaria, and 10% have pure angioedema. If the process occurs for less than 6 weeks, it is termed acute, but if it persists beyond 6 to 8 weeks, it is termed chronic. Most chronic urticaria resolves within a year, although persistence well beyond that occurs in approximately 10% of cases. The primary physician's diagnostic responsibilities include searching for precipitants and underlying causes and distinguishing urticaria from urticarial vasculitis, a manifestation of connective tissue disease. Eliciting the cause can be difficult and is not always possible. In the absence of an identifiable and remediable precipitant, one needs to provide symptomatic relief.

PATHOPHYSIOLOGY AND CLINICAL PRESENTATION

Urticaria

Mechanisms. Urticaria is the consequence of a mast cell release of mediators that increase vascular permeability, which leads to extravasation into the skin of protein-rich fluid from small blood vessels, usually postcapillary venules. A host of mechanisms have been implicated, and much remains incompletely understood, but *mast cell activation* is usually the final common pathway. Precipitants range from physical stimuli to autoimmune mechanisms. In food-induced and some forms of drug-induced disease, ingested or infused antigens trigger mast cell activation by an *immunoglobulin E* (IgE)-mediated pathway. In other drug-induced cases (e.g., opiates, amphetamines), *direct* activation by the drug does not occur. Hyperreactivity to acetylcholine (perhaps related to inadequate production of cholinesterases) is the suspected mechanism in persons with physical urticaria. Physical urticarias may also have some degree of IgE-mediated pathophysiology. In some cases, if not a substantial proportion, idiopathic chronic urticaria may represent a form of *autoimmune* activation of mast cells.

Regardless of the initial trigger, *mast cell activation* remains the final common pathway, with release of mediators from mast cells or circulating basophils increasing vascular permeability. *Histamine* serves as a principal mediator, producing a classic wheal and flare on intracutaneous injection. Transient histamine elevations even occur in the extremities of patients with physical urticarias. Other possible mast cell-derived mediators include bradykinin, eosinophilic and high-molecular-weight neutrophilic chemotactic factors, in addition to prostaglandin D $_2$, leukotrienes, and platelet-activating factors. Substance P may contribute to the flare that surrounds urticarial wheals. Heat, fever, emotional stress, alcohol, and the premenstrual state can exacerbate urticaria independently of the specific pathophysiology. Additional precipitants and mediators of the urticarial reaction are constantly being identified.

Clinical Presentations. The localized accumulation of fluid produces the characteristic edematous, erythematous, well-circumscribed itchy wheals that blanch on pressure, range in size from a few millimeters to several centimeters, and manifest serpiginous borders. Individual lesions may persist for 12 to 24 hours, but most resolve spontaneously much sooner. Central clearing can lead to an annular pattern. The common final pathway for urticaria of most causes produces a rather stereotypical presentation, but each of the common types has a few distinguishing characteristics.

Food- and Drug-induced Urticarias. The attacks tend to be brief and usually do not cause chronic urticaria, but attacks may be accompanied by angioedema. The most commonly implicated foods include *eggs, shellfish, true nuts, peanuts, fish*, and *milk*, and the most common drugs are *penicillins* and *sulfa-containing agents*. IV *iodinated contrast agents, opiates*, and *amphetamines* appear to cause direct release of mediators from the mast cells. *Aspirin* and *NSAIDs* produce urticaria in a dose-related nonimmunologic manner in susceptible persons, perhaps because they have an underlying abnormality in prostaglandin synthesis, which these agents block. Patients with urticarial reactions to aspirin can tolerate sodium salicylate or choline salicylate, which do not inhibit cyclooxygenase. Chronic urticaria is often erroneously ascribed to exposure to *food additives*. Although benzoic acid derivatives (e.g., *sodium benzoate*) and several *azo food dyes* (e.g., tartrazine and sunset yellow) have been implicated, placebo-controlled trials reveal that food additives account for no more than 10% of cases. *Latex* is an increasingly important example of a contact antigen common to medical settings that may trigger urticaria, angioedema, and even anaphylaxis by an IgE-mediated pathway. The latex powder that coats latex examination gloves is especially sensitizing.

Physical Urticarias. These include dermatographism, pressure urticaria, cold urticaria, and cholinergic urticaria. In *dermatographism*, gentle stroking of the skin produces an immediate wheal and flare response. In *pressure urticaria*, application of pressure at a right angle to the skin results in a red swelling after a latent period of up to 4 hours. In *cold urticaria*, application of cold produces pruritic, erythematous eruptions within minutes. *Cholinergic* urticaria is characterized by tiny, 1- to 3-mm punctate lesions surrounded by erythema; they are intensely pruritic and triggered by *exercise* or a *hot shower*. Some exercise-induced disease may require prior ingestion of a food to which the patient is allergic. *Aquagenic urticaria* is characterized by tiny perifollicular hives that appear after contact with water. *Solar urticaria* develops in susceptible persons on exposure to ultraviolet light.

Autoimmune Mast Cell Disease. An autoimmune form of mast cell disease has been postulated and might account for many of the otherwise idiopathic cases of chronic urticaria encountered. A wheal-producing, noncytokine IgG mediator that causes mast cell release of histamine has been identified in up to half of patients with chronic urticaria. Many of these patients also have autoantibodies to thyroid antigens, which perhaps accounts for the increased frequency of urticaria in persons with active Hashimoto's thyroiditis. In studies of such patients (whether euthyroid or with clinical thyroid disease), treatment with exogenous thyroid hormone to lower the level of thyroid-stimulating hormone often resulted in resolution of urticaria. More work remains to test these hypotheses.

Infectious Diseases. The formation of antigen–antibody complexes that trigger mast cell release has been the purported mechanism of the urticaria seen in some infectious diseases. For example, in the prodromal phase of hepatitis B, symmetric arthritis of the small joints of the hands may accompany an urticarial reaction, which is thought to be complement-mediated. Some patients with chronic "idiopathic" urticaria reported that their urticaria resolved with treatment for *Helicobacter pylori* infection. These observations raise the possibility that *H. pylori* antigens may be responsible for some of the "idiopathic" disease encountered.

Angioedema

The mechanisms are basically the same as for urticaria, which accounts for the simultaneous appearance of both types of lesions. In angioedema, the extravasation of fluid occurs in deeper layers of the skin and subcutaneous tissue, especially in the periorbital, perioral, pharyngeal, palmar, and plantar surfaces of the body. The edema is more diffuse, and the overlying skin appears normal and less itchy than in urticaria. Submucosal involvement in the upper airway and gastrointestinal tract can lead to hoarseness, life-threatening airway obstruction, nausea, vomiting, and abdominal discomfort. Sometimes, the abdominal pain is severe enough to mimic an acute abdomen. Most precipitants of urticaria can also trigger angioedema, but a few causes have unique mechanisms.

Hereditary Angioedema is an autosomal dominant hereditary disease characterized by reduced or defective production of the inhibitor of the first component of complement (C1 INH). In *type I*, the most common form, C1 INH levels are markedly reduced and levels of C4 are low, whereas in *type II*, the patient has normal to elevated amounts of a dysfunctional C1 INH. Half of patients have no family history of the condition.

Acquired Angioedemas. In patients with certain malignancies (*adenocarcinoma, lymphoma, chronic lymphocytic leukemia*), autoantibodies to C1 INH may develop and lead to attacks of angioedema. C1 levels fall, as do levels of C4 and C1 INH. The angioedema that is occasionally seen with the use of *angiotensin-converting enzyme inhibitors* appears to be mediated by bradykinins. The related angiotensin II–receptor antagonists, which do not affect bradykinins, are not associated with the same risk for angioedema.

Urticarial Vasculitis

Urticarial vasculitis superficially resembles urticaria but represents a vasculitic process heralding systemic autoimmune disease (e.g., *systemic lupus, Sjögren's*

syndrome). The skin lesions differ from those of urticaria in that the wheals last for longer than 24 hours and manifest a more indolent appearance that includes some central clearing, purpura, and residual pigmentation; the lesions hurt more than they itch. Patients also have systemic symptoms (e.g., fever, arthralgias, and abdominal pain) and may not obtain much relief from antihistamines. Laboratory studies may reveal an elevated sedimentation rate, the presence of antinuclear antibodies, and evidence of glomerulonephritis (microscopic hematuria, albuminuria). Biopsy demonstrates leukocytoclastic changes and extravasation of red cells, findings not seen with urticaria.

DIFFERENTIAL DIAGNOSIS

The causes of acute urticaria/angioedema are usually more straightforward, whereas the causes of chronic disease tend to be more elusive, as the relation to precipitants is often less clear (Table 181.1). Urticaria needs to be differentiated from urticarial vasculitis, a presentation of connective tissue disease.

Acute Disease (episodes stop recurring after ,6 weeks)
Infection (viral, bacterial, fungal, parasitic)
Foods (eggs, shellfish, nuts)
Food additives (sodium benzoate, azo dyes such as tartrazine
and yellow dye No. 5)
Drugs, immunologic release of mediators (penicillins, sulfa-
containing agents)
Drugs, direct mediator release (IV iodinated contrast agents,
opiates, amphetamines)
Drugs, prostaghardin inhibition (aspirin, other NSAIDs)
Other sensitizing antigens (e.g., latex, blood transfusion)
Insect sting
All causes of chronic urticaria
Chronic Disease (episodes continue for ,6 weeks)
Idiopathic
Physical urticarias
 Cold
 Pressure
 Dermatographism
 Cholinergic (exercise, hot shower, emotional stress)
 Solar
 Vibratory
Hereditary C1 inhibitor deficiency
Acquired angioedema (lymphoma, adenocarcinoma, chronic
 lymphocytic leukemia)
Causes of acute urticaria

Table 181.1. Common Causes of Urticaria and Angioderma

WORKUP

The history is the most useful component of the evaluation and yields clues to an underlying cause or precipitant far more often than does the physical examination or laboratory studies. Nonetheless, the latter are essential to identify urticarial vasculitis and should not be overlooked when individual lesions persist for more than 24 hours.

History. A good description of the urticarial response is essential. Is the predominant reaction one of angioedema (suggesting possible C1 INH deficiency) or of urticaria? Do individual wheals persist for more than 24 hours (suggesting urticarial vasculitis, especially if accompanied by purpura and pigmentation), or do they clear quickly? Inquiry into illnesses, medications, foods, activities, and exposures associated with urticaria or angioedema (Table 181.1) is essential to uncovering the proximate cause, especially in cases of acute urticarial disease. Commonly overlooked is nonprescription use of NSAIDs and aspirin. Latex allergy should be considered in health care workers who present with urticaria. When a food allergy is suspected, the patient should be encouraged to keep a food diary. One should not overlook agents that may be entering through the conjunctivae, nasal mucosa, rectum, or vaginal area. Although allergy to milk and beer antigens is rare in adults, penicillin antigen may be present in dairy products and yeast in beer, factors that can precipitate urticaria in sensitized patients. It is important to determine whether exposure to pressure, cold, light, heat, or exercise precipitates lesions. A travel history may suggest a parasitic infestation. Inquiry into agents and factors that might modulate the intensity of an urticarial reaction (e.g., alcohol, NSAIDs, heat, humidity, occlusive clothing, psychological stress) can provide clinically useful information. A positive family history of angioedema is helpful, but a negative family history does not rule out C1 INH deficiency.

The review of systems should be used to check for systemic illnesses, infections, and malignancies that might present with urticaria and angioedema. Patients should be asked about night sweats, fatigue, weight loss, lymphadenopathy, recurrent peptic ulcer disease, jaundice, easy bruising, cold intolerance, dry skin, thyroid enlargement, dysuria, vaginal or sinus discharge, and pain in the teeth, joints, or sinuses.

Physical Examination. The severity of the condition and occasionally its cause are revealed by the physical examination. Dermatographism is associated with linear wheals. Small lesions with erythematous flares are typical of cholinergic urticaria. Periorbital or perioral swelling is suggestive of angioedema. Lesions that persist for more than 24 hours and are accompanied by purpura and hyperpigmentation are characteristic of urticarial vasculitis. Careful examination of the ears, pharynx, sinuses, and teeth may help uncover a focal infection. One should check for lymphadenopathy and hepatosplenomegaly, suggestive of an underlying lymphoma or hepatocellular disease. The joints are noted for swelling, effusion, and warmth, suggestive of active rheumatoid disease.

Laboratory Studies. It is usually unproductive to attempt diagnosis through the performance of an extensive panel of laboratory tests in the absence of suggestive historical and physical examination evidence. Initial studies can be limited to a *complete blood cell count* and *differential* (for infection and myeloproliferative disease) and a *sedimentation rate* (for active connective tissue disease). *Skin biopsy* is usually not necessary to diagnose urticaria but should be considered if vasculitis is suspected. The sample is taken at the margin of a lesion to include normal and involved skin. Measurement of the serum *C4 complement* level is indicated in the patient with suspected C1 INH deficiency. Checking for *antithyroid antibodies* and *thyroid-stimulating hormone* levels may provide a clue to an autoimmune pathophysiology. For the patient with clinically suspected urticarial vasculitis, an *antinuclear antibody* determination and a *urinalysis* might be ordered if the sedimentation rate is high, suggesting active disease. For the patient with idiopathic urticaria and recurrent peptic ulcer disease, *serology* for *Helicobacter* or a related test should be obtained (see Chapter 68).

A number of tests are of limited or no value. *Skin testing* is of minimal value, and the costly IgE *radioallergosorbent test* (RAST) rarely reveals a cause in elusive cases. Mean serum levels of *IgE* are usually normal. Radiologic examinations are indicated only if clinical evidence suggests a focal infection or malignancy. *Stool examination* for ova and parasites is appropriate only if recent diarrheal illness or travel to endemic areas has taken place or if peripheral eosinophilia is noted. *"Cytotoxic food allergy"* testing has no scientific validity and should be firmly discouraged.

Provocative tests can help ascertain the precipitants of physical urticarias. Placing an ice cube on the skin may induce cold urticaria, and stroking can reveal dermatographism. Cholinergic urticaria may be revealed by an intradermal injection of methacholine (0.1 mL of a 1:500 dilution). Pressure urticaria may be elicited by pressing at a right angle to the skin surface and noting whether a red swelling appears at the site after a latent period of 30 minutes to 4 hours. Placebo-controlled challenge testing for reactivity to food additives is sometimes performed by allergists, who administer capsules containing the additives in addition to placebo capsules and monitor symptoms. Such testing is not appropriate in persons with a history of asthma or airway involvement.

Therapeutic trials may be helpful in identifying a cause. An elimination diet that consists of lamb, rice, string beans, fresh peas, tea, and rye crackers excludes most common food allergens. A more limited approach would be to eliminate dairy products, beer, nuts, shellfish, berries, and food additives. It is often useful to stop all drugs or change preparations or brands to eliminate tartrazine dyes or the peculiar additives of particular toothpastes or cosmetics.

Chronic urticaria poses significant diagnostic and management challenges. Hospitalization for control of diet and observation is both expensive and low in diagnostic yield. A specific cause is identified in fewer than 10% of patients, and the idiopathic designation often applies even after extensive evaluation.

SYMPTOMATIC MANAGEMENT

The best treatment is identification and avoidance of etiologic agents, but in the many instances of chronic urticaria in which this is not possible, empiric measures for symptomatic relief are indicated. Even if an etiologic diagnosis has not been made, avoidance of substances that may aggravate symptoms (e.g., aspirin, NSAIDs, alcohol, angiotensin-converting enzyme inhibitors) should be part of any program. Half of patients with urticaria alone and 25% with associated angioedema are free of lesions within 1 year; however, 10% to 20% may experience episodes for more than 20 years.

Available Agents

Antihistamines provide excellent symptomatic control. The *histamine*$_1$ blockers, such as *hydroxyzine* (10 to 25 mg daily at bedtime) and *diphenhydramine* (25 to 50 mg daily at bedtime), have been the mainstay of antihistamine therapy. They are inexpensive and effective but have a sedating effect. The *nonsedating H$_1$-blockers* (e.g., 60 mg of fexofenadine every morning) are also effective and are better tolerated for daytime use. Disadvantages are their substantial cost and, with some H$_1$-blockers, drug–drug interactions (see Chapter 222). It is often best to use a nonsedating antihistamine during the dayand a more sedating agent at night. *Chlorpheniramine* and *diphenhydramine* are useful alternatives for nighttime use because they are available over the counter and are much less expensive; chlorpheniramine can be used in pregnancy.

In refractory cases, *H$_2$-blockers* (e.g., 400 mg of cimetidine three times daily) may improve control in combination with H$_1$-antihistamines. The rationale for the use of H$_2$-blockers is that 15% of the receptors in the cutaneous vasculature are H$_2$-receptors. *Doxepin*, a tricyclic antidepressant with H$_1$-blocker activity, has proved helpful in persons with urticaria complicated by anxiety or depression. Low doses (e.g., 25 mg twice daily or 25 mg daily at bedtime) may be useful. Doxepin should not be used concurrently with the H$_1$-blocker terfenadine.

Steroids and Other Drugs. For severe refractory cases, oral *glucocorticosteroids* are worth considering (see below), but they must be used with care if prescribed for more than 1 to 2 weeks (see Chapter 105). Some reports suggest that the b$_2$-agonist *terbutaline* in fairly high doses (1.25 mg three times daily) can decrease itching and the number of episodes, but others find little benefit, whether it is used alone or in combination with antihistamines. *Nifedipine*, a calcium channel blocker, can improve the clinical appearance of lesions by interfering with mast cell activity, but overall efficacy is not impressive. *Anabolic steroids* have been used with success in hereditary angioedema (see below).

Agents of No Proven Efficacy. *Empiric trials* of broad-spectrum *antibiotics* and *antifungal agents* have been advocated for the treatment of patients with idiopathic urticaria as a means of eliminating any occult infection, but there are no data to justify this hypothesis or their use. Specific treatment of infections such as sinusitis or vaginitis is appropriate only if infection is confirmed. *Topical preparations* of corticosteroids, antihistamines, and local anesthetics are expensive and without benefit in chronic urticaria.

Treatment Applications

Acute Attacks. Mild to moderate attacks usually respond well to a full program of oral antihistamines. Severe attacks complicated by angioedema are an indication for prompt administration of SQ aqueous *epinephrine* (0.3 mL of a 1:1,000 dilution). For severe acute urticaria uncomplicated by angioedema, a short course of systemic steroids (e.g., *prednisone* started at 40 mg/d and rapidly tapered to full cessation by 1 week) can help provide symptomatic relief but should not be a substitute for a careful etiologic evaluation.

Physical Urticaria. The physical urticarias are also treated with antihistamines. *Cyproheptadine* is an H$_1$-blocker that is particularly useful for aquagenic, cold-induced, and dermatographic urticaria. Topical *capsaicin* has been tried in patients with cold-induced and localized heat-induced urticaria; results are variable. Antihistamines have been useful in vibratory physical urticaria. Exercise-induced urticaria can be treated by avoiding vigorous exercise, and it is important for the patient not to exercise after eating or when taking aspirin or NSAIDs.

Chronic and Refractory Urticaria. Controlling chronic urticaria requires empiricism and careful follow-up. One begins with an H$_1$-blocker, usually a nonsedating agent. If this fails, an H$_2$-blocker, such as cimetidine, is added. If the patient fails to respond, doxepin is substituted. In severe cases, a brief course of *systemic corticosteroids* (e.g., 20 to 40 mg of prednisone daily), with rapid taper after 10 to 14 days and a switch to alternate-day therapy with ultimate elimination by 3 to 4 weeks, is reasonable. Longer-term systemic steroid therapy usually fails to provide adequate control and is associated with adverse effects more serious than the condition for which it is being taken (see Chapter 105). Patients with chronic refractory disease who manifest antithyroid antibodies should be given a trial of exogenous *thyroid hormone* sufficient to lower the level of thyroid-stimulating hormone. The patient with idiopathic urticaria and positive *Helicobacter* serology is a reasonable candidate for consideration of *antibiotic therapy*, but antibiotics should not be administered unless evidence of active infection is present (see Chapter 68).

Hereditary Angioedema. An acute attack that threatens airway obstruction should be treated with SQ *epinephrine* (0.3 mL of a 1:1,000 dilution). Patients with known angioedema should carry an epinephrine self-administration kit. The best treatment is prevention of attacks. Synthetic *anabolic steroids* (e.g., danazol, stanozolol) have been used in cases of frequent or severe attacks. They appear to induce synthesis of normally functioning C1 esterase inhibitor. Periodic monitoring of the C1 esterase inhibitor level and of liver function is required. A purified C1 INH is under development for prophylaxis and treatment of acute attacks.

INDICATIONS FOR REFERRAL AND ADMISSION

The management of urticaria can be frustrating, and it is often useful both for physician and patient to enlist the aid of a specialist. Allergists can help evaluate patients with repeated eruptions possibly caused by food allergies that can be detected on testing, although the probability of food allergy being the cause of chronic urticaria is low. They may also perform penicillin skin testing, particularly with minor determinants. Their experience in seeing a large number of patients with urticaria helps provides comfort and reassurance to the concerned patient. The patient with suspected urticarial vasculitis should be referred to the rheumatologist or dermatologist for skin biopsy and immunohistologic staining of the sample.

Admission for patients with acute angioedema complicated by airway symptoms or gastrointestinal symptoms may be necessary briefly for respiratory support and observation. Hospitalizations that are sometimes advocated for elimination diets are far too costly in a climate of cost containment.

PATIENT EDUCATION

It is important to educate the patient in advance of the workup that a cause is usually not found. Emphasize the variable natural history of hives and the high probability that the lesions will disappear spontaneously. Prepare the patient for the likelihood that urticaria will recur. Instruct patients to avoid exacerbating factors (e.g., aspirin, NSAIDs, heat, exertion, alcoholicbeverages). Specific advice, such as the avoidance of swimming in cold water for patients with cold urticaria, can be life-saving. Reassure the patient that the medical workup will exclude serious and treatable diseases and that many options are available to shorten the process and alleviate symptoms. Eliminating unrealistic expectations can prevent the disappointment that may follow a negative workup. It is important to emphasize the overall good prognosis and the high probability that remission will occur, although it may be delayed.

CHAPTER 182 APPROACH TO THE PATIENT WITH HAIR LOSS

WILLIAM V. R. SHELLOW

Alopecia may be described as the lack of hair in areas where it normally grows. The most noticeable area in which alopecia develops is the scalp, but a loss of body hair may also occur. Patients may seek medical care for what is perceived as excessive hair loss even when alopecia is not present. Whether the problem is genetically induced male-pattern baldness or alopecia resulting from systemic illness, the primary care physician may be the first one to whom the problem is presented and must be able to offer the patient a rational approach to diagnosis and treatment.

PATHOPHYSIOLOGY AND CLINICAL PRESENTATION

Normal Hair Growth

Hair is a product of keratinocytes in the hair bulb. The hair shaft is made of hard keratin. Synthesis results from mitoses of cells within the hair matrix. The growth of hair is cyclical, the length of the cycle varying with the location. Scalp hair grows from 3 to 10 years, involutes over 3 months, and rests for another 3 months. In healthy young persons, about 85% to 90% of all scalp hairs are in anagen, the phase of active growth. Most of the remainder are in telogen, the resting phase of the hair cycle. The number of hairs on the scalp is estimated to be 100,000. If 10% to 15% are assumed to be in the telogen phase, then an average daily loss of 100 hairs in telogen is expected.

Hairs that grow for long periods and rest briefly are the most susceptible to interruptions of the growth cycle, and variations in the ratio of growth phase to resting phase are most noticeable. The longer the growth period, the longer the hair. Scalp hair grows at the rate of approximately 0.25 mm daily, but various factors can affect the rate.

Hair Loss

The primary pathogenic mechanisms of hair loss are destruction of the hair matrix by physical agents and by infectious or immunologically mediated inflammation. Hair loss may occur when hair growth slows secondary to metabolic diseases or the administration of antimetabolites or other drugs. Physiologic alterations may also produce hair loss by altering the relation between the growing and resting phases of hair follicles. During pregnancy, fewer hairs are shed, so that fewer telogen hairs are produced. After parturition, the percentage of telogen hairs increases, and hair is lost. The process is diffuse and short-lived. This alteration in the ratio of resting hairs to the total may also develop secondary to pharmacologic changes induced by oral contraceptives. Destructive pathogenic mechanisms often produce scarring alopecia, whereas systemic illnesses and drugs usually result in nonscarring alopecia.

Alopecia can be divided into two categories, *scarring (cicatricial)* and *nonscarring (noncicatricial).* In the latter, the hair follicles are retained and the process is potentially reversible. In the scarring type, follicles are destroyed and hair never regrows. A few conditions that begin as nonscarring alopecia may later develop into scarring alopecia as a result of chronicity.

Scarring Alopecia. An inflammatory response to injury is often present. Forms of physical trauma, such as burns, radiation, injury, and chronic traction, are commonly responsible. Traction alopecia usually results from braiding or the use of tight hair rollers. The pattern of hair loss depends on the styling. The process is initially reversible but progresses to a scarringphase with chronicity. The use of hot combs in combination with petrolatum to straighten hair may result in inflammation with consequent fibrosis and hair loss. Infections—whether bacterial (resulting in deep cellulitis), fungal (*Trichophyton schoenleinii*), or viral (e.g., recurrent herpes simplex or herpes zoster)—produce inflammatory change and alopecia. Dermatologic processes such as discoid lupus erythematosus, scleroderma, lichen planus, cutaneous neoplasms, and granulomas may produce scarring alopecia, as can factitious conditions and neurotic excoriations.

Nonscarring Alopecia. Most often, alopecia is nonscarring, with male- and female-pattern baldness accounting for most cases. *Male-pattern baldness* (androgenetic alopecia) is symmetric, usually beginning in the frontoparietal scalp. Its development is related to age, genetic predisposition, and the presence of androgenic hormones. The inheritance is probably dominant, with incomplete penetrance. The process is permanent, with pigmented scalp hairs replaced by fine, unpigmented vellus hairs.

The presence of male-pattern hair loss in a female patient should provoke concern about *androgen excess*, manifested by hirsutism in mild cases and virilization in more serious cases. Polycystic ovary disease and hyperprolactinemia are common causes of mild androgen excess and hirsutism. Frank virilization occurs with androgen-producing ovarian and adrenal tumors (see Chapter 98). Dihydrotestosterone inhibits the growth of scalp hair while it stimulates the growth of facial hair and promotes a male pattern of pubic hair growth. Laboratory investigation reveals increased levels of free testosterone, sulfated dehydroepiandrosterone (DHEA), or both.

The mechanisms of *female-pattern baldness* are similar to those of male-pattern baldness, but female-pattern baldness is more diffuse; usually, the central and frontal areas are affected, without complete baldness. Age, family tendency, and androgenic hormones are important factors. *Postpartum alopecia* resolves within 18 months, but about half of women feel they have less hair after childbirth than they did before pregnancy.

Nonscarring alopecia often is associated with systemic disease, a metabolic abnormality, or the use of certain medications. *Alopecia areata*, a condition of unknown cause in which hair is rapidly lost, usually in circular patterns, is probably the second most common form of nonscarring alopecia. *Alopecia totalis* is the loss of all scalp hair, and in *alopecia universalis*, facial and body hair are lost as well. The course of alopecia areata is unpredictable. Some persons have one episode, in which the development of one or several bald spots is followed by spontaneous regrowth. In others, new areas of baldness may develop, and they become totally bald. Onset before puberty is associated with a poorer prognosis. Most investigators believe that an autoimmune mechanism is involved and that an association with other autoimmune diseases exists.

Alopecia may follow *infectious diseases* that produce a high, persistent fever, such as typhoid or pneumonia. Secondary syphilis, superficial folliculitis, and tinea capitis also may produce nonscarring alopecia. Commonly used *medications* that can cause alopecia include b-blockers, tricyclic antidepressants, anticonvulsants, warfarin anticoagulants, allopurinol, antithyroid drugs, quinine, verapamil, indomethacin, sulfasalazine, haloperidol, and vitamin A in excessive doses. Antineoplastic agents such as 5-fluorouracil, paclitaxel, cyclophosphamide, and methotrexate predictably produce hair loss. Oral contraceptives, hyperandrogenism, and pregnancy are known to interfere with the relation between resting and growing hairs and cause hair loss.

Diffuse hair thinning may occur in *thyroid disease* and *iron deficiency*. Less commonly, hypopituitarism and parathyroid disease produce hair loss. Alopecia is a manifestation of *connective tissue diseases*, notably systemic lupus erythematosus and dermatomyositis. Occasionally, hair loss is self-induced, a condition known as *trichotillomania*. Such patients may not be aware that they are plucking hairs, and the condition may indicate significant psychiatric disturbance.

Hair Breakage. Hair loss must be differentiated from hair breakage, which results from physical or chemical stress to the shaft. The term *proximal trichorrhexis* is sometimes used to describe hair breakage within the first centimeter from the scalp, whereas breakage beyond this point is called *distal trichorrhexis*. Hair straightening can cause proximal trichorrhexis. Patients often recognize distal breakage as split ends; such breakage may be accelerated by exposure to sunshine or swimming in chlorinated pools.

DIFFERENTIAL DIAGNOSIS

(See Table 182.1.)

Nonscarring alopecia	Antidepressants
Androgenic	Anticonvulsants
Male pattern	Anticoagulants
Female pattern	Allopurinol, probenecid
Alopecia areata	β-Blockers
Post febrile infection	Quinine
Folliculitis (mild)	High-dose vitamin A,
Tinea capitis (ectothrix)	isotretinoin
Hypothyroidism	Oral contraceptives
Iron deficiency	Discontinuation of
Systemic lupus erythematosus	corticosteroids
Syphilis	Psychiatric
Medications	Trichotillomania
Antineoplastics	Telogen effluvium
Antimetabolites	Crash diets
Propylthiouracil	Post pregnancy
Scarring alopecia	
Physical trauma	Discoid lupus erythematosus
Burns	Morphea
Radiation	Lichen planopilaris
Chronic traction	Pseudopelade
Infection	Neoplasms
Bacterial folliculitis (severe)	Granulomatous disease
Fungal (endothrix)	Factitial

Table 182.1. Differential Diagnosis of Hair Loss

WORKUP

History. The history should begin by identifying the nature of the problem. Is the patient troubled by a specific area of hair loss or by generalized hair loss? Are symptoms of a precipitating illness, such as hypothyroidism, systemic lupus, granulomatous disease, iron deficiency, or febrile infection, present? Is there a history of physical trauma (e.g., pulling the hair; use ofcurlers, bleaches, permanent wave lotions, straightening lotions, hot combs)? It is helpful to review the family history for male- or female-pattern baldness and to review the medication history for antimetabolites, anticonvulsants, anticoagulants, b-blockers, colchicine, antithyroid drugs, androgens, oral contraceptives, and excessive amounts of isotretinoin (Accutane) and vitamin A. Other precipitants worth noting include recent pregnancy, strenuous dieting, and the presence of skin conditions such as folliculitis and tinea.

Physical Examination. The pattern of hair loss is noted. Is it localized or diffuse? Is an androgenetic pattern present? It is essential to differentiate scarring from nonscarring alopecia. The scalp is examined carefully for areas of reduced hair growth, hair loss, and scarring. The presence of short, broken hairs suggests pulling of the hair. One examines the surrounding areas for evidence of inflammation, cellulitis, folliculitis, and fungal infection. If available, a Wood's light will produce a fluorescent glow in an area infected by some fungal organisms. Any area of inflammation should be scraped for microscopic examination (see Chapter 191) and culture.

Hair loss in women is especially troubling. It is often helpful to obtain objective evidence of hair loss to differentiate perceived from actual problems. One method is to have the patient collect the hairs lost each day in separate envelopes and count the total. Fewer than 100 hairs per day is within normal limits. Also helpful in making the differentiation between normal and excessive hair loss is the "pluck" or "pull" test. Twenty-five to 30 hairs should be grasped and extracted from the scalp by hand or with an instrument such as a hemostat. In the normal scalp, fewer than five or six telogen hairs are found.

If the circular areas characteristic of alopecia areata are seen, applying light traction to the hairs at the edge of the bald area will indicate whether disease is active at that location. If hairs come out with ease, then extension of the alopecic area is to be expected.

A *clip test* can be performed by grasping 25 to 30 hairs between the thumb and forefinger at the scalp. This sample is cut with scissors, and the portion of the hair more than 1 cm above the fingers is cut and discarded. The remaining sample is placed on a glass slide, and mounting medium and a coverslip are added. Hair shaft diameters are evaluated under the scanning objective of a microscope. In patients with resolving telogen effluvium, more than 10% of the hairs examined will have a small diameter.

Some dermatologists perform *telogen counts* by removing 100 hairs and counting how many are in the telogen phase. Telogen hair is identified by the presence of a terminal club on the hair shaft. With this procedure, the examiner can distinguish between conditions resulting from telogen excess and those resulting from broken hairs, but it may be too time-consuming to be useful to the primary physician and best reserved for the dermatologist experienced in its performance.

Evidence of systemic illness should be sought, including signs of hypothyroidism (see Chapter 104), lupus (see Chapter 146), iron deficiency (see Chapter 79), and sarcoidosis (see Chapter 51). One checks the woman with male-pattern hair loss for signs of hirsutism and virilization (see Chapter 98). It is useful to examine the nails; the presence of Beau's lines may correlate with a systemic process affecting both nail and hair growth.

Laboratory Studies. A biopsy may be helpful, particularly in cases of scarring alopecia with suspected inflammation, both to add histologic evidence and to identify areas of activity that might respond to antiinflammatory therapy. Whether to perform laboratory tests to detect systemic disease (e.g., complete blood cell count; determination of serum iron, ferritin, total iron binding capacity, thyroid-stimulating hormone, thyroxine, antinuclear antibody, androgenic hormones) depends on the history and physical findings.

PRINCIPLES OF THERAPY

The primary physician can provide the patient with reassurance, advice, and occasionally specific therapy. The treatment of alopecia depends on the identification of a probable cause. Patients with a perception of excessive hair loss that is not substantiated should be reassured, as should women with hair loss following pregnancy. Drugs associated with hair loss should be discontinued if possible and alternatives sought. Scalp infection, either bacterial or fungal, requires specific treatment (see Chapter 190 and Chapter 191), as does any underlying disease. Hair loss often resolves with successful etiologic therapy. The hair loss associated with chemotherapy is usually self-limited; it is best managed by temporarily wearing a wig or a scarf (see Chapter 88).

Symptomatic Measures

In the vast majority of cases of hair loss, the cause is either alopecia areata or androgenetic baldness, and treatment is symptomatic for those troubled by the cosmetic effects.

Alopecia Areata is often self-limited, but if the condition is severe, it may be worthwhile to consider specific medical therapy, which should be undertaken only by a dermatologist or physician skilled in its application. A traditional treatment for stimulating new hair growth is irritation with *phenol* or *ultraviolet light*. The use of *topical fluorinated corticosteroids* under occlusion may be helpful, and this may be tried by the primary physician. A superpotent corticosteroid such as clobetasol solution can be used without occlusion. *Injection* of *triamcinolone acetonide* into the scalp may be considered if topical therapy fails. When prepared as a dilute solution for injection (5 mg/mL), it is less likely to cause dermal atrophy than are other injected steroids. Small volumes are used, and multiple injections may be necessary to cover a large area. *Systemic corticosteroids* have on occasion been helpful, but their effectiveness is often lost when the drugs are discontinued, and the risks of long-term therapy (see Chapter 105) outweigh the benefits. They should be used only under exceptional circumstances and only by a dermatologist experienced in treating patients with hair problems.

Approaches under investigation include the use of agents that induce an immune-mediated hypersensitivity response, which stimulates regrowth of hair. The response rate is approximately 70%, but treatment often must be repeated, and some of the agents used are potentially mutagenic. *Anthralin*, used in the management of psoriasis, has also been used to stimulate hair growth, but it must be applied nightly and removed in the morning. Therapy with *psoralen* plus *ultraviolet A light* (PUVA) therapy has also been successful to a degree.

Despite the substantial interest in various therapies and the literature extolling them, no approach can be judged effective enough to recommend. Many experienced clinicians believe that treatment merely accelerates resolution in the approximately 50% of patients with alopecia areata in whom hair would spontaneously regrow

anyway. Some argue that except in a study situation, watchful waiting is the safest and most cost-effective approach.

Male-pattern Baldness compromises the self-image and self-confidence of many young men.

Available treatments include oral *finasteride* (Propecia) and topical *minoxidil*.

Finasteride blocks the conversion of testosterone to its metabolite dihydrotestosterone, a potent androgen. In men ages 18 to 41 years, careful studies have shown that after 1 year, men treated with finasteride (1 mg daily) have higher vertex hair counts, which are maintained for up to 24 months. Fifty percent of treated men find the appearance of their hair improved. A small number of adverse events are seen, but not much more than in placebo-treated patients. These include loss of libido, erectile dysfunction, or a decrease in ejaculatory volume (occurring in about 2%). Serum levels of prostate-specific antigen are reduced by 40% to 50%, so that the values obtained must be doubled when being interpreted in prostate cancer screening. The ratio of bound to unbound (percentage of free) prostate-specific antigen is not affected by finasteride.

Minoxidil. A topical nonprescription 5% solution of the antihypertensive *minoxidil* (Rogaine) works best in younger men (<40 years) who have been bald for less than 10 years and have a balding area on the vertex that is smaller than 4 inches in diameter. The patient needs to understand that 6 months of daily treatment may be necessary before hair growth becomes apparent and that new hair persists only as long as the twice-daily applications are continued. New growth may be lost within 2 to 6 months of stopping treatment. The only side effect is local irritation, although patients with a low systolic pressure may experience postural hypotension with dizziness.

Many men use both finasteride and topical minoxidil. Both drugs may to some extent prevent further hair loss. Most patients feel that progression of their alopecia is halted by regular use of the medications. In one long-term study, hair growth tended to peak at 1 year, with a slow decline in regrowth subsequently. After 4 1/2 to 5 years of use, nonvellus hairs were maintained above the baseline counts.

Spironolactone and Dexamethasone. Women with male-pattern hair loss may have associated hirsutism. This combination suggests androgen excess and should be treated etiologically (see Chapter 98). Symptomatically, androgen excess can be treated with spironolactone (75 to 200 mg/d for at least 6 months) or dexamethasone (0.125 to 0.250 mg at bedtime for at least 6 months). The hirsutism may improve before the alopecia does.

Female-pattern Hair Loss is an increasingly common complaint, with 40% of women experiencing cosmetically significant hair loss by the sixth decade. Women whose hair is thinning, even though no baldness is apparent to the examining physician, fear that they will become bald like men with common baldness. This rarely happens, and they can be reassured concerning the prognosis. Although initially approved for use only in men, low-strength (2%) *minoxidil* can be prescribed for women, one third of whom also experience androgenetic alopecia. Some women initially experience increased hair loss, which makes them fearful of continuing minoxidil, but decreased shedding and stimulation of new hair growth within 12 months can be expected. Women should not use the 5% strength of minoxidil because hirsutism may develop on the face. Women of childbearing age must not take *finasteride*, and pregnant women should not even handle crushed or broken tablets because of the risk for development of congenital genitourinary abnormalities in male offspring. This drug may be shown safe for use in postmenopausal women, but currently it is not to be prescribed for them either.

PATIENT EDUCATION

Education can be the most important part of the primary physician's management of the patient with alopecia. Once the diagnosis is established and serious diseases are excluded, the patient can be reassured. Patients are often concerned that the hair loss will progress, and the most useful information that can be provided is the actual likelihood of progressive or total hair loss. Even men with genetic baldness are often reassured to know that they do not have a systemic disease. Success in the management of alopecia often depends on the physician's ability to help patients come to terms with their hair loss.

Hair Care. Advice on hair care is appreciated. Patients should be advised to avoid alkaline pH shampoos and excessive toweling after washing the hair. Use of a conditioner may be helpful. Combing is less injurious than brushing. If one must brush, it is useful to disentangle the hair from the brush gently and to use a brush with natural bristles or a nylon brush with rounded edges. Patients should avoid bleaching, permanent waving, straightening, use of hot combs, and excessive exposure to the sun.

Hair Weaving and Transplants. Patients are often well aware of the option of wigs but may ask the primary physician about such issues as hair weaving or hair transplants. Weaving is a relatively safe procedure performed by nonphysicians. It is successful but must be repeated periodically and so becomes expensive and a nuisance. Hair transplants are expensive and have varying rate of success. The procedure is painful and is usually not covered by insurance. Patients with coarse, dark hair are the best candidates for hair transplants. Implants of artificial hair should be discouraged because they usually fall out or elicit a chronic foreign body reaction.

CHAPTER 183 DISTURBANCES OF SKIN HYDRATION: DRY SKIN AND EXCESSIVE SWEATING

WILLIAM V. R. SHELLOW

Part 1: Management of Dry Skin

Dry skin, or simple xerosis, is commonly seen during the winter months and occurs more often in the elderly. The most common clinical presentation is mild to moderate itching (see Chapter 178). A related condition is mild irritant dermatitis or chapping. This is seen particularly on the hands and face. Fingertip fissuring is another common problem during winter months. Severe chronic dry skin can become eczematous (*asteatotic eczema*). The primary physician should recognize dry skin and use simple measures and effective patient education to relieve the symptom.

PATHOPHYSIOLOGY AND CLINICAL PRESENTATION

Although the term "dry" implies that the basic defect is a lack of water, the cause of dry skin is not fully understood. No significant differences are found in the amounts of water present in the stratum corneum of "dry" and "normal" skin. The condition is more likely related to an increase in evaporative water loss through a defective stratum corneum.

The lipids that aid in the retention of water within the stratum corneum diminish with age. Xerosis in the elderly reflects a decrease in both the number and activity of sebaceous glands and a reduced rate of perspiration. Excessive use of soap, detergent, or disinfectants damages the stratum corneum and increases water loss up to 50 times the normal rate. Environmental factors such as low humidity, forced-air heat, or cold winter winds contribute to dryness. A familial tendency toward the development of dry skin remains unexplained. A variety of hygroscopic chemicals are known to retain water in the skin, including lactic acid, urea, and sodium pyrrolidine carboxylic acid. Collectively, these substances are referred to as moisturizing agents.

Dry skin is characterized by scaling and loss of suppleness and elasticity. The clinical appearance is one of fine scaling of the lower portions of the legs. In severe xerosis, loss of elasticity leads to cracking and fissuring, producing a superficial appearance of "cracked porcelain," referred to as *eczema craquelé*. Itching is a frequent concomitant and may lead to scratching and excoriation. Occasionally, dry skin is a consequence of hypovitaminosis A, drug reactions, hypothyroidism, or ichthyosis (vulgaris or acquired types).

PRINCIPLES OF THERAPY

After such systemic causes as hypothyroidism have been ruled out (see Chapter 104), treatment is largely symptomatic. The goals are to prevent loss of water and restore hydration. The modalities available include environmental manipulations, modifications in habits, and the judicious use of agents that hold water in the skin.

Preventive Measures. It is important to humidify the indoor environment, particularly during the winter months. In cold climates, humidification can be economically achieved by leaving pails of water near radiators, but if necessary, humidifiers may be installed into forced-air heating systems.

One should teach the patient to avoid very strong soaps and detergents, which dry the skin. Many toilet bars are essentially detergents and are extremely dehydrating. Substituting a well-oilated soap is recommended. Daily bathing may also be too drying, although a brief shower is much less drying than a bath. If baths are taken, adding a bath oil is helpful. It is also wise to avoid exposure to mild irritants, such as solvents, and to wool clothing.

Restoring Hydration. The treatment of preexisting dryness requires the addition of water and the application of hydrophobic agents. The physician should instruct patients to soak affected areas several minutes and then apply a hydrophobic substance. Basically, most of the lotions and creams contain combinations of *petrolatum* (Vaseline), *mineral oil, lanolin, glycerin*, and *water* in proprietary blends. Lotions contain more water, creams have more hydrophobic ingredients, and ointments have the smallest water content. Plain petrolatum is inexpensive and effective, but it is not as pleasant to use as many proprietary preparations. Patient with an allergy to wool should avoid lanolin-based emollients.

A wide variety of agents are available, and patients are subjected to multimedia advertising for many of these products. Lubriderm and Keri lotions are light and easily applied but less occlusive than emollient creams. Lac-Hydrin Five is a 5% ammonium lactate that is available over the counter. The prescription version of Lac-Hydrin, which contains a 12% concentration, is the most potent emollient available. Aquaphor and Eucerin are greasier than the above-mentioned lotions and creams. Crisco may be the most economical emollient. To avoid the greasiness felt with petrolatum-based preparations, newer formulations such as Moisturel use esterified alcohols as emollients.

The plethora of expensive skin creams do little to retain moisture in the skin. Hygroscopic agents such as urea, a-hydroxy acids, sorbitol, and glycerol have chemical properties that retain moisture in the skin. The apparent benefit may be as much a consequence of their ability to plasticize the stratum corneum as of any real increase in moisture. Most moisturizers contain propylene glycol. If a patient experiences irritation with use of a facial moisturizer, it may be the propylene glycol that is causing the problem.

In severe cases, or to achieve immediate results, *topical corticosteroids*, often applied with an occlusive dressing, produce effective and rapid results. The use of Lac-Hydrin or Epilyt may help to relieve fissured fingertips, but sometimes a medium-potency corticosteroid ointment is required.

Occasionally, oral *antipruritic agents*, such as the antihistamines, may be required for severe, generalized itching that results from xerosis (see Chapter 178). The physician should emphasize patient education to prevent recurrence.

THERAPEUTIC RECOMMENDATIONS

- Instruct the patient about environmental modifications to increase ambient humidity. Room temperature should be kept as low as is compatible with comfort.
- Caution the patient to avoid dehydrating soaps, solvents, or disinfectants. The skin should not be scrubbed.
- Encourage the use of bath oils and well-oilated soaps. The patient should soak in the tub for 1 to 10 minutes before the bath oil is added. Warn the patient about the potential for bath oil to cause slipping.
- Emollients should be used after showering or bathing. A variety of agents can be tried, beginning with the cheapest, to find one that is acceptable. The newer emollients that use esterified alcohols or emulsifiers are the most cosmetically acceptable and also the most costly.
- Lotions or creams that contain from 2% to 20% urea or from 5% to 12% ammonium lactate help hold water in the stratum corneum and may increase the plasticity of the skin.
- In the presence of eczematous change or for a patient who insists on rapid resolution, topical corticosteroid ointments with or without occlusion may be used.
- The most important aspect of management is patient education. The physician should reinforce the adjustments that prevent the development of dryness.

Part 2: Approach to Excessive Sweating

Excessive sweating (hyperhidrosis) is a common complaint, but it rarely signifies underlying pathology. Medical consultation may be sought because of abnormal wetness, a change in the pattern or amount of sweating, sweaty palms, stained clothing, or offensive odor. The amount that people sweat in response to the physiologic stimuli of heat, emotion, or eating varies greatly. The interaction of the person, the environment, and the emotions influences the amount of sweating. The primary physician must offer a scientific explanation and symptomatic management to the patient who complains of excessive sweating.

PATHOPHYSIOLOGY AND CLINICAL PRESENTATION

Sweating helps maintain temperature and fluid and electrolyte homeostasis, particularly under the environmental stresses of heat. There are two kinds of sweat glands, eccrine and apocrine. Cooling results from evaporation of eccrine sweat. Eccrine glands are concentrated on the palms and soles and are present on the face, axillae, and, to a lesser extent, the back and chest. Heat causes sweating on the face, upper chest, and back. Sweating of the palms and soles is a characteristic response to stress. Gustatory sweating occurs on the face, particularly on the upper lip, often following ingestion of spicy foods. The eccrine glands have no anatomic relation to other cutaneous appendages.

Sebaceous and apocrine glands are closely associated with hair follicles. The apocrine glands are concentrated in the axillae, areolae, groin, and perineum. Apocrine secretions consist of minuscule viscid and milky drops that produce odor after bacteria act on them.

Eccrine sweating is controlled by neural factors or a reflex. Thermal sweating is governed by the hypothalamus, and emotional sweating by the cerebral cortex. The innervation of eccrine glands is anatomically sympathetic, but for unexplained reasons, the sweat glands are under cholinergic control and are therefore mediated by acetylcholine rather than by epinephrine. Excess sweating may be induced by abnormalities of the autonomic nervous system. Autonomic overactivity of the sweat glands may occur without any identifiable cause. Sweating is associated with medical diseases that cause an increase in metabolic activity, so that heat must be dissipated. It is well-known that sweating occurs during defervescence, particularly at night. Although the eccrine glands are under cholinergic control, epinephrine stimulates excessive sweating.

Most cases of excess sweating are caused by exaggerated physiologic responses or functional variations of no pathologic consequence. Hyperhidrosis most commonly involves the palms, soles, or axillae. This may be a result of an increase in impulses from the central nervous system, or it may reflect underlying problems with the sweat glands. A relation to emotional stress is often noted, and the problem becomes disabling if it interferes with work or social interactions. Axillary hyperhidrosis is less common than palmar or plantar hyperhidrosis and makes frequent clothing changes necessary.

DIFFERENTIAL DIAGNOSIS

The most common cause of localized hyperhidrosis is the normal physiologic response to everyday stress. Menopause is the leading cause of generalized sweats. Of the pathologic causes, *fever* is the most common. Night sweats raise the possibility of underlying *infectious disease* and *malignancy*. Central neurologic injury from stroke or tumor may produce hyperhidrosis. *Peripheral neuropathy* involving the autonomic nerves is associated with excess sweating, as are such medical conditions as *thyrotoxicosis* and, uncommonly, *pheochromocytoma*. *Parkinson's disease* may lead to increases in both sweating and sebaceous gland activity. Various *drugs*, such as antipyretics, insulin, meperidine, emetics, alcohol, and pilocarpine, may induce sweating. Gustatory sweating, although uncommon, may be caused by compensatory diabetic neuropathy, damage to the seventh cranial nerve during parotid surgery, the rare Frey's syndrome, or injury to the sympathetic trunk following surgery.

WORKUP

History. Is the excess sweating restricted to the axillae, palms, and soles, indicative of a normal response to everyday events, or is it more generalized, suggesting an underlying medical condition? If sweating occurs primarily at night, then inquiry into fever, fatigue, adenopathy, cough, sputum production, and other symptoms of infection and malignancy should be sought (see Chapter 11). Generalized sweating should also trigger questions regarding hyperthyroidism (see Chapter 103) and menopause (see Chapter 118). Paroxysms of sweating are consistent with panic disorder (see Chapter 226) and pheochromocytoma (see Chapter 19). A careful drug history is needed, with a check for use of antipyretics, insulin, meperidine, emetics, alcohol, and pilocarpine. The physician should ask whether excess sweating began relatively recently and whether it can be correlated with stress.

Physical Examination. The degree of sweating and its location are noted. If fever or generalized night sweats are reported, careful examination for underlying infection and cancer is required (see Chapter 11). The patient should also be examined for signs of hyperthyroidism (see Chapter 103). The presence of increases in blood pressure should be noted because if the blood pressure is elevated in the setting of paroxysmal flushing and sweating, then pheochromocytoma should be considered. A careful neurologic examination is needed in patients suspected of central nervous system disease or peripheral autonomic neuropathy.

Laboratory Testing. No laboratory investigations are mandatory. Test selection is based entirely on the findings from history and physical examination. A screening "panscan" is of little use and is more likely to generate false-positive results than a true-positive one.

SYMPTOMATIC MANAGEMENT

Excessive sweating can interfere with employment and social intercourse. Many therapies have been used; several areeffective, but some are associated with undesirable side effects.

Topical Therapy. The most effective topical agent for use on the hands and the axillae is a 20% alcoholic solution of *aluminum chloride hexahydrate* (Drysol). A preparation of 6.25% aluminum tetrachloride (Xerac) is a less potent alternative. A clinical improvement in axillary hyperhidrosis may be seen after one to three consecutive treatments per week. Maintenance is usually possible with only one treatment per week after dryness has been achieved. Other topical therapies include

10% *formalin compresses*, which work well but can induce allergic sensitization. Buffered *glutaraldehyde* is effective but stains the skin. *Electrical current* may be used to block sweat glands temporarily. Topical iontophoresis with either tap water or an anticholinergic agent and aluminum chloride can reduce sweating of the palms. Tap water units can be used at home. Response rates are in excess of 80% and have been reported with an average remission of about 1 month.

Systemic Therapy. *Scopolamine* and other cholinergic agents decrease sweating but can cause central nervous system side effects and precipitate glaucoma or urinary obstruction in patients with underlying prostatic hypertrophy. *Phenoxybenzamine*, an adrenergic antagonist, has been reported to be successful in several cases of generalized hyperhidrosis.

Surgery. In rare instances of genuinely incapacitating hyperhidrosis, surgery is sometimes considered. Axillary hyperhidrosis may be cured with surgical *extirpation of the eccrine glands* in the axillae. Studies suggest that liposuction of the axillae may remove the sweat glands without altering the normal architecture. Palmar sweating may respond to *sympathectomy*, which can be performed endoscopically. This is a much less invasive procedure than it once was, thanks to newer instrumentation.

Botulinum A Neurotoxin (Botox) has been used successfully for both axillary and palmar hyperhidrosis. Intradermal injection of Botox results in long-term reduction in sweating in both locations. When Botox is injected into the palm, some patients experienced reversible minor weakness in their handgrip.

PATIENT EDUCATION

Patient education is crucial to the treatment of excess sweating. Providing the patient with a scientific explanation and a firm understanding of sweating is helpful in relieving anxiety. Patients with night sweats should record their temperature so that any significant febrile illness can be identified. The application of topical agents should be well explained and carefully carried out by patients. Surgical intervention for a problem as minor as hyperhidrosis requires the patient's understanding of the risks and benefits of such a procedure and the active involvement of the primary physician in helping the patient reach a decision.

THERAPEUTIC RECOMMENDATIONS

- Reassure the patient that excess sweating is not the consequence of a pathologic condition once medical causes have been ruled out.
- For axillary sweating, recommend frequent washing and changes of clothing.
- For excess sweating of the palms or the axillae, recommend a 20% alcoholic solution of aluminum chloride hexahydrate (Drysol). An effective alternative is 6.25% aluminum tetrachloride (Xerac). It should be applied at bedtime and covered with a plastic food wrap; polyethylene or vinyl gloves can be worn if the palms are affected. In the morning, the treated areas should be washed with soap and water. Prescribe 1-3 consecutive treatments per week. Once dryness has been achieved, maintenance with one treatment per week should suffice.
- Electrical current may be used to block sweat glands temporarily. Use of the device (Drionic) daily for 1 week may relieve sweating for up to 1 month.
- Intradermal injection of botulinum toxin is gaining in popularity and should also be considered as a relatively noninvasive therapy. Liposuction techniques may also be useful.
- If topical therapy and reassurance and less invasive approaches fail, sympathectomy performed via a thoracoscope may be considered, but only if the patient's hyperhidrosis is truly incapacitating. Referral should be made to a neurosurgeon or vascular surgeon for evaluation.

CHAPTER 184 APPROACH TO THE PATIENT WITH DERMATITIS

WILLIAM V. R. SHELLOW

Part 1: Atopic or Contact Dermatitis

The atopic and contact dermatitides (also referred to as " *eczema*") are frequently encountered in medical practice and may be acute or chronic. The acute form is characterized by erythema, edema, vesiculation, oozing, crusting, and scaling. The chronic stage manifests excoriation, thickening, hyperpigmentation, and often lichenification. These conditions are defined clinically by the observable changes in the skin, which reflect a common cutaneous reaction to a variety of pathogenetic stimuli. The clinical challenges for the primary care physician are to provide symptomatic relief and identify the underlying precipitant. These tasks can be difficult, often necessitating consultation with a dermatologist.

PATHOPHYSIOLOGY AND CLINICAL PRESENTATION

Pathophysiology

Atopic Dermatitis. The pathogenesis of atopic dermatitis remains incompletely understood, but a genetic predisposition and exposure to environmental irritants are believed to be important. Certain lymphocyte subpopulations show disordered metabolism. Underactivity of thy-1 lymphocytes that produce interferon-g and interleukin-2 (IL-2) seems to be linked with oversecretion of IL-4 and IL-5 by thy-2 lymphocytes. Elevations of immunoglobulin E are seen in 40% to 80% of patients. Two thirds of patients have family members with asthma, hay fever, or atopic dermatitis and often exhibit other forms of atopy themselves. Psychological stress may induce flares. Environmental factors also contribute. Certain fabrics, notably wool, may induce itching. Lesions are exacerbated by extremes of temperature and humidity. Defects in cell-mediated immunity have been noted, perhaps accounting for the observed increase in susceptibility to cutaneous viral infections.

Infection may also precipitate an attack. The skin of atopic persons is frequently colonized by *Staphylococcus aureus*, whereas fewer than 5% of those without atopy carry *S. aureus*. Other differences in atopic skin include the following: alteration in vascular activity, demonstrated by the formation of a white rather than a red line when the skin is stroked (white *dermatographism*); greater sweating response to acetylcholine than is seen in normal controls; deficiency of sebaceous gland lipids on the skin surface; lowered threshold for the release of histamine from basophils; and increased histamine levels in both skin and plasma.

Contact Dermatitis. The cause is exposure of the skin to a precipitant, which may have a purely irritant or an immunologic effect. Irritants penetrate and disrupt the stratum corneum, injuring the underlying epidermis and causing an inflammatory reaction. Irritant effects are universal and require no previous exposure. Strong acids, alkalis, detergents, and organic solvents are among the important irritants.

Immunologically mediated contact reactions occur only in patients who have been previously sensitized to an allergen. Important sensitizing antigens include nickel, rubber, topical anesthetics, neomycin, and the antigens of poison ivy, oak, and sumac.

Clinical Presentation

Atopic Dermatitis is characterized by intense itching that leads to scratching, eczematous change, and lichenification. In adults, the lesions characteristically involve the neck, wrists, area behind the ears, and antecubital and popliteal flexure areas. *Nummular eczema* is a variant characterized by pruritic, coin-shaped lesions on the external aspects of the extremities, the buttocks, and the posterior aspect of the trunk. The lesions may ooze, crust, and become purulent. The course varies; a few constant lesions may be present, or the number of lesions may increase gradually. The prognosis is good, with eventual clearing, although it may take years.

Contact Dermatitis can affect any area of the body. Linear patterns are pathognomonic, but almost any pattern may be seen. The distribution and location of the rash may provide clues to the irritant or allergen. Patch testing can help to identify the contactant.

Chronic Hand Dermatitis presents a diagnostic and therapeutic challenge that can frustrate the most experienced dermatologist. It may be irritant in nature (e.g., "housewives' hands"), pustular (chronic pustular eruption), or even vesicular (pompholyx or dyshidrosis). It can occur in the context of a fungal infection with "id" reaction, contact with household irritants, or dyshidrosis.

Lichen Simplex Chronicus. Regardless of the cause, chronic eczematous change may lead to *lichen simplex chronicus*. Itching can be intense, and the condition may be complicated by secondary infection. Lichen simplex chronicus can also result from localized neurodermatitis and present as a circumscribed plaque of thickened skin with increased markings, some scaling, and papulation. The occipital region is a common site. Lesions may also be seen on the wrists, thighs, or lower aspects of the legs. Women are more commonly affected. The prognosis is variable, but when scratching is stopped, lesions regress.

PRINCIPLES OF MANAGEMENT

The management of eczema embodies the fundamental principles of dermatologic therapy: precipitants should be eliminated, wet lesions dried, dry lesions hydrated, and inflammation treated with corticosteroids. Resistance to treatment shouldbe anticipated, and if basic management fails, referral to an experienced dermatologist should be prompt. A search for precipitating factors is mandatory. Topical corticosteroids are always required.

Use of Topical Corticosteroids

Topical steroids exert antiinflammatory, antipruritic, and antiproliferative effects. Available agents vary widely in potency, as measured by vasoconstriction assays (Table 184.1). The strongest steroid is 500 times more effective in blanching the skin than is the weakest. Often, differences in potency are found between generic products and those with brand names.

Table 184.1. Topical Corticosteroid Preparations [a]

Preparations and Their Selection. Preparations are categorized according to strength (Table 184.1). The halogenated preparations are the most potent, particularly those available in ointment formulation (see below). One starts with a sufficiently potent formulation to establish control of the eczematous process and then switches to a preparation with lower potency if maintenance therapy is indicated. Because of the large number of available preparations, it is recommended that the clinician become familiar with one agent from each category and make the choice on the basis of cost, cosmetic acceptability, and efficacy.

Topical hydrocortisone is available over the counter in strengths that cannot exceed 1%. Mild forms of dermatitis may respond, but the patient often selects the wrong vehicle—for example, an ointment when a lotion or cream would be better.

Formulations and Application. The vehicle affects potency and cosmetic acceptability. *Ointment* formulations are more potent than *creams* and are best reserved for thick, scaling lesions. Nongreasy cream formulations are quite acceptable cosmetically and easy to use on the trunk, extremities, or face. *Gels* can be used in hairy areas and on glabrous skin, although gels are somewhat drying when used on nonhairy skin. *Lotions* are usually creamy, whereas solutions have an alcohol or propylene glycol base, but in either case, lotions are more drying than creams. Specialized formulations include aerosol *sprays*, which are used on the scalp or to cover large areas of skin in acute dermatitis.

Occlusion of the skin enhances penetration, with up to 100 times more vasoconstriction observed if a polyethylene film is used over a given formulation than if no occlusion is used. Steroid-impregnated tape (Cordran tape) provides occlusion as well, but the convenience is rarely justified by the expense. Ointments are generally not occluded because folliculitis may develop.

Topical agents are normally applied two to four times daily, but retention of corticosteroid in the stratum corneum makes one or two applications per day sufficient. Because hydration of the epidermis is salutary for healing, concomitant use of a moisturizer is beneficial.

When a topical agent is prescribed, it is helpful to estimate the quantity of topical medication that will be required. A 10-day to 2-week course of therapy applied two to three times daily requires 30 g for the face, 45 g for feet or hands, 60 g for arms or legs, 60 to 90 g for the trunk, and 120 to 150 g for the whole body.

Adverse Effects. The potent halogenated corticosteroids are the most likely to cause *atrophy, telangiectasia, purpura, striae*, and an *acneiform eruption*. Restrictions are recommended for the use of certain superpotent corticosteroids—no more than 45 g of medication per week for no longer than 2 weeks. Suppression of the pituitary–adrenal axis, measured by plasma cortisol levels, may be demonstrable but is rarely clinically significant. Thin-skinned areas are especially susceptible to the development of atrophy. Less potent formulations should also be used on areas such as the face, dorsum of the hands, and the scrotum. Fluorinated steroids may cause *rosacea* if used on the face. Only low-potency ophthalmic preparations should be used around the eye. Low-potency products are also preferred in the groin and axillae because of the risk for the development of striae with more potent preparations. Purpura may be seen on the dorsal aspect of the forearms and hands after prolonged use of potent topical agents.

Treatment of Specific Dermatitides

Acute Eczematous Dermatitis benefits from drying with such measures as *Burow's solution* compresses. *Systemic corticosteroids* are sometimes used on a short-term basis for generalized or incapacitating dermatitis. Topical corticosteroids are used in milder cases. Secondary bacterial infection may require topical mupirocin ointment three times per day, or systemic antibiotics if the condition is extensive.

Chronic Eczematous Dermatitis usually is of an irritant nature and benefits from the identification and withdrawal of possible irritants. Detergents, gasoline, polishes, and other occupational and household products should be avoided. Frequent baths or showers, exposure to hot water, and the use of drying soaps should be reduced. Although systemic corticosteroids are contraindicated in chronic eczema, *topical steroids* are helpful and are often needed for prolonged periods. Some *coal tar* preparations are useful in the treatment of chronic dermatitis.

PATIENT EDUCATION AND INDICATIONS FOR REFERRAL

Patients must be instructed about the proper use of topical steroids. They need to be warned specifically to avoid contact with the eyes and eyelids (unless a low-dose ophthalmic preparation is prescribed) and to avoid using a potent topical formulation on the face. If a brief course of oral prednisone therapy is necessary, the patient should be given a written schedule to ensure proper tapering and cessation within 10 to 14 days. For those with atopic disease, advice on substances to avoid is greatly appreciated. Simple measures such as clipping fingernails and wearing cotton gloves can reduce secondary excoriation. Early identification and treatment of eczematous exacerbations helps facilitate treatment. Patients with chronic hand dermatitis need to know that prolonged treatment may be necessary.

Chronic hand dermatitis often proves refractory to the basic measures prescribed by the primary physician. Referral to a dermatologist for more detailed identification of precipitants and advancement of the treatment program may be helpful.

THERAPEUTIC RECOMMENDATIONS

- Identify and remove potential contacts, allergens, and irritants. Treat any skin dryness (see Chapter 183). Use of rubber gloves with cotton linings may be beneficial.
- Oozing lesions should be dried with Burow's solution compresses applied two to four times a day for 10 to 30 minutes, depending on the degree of vesiculation; colloidal oatmeal baths are indicated for more generalized lesions.
- Pruritus should be suppressed, if possible, with a topical antipruritic (e.g., Pramosone cream/lotion) or a systemic antihistamine (see Chapter 178).
- For acute dermatitis, begin with a fluorinated corticosteroid cream. Start with the highest-potency steroid preparation necessary and reduce potency as soon as the acute inflammation has been controlled. If the acute process is extensive and severe, begin oral prednisone at a starting dose of 1 mg/kg daily and taper rapidly to full cessation within 10 to 14 days. Alternatively, parenteral corticosteroid IM injections can be given as triamcinolone acetonide (40 mg/mL).
- For chronic lichenified eruptions, treat for prolonged periods with ointment formulations or, if unresponsive, steroid cream under occlusion. In refractory cases, intralesional injection of a diluted triamcinolone solution (2.0 to 3.0 mg/mL) by an experienced physician may be effective.
- Refer patients with refractory hand dermatitis to a dermatologist.

Part 2: Management of Seborrheic Dermatitis

Seborrheic dermatitis affects almost 5% of the adult population. It is a benign but chronic inflammatory skin disease that is constitutionally determined and has no single defined cause. Its high prevalence and incurability render it a therapeutic challenge. The primary physician must be capable of treating seborrheic dermatitis and educating the patient about chronicity and the need for continued management.

PATHOPHYSIOLOGY AND CLINICAL PRESENTATION

Pathogenesis. The cause of seborrheic dermatitis remains unknown. The anatomic localization correlates with areas of sebaceous gland concentration. The quantity or composition of sebum is not the main factor necessary for its development. Hormonal influences, fatigue, and anxiety may trigger or aggravate the condition. An etiologic relation between the yeast *Pityrosporum ovale* and seborrheic dermatitis has been postulated and is supported by the finding that topical ketoconazole or other antifungal agents produce improvement or resolution in some patients. Conversely, if the number of yeast organisms increases, the problem recurs.

Clinical Presentation. Common dandruff may be the mildest expression of this disease. Seborrheic dermatitis presents as scaly patches that are occasionally slightly papular, surrounded by minimal to moderate erythema. The borders of the lesions are ill defined, and the scales may be greasy and appear yellow. The lesion is usually asymptomatic, but pruritus may occur. More extensive disease involves the forehead at the margin of the hair, eyebrows, nasal folds, and the retroauricular and presternal area. In more severe cases, intertriginous areas, the external ear canal, and the umbilicus are involved. In these areas, erythema and exudation predominate, sometimes progressing to chronic dermatitis with scaling. The scalp is most often involved, and the condition is differentiated from common dandruff by its association with erythema. At the extreme end of the spectrum, total body erythroderma may be seen. Seborrheic dermatitis can occur at any age but is most common during infancy and after the second decade of life, with the highest prevalence in the fourth and fifth decades.

Seborrheic dermatitis is associated with several conditions, such as Parkinson's disease, phenylketonuria, prior cardiac failure, zinc deficiency, and epilepsy. Cutaneous diseases such as acne vulgaris, rosacea, and psoriasis may be associated with it. Florid manifestations of seborrhea may be an early cutaneous indicator of HIV infection. The dermatitis in such patients can be very extensive and resistant to therapy.

The differential diagnosis of seborrheic dermatitis includes psoriasis vulgaris (sebopsoriasis), atopic dermatitis, contact dermatitis of the face, tinea capitis, and candidiasis.

PRINCIPLES OF MANAGEMENT

As noted earlier, the condition is chronic and persistent. The approach to treatment has evolved with the growing realization of the role of *P. ovale* in pathogenesis. Previously, treatment was strictly symptomatic, directed at removing scale, reducing oiliness and redness, and controlling itching. Currently, the approach is somewhat more etiologic and includes reducing the yeast count on the skin. Therapy is guided by severity, anatomic location, and relative degree of scale, erythema, and oiliness.

Ketoconazole (Nizoral) has proved to be very useful for topical use. It has both fungistatic and fungicidal action, depending on the concentration used. Its 3- to 9-day residual effect between applications is an added advantage. Cream and shampoo formulations are available. For mild to moderate facial or chest involvement, 2% ketoconazole cream applied to the affected areas twice a day until clearing is noted often suffices. Indefinite maintenance therapy may be required once or twice weekly. Although effective, this therapy is expensive, especially if prolonged use is required.

Shampoos to Control Scaling. Scaling can be prominent in cases of scalp involvement, and it responds well to shampoo formulations. The regular use of an over-the-counter dandruff or antiseborrheic shampoo is often sufficient. To be effective, the shampoos should generate good detergent action and be allowed to remain in contact with the scalp for at least 5 to 7 minutes. Commercially available shampoos to combat seborrhea may contain *selenium sulfide, zinc pyrithione, tar, salicylic acid*, and/or *sulfur*. Most preparations contain multiple agents but have one predominant active ingredient. Zinc pyrithione (Danex, DHS Zinc, Head & Shoulders, Sebulon, Zincon, and ZNP bar shampoos) and selenium sulfide (Selsun Blue and prescription Exsel and Selsun shampoos) have been classified as keratolytic agents. Their mode of action also appears to be fungicidal and cytostatic. The combination of sulfur and salicylic acid (Sebulex, Ionil, and Vanseb shampoos) has keratolytic, mild antifungal, and antiseptic effects. Coal tar is the prominent ingredient in Sebutone, Pentrax, T/Gel, and Zetar shampoos, which must be used cautiously, if at all, by people with blond or light gray hair because they can change the color of the hair.

Patients should be given a list of recommended antiseborrheic agents as a guide and advised to find one suitable to their preferences for lather, odor, and efficacy. Many patients find that a shampoo works for a period, then becomes less effective, and a new product must be chosen.

For patients with resistant seborrheic dermatitis who have tried many over-the-counter shampoos before reaching the physician, a prescription shampoo may be of benefit: 2.5% selenium sulfide shampoo (Exsel or Selsun), chloroxine shampoo (Capitrol), or 2% ketoconazole shampoo (Nizoral) may be prescribed. Heavy crusts may be softened with keratolytic lotions (Sebizon, Sebucare) or oil-based agents (DermaSmoothe F/S liquid, P & S liquid) before the hair is washed.

Topical Corticosteroids. Significant erythema requires use of a topical corticosteroid preparation. In hairy areas, a lotion, spray, or gel may be applied two to four times daily. Creams should be avoided because they cause hair to become matted. Ointments are satisfactory to use at night but make the hair greasy, so that shampooing is required again in the morning. On the scalp, a fluorinated corticosteroid is acceptable. Mild erythema on glabrous skin should be treated by washing with a mild soap twice a day, followed by application of 0.5% to 1.0% hydrocortisone cream. Hydrocortisone is relatively inexpensive and is considerably less likely to cause telangiectasia and atrophy; a 1% concentration may be used for erythematous or papular lesions.

After initial success, a period of tachyphylaxis may ensue, requiring increased concentrations of medium-potency, nonfluorinated steroids. Telangiectasia and other signs of dermal atrophy may occur with the long-term use of these products, and application on the face should be avoided. Topical ketoconazole produces no such adverse skin changes. Other over-the-counter and prescription antifungal agents may also be effective. Exudative lesions of intertriginous seborrheic dermatitis may require application of Burow's solution compresses, followed by a fluorinated corticosteroid lotion. Secondary bacterial infection may require the use of systemic antimicrobial agents.

PATIENT EDUCATION

It is reassuring for the patient to know that seborrhea is neither contagious nor progressive, but the chronic nature of the condition also needs to be emphasized. Its relation to stress may help explain flares to the patient. The patient will appreciate being provided with a list of over-the-counter preparations. If topical steroid therapy is needed, the patient should be cautioned about its potential adverse effects and instructed in proper application.

THERAPEUTIC RECOMMENDATIONS

- Provide the patient with a list of over-the-counter shampoos and suggest selecting one that meets personal preferences. For oily hair, advise daily shampooing daily for the first week; this can sometimes be decreased to two or three times a week for maintenance. For resistant cases, ketoconazole shampoo should be used every other day.
- For mild to moderate facial or chest involvement, 2% ketoconazole cream may be applied to the affected areas twice a day until clearing is noted. Maintenance therapy may be required once or twice weekly indefinitely.
- If erythema is present, prescribe a topical nonfluorinated corticosteroid preparation (e.g., 1% or 2.5% hydrocortisone cream) for the face; a fluorinated lotion is

appropriate for the scalp (e.g., 0.1% betamethasone valerate lotion).
- Heavy crusts can be removed by softening with keratolytic lotions or oil-based agents before shampooing.
- Treat exudative intertriginous lesions with drying and a nonfluorinated topical steroid lotion.
- Blepharitis may be treated hygienically by gentle rubbing of the eyelashes with a washcloth and No More Tears shampoo. Occasionally, a steroid-containing eye ointment, such as Metimyd or Blephamide solution, can be used, but care must be taken not to allow prolonged use.

CHAPTER 185 MANAGEMENT OF ACNE

PAUL J. GETHNER

Acne, the most common of all skin diseases, is a polygenic, multifactorial disease that, depending on how strictly it is defined, afflicts between 50% and 100% of adolescents in the United States. It ranges in severity from a few scattered whiteheads and blackheads to disfiguring, painful, deep-seated, pus-filled and bleeding nodulocystic lesions. About 15% of surveyed patients with acne seek medical care. The primary care physician is in a unique position to identify and treat a high proportion of acne sufferers. Properly managing acne requires a thorough understanding of the development of acne in all its phases, so that therapy appropriate to the circumstances can be selected from the available modalities. Early effective treatment minimizes the physical scarring of the disease and prevents or reduces equally important psychic trauma.

PATHOPHYSIOLOGY AND CLINICAL PRESENTATION

Pathogenesis

The pathogenesis of acne involves the interaction of enzymatic, immunologic, and chemotactic effects of normal cutaneous microflora; hormonal influences; abnormal keratinization of the sebaceous follicular duct wall; increased sebum production; follicular fragility; and host responsiveness.

Acne is a disease of the sebaceous follicles. Each person has approximately 5,000 sebaceous follicles, scattered predominantly on the face and central upper back and chest. The initial event in the pathogenesis of acne is conversion of the loose, easily shed, horny layer of the epithelium lining the follicular duct wall to a self-adhering mass that gradually obstructs the follicular duct. This has been called " *retention hyperkeratosis.*" It takes 1 to 2 months for the accumulated mass of keratin, sebum, and bacteria to reach visible size as a *closed comedo*, or whitehead. Whiteheads may expand the duct ("pore") opening to communicate freely with the outside. The compact, melanin-rich tip then takes on the appearance of a *blackhead.*

Chemotactic agents produced by bacteria within the duct attract leukocytes, and, in ensuing events, duct walls may rupture to release follicular contents into the surrounding dermis. This provokes a profound inflammatory response, leading to the development of papules, pustules, nodules, and suppurative nodulesthat are commonly, but mistakenly, termed cysts. These inflammatory lesions may cause permanent scarring.

Propionibacterium acnes, a normal inhabitant of the follicular canal in humans, may participate in the initiation and aggravation of inflammatory lesions by elaborating enzymes, such as lipases, that act on sebum to release potentially irritating free fatty acids. Its hyaluronidase may increase the permeability of the follicular duct wall, and its protease can damage it, which increases the leakage of materials into the surrounding dermis. In addition, *P. acnes* produces chemotactic substances that contribute to the initiation and evolution of inflammatory lesions.

Clinical Presentation

Acne can most conveniently be divided into two categories, *obstructive* and *inflammatory*. The former, resulting from the impaction of horny material, bacteria, and sebum in the dilated follicular duct wall, is characterized by *closed comedones* (whiteheads) and *open comedones* (blackheads). Leakage of intrafollicular contents from comedones produces an inflammatory response. Depending on the level of leakage into the dermis and the amount of material released, lesions vary from small, erythematous *papules* and superficial *pustules* to deeper pustules and larger, persistent, and occasionally suppurative nodules. Genetically determined immunologic factors may contribute to an exaggerated inflammatory response and more severe cystic forms of acne.

PRINCIPLES OF THERAPY

Removal of acnegenic agents is an important component of therapy. Some cosmetics, including makeup, hair sprays, oils, and moisturizing creams, are capable of producing comedones, and their use should be reduced or discontinued. The physician should advise against using acnegenic drugs as androgens, steroids, iodides, and bromides. Foods do not appear to play a role in acne. After precipitants have been eliminated, the goals of therapy shift to the treatment of existing lesions and further prevention of new lesions. The modalities employed depend on the kind of lesions present.

Obstructive Acne

The basic approach involves the use of comedolytic agents. Retinoic acid and the newer comedolytic agents are quite effective.

Retinoic Acid (Tretinoin) (Avita, Retin-A, Retin-A Micro) is the main comedolytic agent currently available. Retinoids normalize desquamation of the follicular epithelium, promote drainage of existing comedones, and prevent the formation of new comedones. Irritation is the primary adverse reaction to tretinoin. Frequency of application can be adjusted to produce minimal desquamation.

Newer Comedolytic Agents include *azelaic acid, adapalene*, and *tazarotene*. Azelaic acid is a naturally occurring compound that has antikeratinizing, antibacterial, and antiinflammatory properties. Adapalene is a synthetic retinoid with some of the biologic activities of tretinoin; it is highly lipophilic. Tazarotene is also a synthetic retinoid that is used primarily for psoriasis, but it has recently been approved for use in acne.

Mild Inflammatory Acne

Mild inflammatory acne often responds to topical agents such as benzoyl peroxide and topical antibiotics.

Topical Agents. *Benzoyl peroxide* and *retinoic acid* appear to act synergistically with antibiotic therapy, possibly increasing antibiotic concentration in the follicular duct. Benzoyl peroxide is a potent bactericidal agent available in concentrations of 2.5% to 10% and in formulations that include gels, creams, lotions, and washes. a-*Hydroxy acids*, such as glycolic acid, have gained popularity in over-the-counter products and cosmetics promoted directly to patients as being helpful in the treatment of acne.

Topical Antibiotics are used in mild inflammatory acne to suppress *P. acnes* and its elaborations of harmful enzymes. This is both an active and preventive form of treatment. The topical antibiotics used for acne include *clindamycin* and *erythromycin*. These antibiotics are available in convenient roll-on dispensers, individually wrapped throw-away pledgets, and gels. Topical antibiotics are simple to use and not likely to cause the dryness and irritation associated with retinoic acid or benzoyl peroxide treatment. The efficacy of *metronidazole gel* is well-established in acne rosacea (see Chapter 186). It has been found to be equal in efficacy to systemic tetracycline when applied in conjunction with 5% benzoyl peroxide cream.

Intralesional Administration of Corticosteroids may hasten the involution of nodulocystic lesions and reduce the risk for permanent scarring. The injection of *triamcinolone acetonide* (2.0 or 2.5 mg/mL of saline solution) with a 30-gauge needle directly into specific lesions is often remarkably effective. Pseudoatrophy is a danger.

Severe Inflammatory Acne

This form of acne is characterized by large, deep papules and pustules and destructive, suppurating, nodular lesions. Systemic therapy is required. Because *P. acnes*

is believed to play an important role in the pathogenesis of inflammatory acne, systemic antibiotics have become the mainstay of therapy.

Systemic Antibiotic Therapy is the best means of preventing the formation of new inflammatory lesions. When *P. acnes* is suppressed, the risk for enzymatic injury to glands is also markedly reduced. Four decades of experience with systemic antibiotic therapy, including a detailed review of the indications and hazards of such therapy by an *ad hoc* committee of the American Academy of Dermatology, has established it as rational, effective, and remarkably safe.

The usual approach to systemic antibiotic therapy is to initiate treatment with either *tetracycline* or a synthetic derivative (*doxycycline* or *minocycline*) or *erythromycin*. Response consists of clearing of old lesions and a decrease in new lesions. After a response is observed, the dosage may be gradually decreased during a period of weeks to the lowest effective maintenance dose.

Because tetracycline must be taken on an empty stomach and erythromycin often has gastrointestinal side effects, the use of the synthetic tetracyclines has gained acceptance in recent years. Although they are more expensive, they are more convenient and highly efficacious. The initial dose of doxycycline or minocycline is 100 to 200 mg daily, with gradual reduction to a maintenance dose as low as 50 mg daily or every other day.

Side Effects. In rare instances, minocycline can cause pigmentation of the mucous membranes and sun-exposed skin. Other rare adverse reactions include a lupuslike syndrome with positive findings on autoimmune blood tests, autoimmune hepatitis, and a hypersensitivity syndrome associated with pulmonary infiltrates. With the use of doxycycline or tetracycline, the development of photodermatitis on exposure to the sun is possible. Because of concern about serious side effects of minocycline, doxycycline might be a better choice if treatment is going to be prolonged. Azithromycin has been reported to be as effective as minocycline in the treatment of inflammatory acne, but it is very expensive.

Accutane (13-*cis*-retinoic acid, isotretinoin) is a powerful systemic agent for the treatment of nodulocystic inflammatory acne. It is the only agent proven to reduce sebaceous gland secretion. A 16- to 20-week course often brings severe acne under complete control, with little or no further therapy needed. However, it is essential for the physician to recognize that this is a potent *teratogen* that has caused numerous tragic birth defects. The Guidelines of Care for Acne Vulgaris, published by the American Academy of Dermatology, clearly state that 13-*cis*-retinoic acid should not be first-choice therapy; its use should be limited to patients who are unresponsive to other standard therapies. In the treatment of women of childbearing potential, it should be considered only for patients with severe, disfiguring cystic acne.

Guidelines for use in women are very well presented in a special patient use kit provided by the manufacturer. This includes a detailed informed consent protocol that must be completed by the patient. A copy is given to the patient and one is kept in the patient's record. The patient must either use two methods of contraception simultaneously or abstain totally from coitus. This program of contraception must begin at least 1 month before Accutane is started and must continue for at least 1 month after Accutane is no longer taken. The drug should not be prescribed until a negative result of a pregnancy test has been obtained within 1 week before the next menses. The patient is instructed to initiate therapy during the second or third day of the next menstrual period. She should be seen monthly or bimonthly thereafter, with suitable laboratory studies performed periodically, including a recommended monthly pregnancy test. Should a pregnancy occur, suitable counseling must be undertaken to assist the patient in deciding on the management of the pregnancy, including possible termination.

Other side effects associated with 13-*cis*-retinoic acid include hypertriglyceridemia, pseudotumor cerebri, idiopathic skeletal hyperostosis, cheilitis, nasal mucosal dryness, nosebleeds, conjunctivitis, skin fragility, the development of pyogenic granuloma-like lesions, arthralgia, headaches, and transaminase elevations, but most of these effects are reversible. A flare may be seen shortly after therapy is initiated, and the patient should be warned of the possibility.

Oral Contraceptives. Ortho Tri-Cyclen has been approved for the treatment of acne in women. However, hormone treatment introduces another dimension of possible side effects, plus the risk for a flare on introduction and a possible rebound flare on discontinuation. The possible interaction between oral antibiotics and oral contraceptives and the need for additional forms of birth control should be discussed with patients.

Spironolactone, an antiandrogen, has been prescribed empirically for women with refractory acne. Doses of 200 mg/d are effective in two thirds of women treated, but menstrual irregularities occur in 22%, and some women experience breast tenderness.

INDICATIONS FOR REFERRAL AND PATIENT EDUCATION

The treatment of acne often falls within the domain of the primary physician. The dermatologist should be consulted if basic topical and systemic therapies fail.

Patient education and cooperation are crucial to the success of therapy. Patients must understand the chronic nature of the process and not be discouraged when lesions continue to appear. Patients who unrealistically expect an immediate cure may become discouraged, uncooperative, and eventually angry.

A vast mythology about acne has developed. The patient should be assured that acne has no relation to diet, masturbation, sexual activity or inactivity, constipation, lack of cleanliness, or angry feelings. The patient should be helped to gain perspective and discouraged from self-examination in magnifying mirrors, which often produces a distorted self-image. Instructions for the use of topical and systemic agents must be precise and carefully followed. The patient should be reminded that therapeutic results are not achieved immediately, and that treatment must be continued for an extended period of time. The single most common reason for failure of therapy is lack of compliance.

THERAPEUTIC RECOMMENDATIONS

- Patient education is an essential part of treating acne, so that understanding and cooperation can be enlisted.
- Eliminate acnegenic drugs, such as steroids or androgens, exposure to oils, and habits such as rubbing the face.
- For obstructive acne, use 0.025% or 0.05% retinoic acid cream or gel. This is applied at bedtime. Sunscreens should also be recommended because tretinoin causes increased sensitivity to the sun.
- If papules or pustules are present concurrently, prescribe a topical antibiotic (e.g., erythromycin or clindamycin) in the form of a lotion, solution, or gel, topical benzoyl peroxide, or both. The topical combination preparation of erythromycin and benzoyl peroxide (Benzamycin) is a useful product in treating some patients.
- In more severe cases of inflammatory acne, prescribe a systemic antibiotic (e.g., tetracycline, doxycycline, minocycline, or erythromycin). Start with a full dose and reduce to maintenance after the acne is under control. If doxycycline is used, it should be taken with an adequate amount of liquid because it can cause esophagitis if taken with only small sips.
- For severe nodulocystic acne resistant to conventional therapy, consider systemic 13-*cis*-retinoic acid, with full awareness of its risks, especially teratogenesis, and the requirement for appropriate monitoring.

CHAPTER 186 MANAGEMENT OF ROSACEA AND OTHER ACNEIFORM DERMATOSES

ALICE Y. LIU AND WILLIAM V. R. SHELLOW

Acneiform lesions are seen in rosacea, perioral dermatitis, and Favre-Racouchot syndrome. Rosacea is a common condition that affects men and women between the ages of 25 and 60. Perioral dermatitis is typically seen in women between ages 20 and 40. Favre-Racouchot syndrome, or nodular elastosis with cysts and comedones, presents as periorbital comedones (blackheads) in elderly patients with actinic damage. Patients may present to the primary care physician with specific disease symptoms, or signs can be noted incidentally during examination for an unrelated diagnosis. The primary care physician should be able to identify these acneiform conditions, differentiate them from other diseases, and institute proper treatment.

PATHOPHYSIOLOGY AND CLINICAL PRESENTATION

Rosacea

Pathophysiology. Rosacea is a chronic inflammatory condition of unknown cause that involves the central face. Although rosacea can develop in persons of all races, it affects those of Irish, Scottish, and English descent more frequently. The earliest pathophysiologic change is instability of the vasculature, manifested as flushing, blushing, and eventual telangiectases. Flushing may result from a heat-regulating reflex involving the countercurrent thermal exchange between the common carotid artery and the internal jugular vein. Substance P and vasoactive peptides may also contribute. An increased prevalence of migraine headaches accompanying rosacea further suggests a background of vascular hyperreactivity. Ultraviolet damage may contribute, as dermal elastotic degeneration is noted in most patients. The role of infection is being explored. The concentration of mites (*Demodex folliculorum* and *Demodex brevis*) appears to be increased, and an increased frequency of *Helicobacter pylori* gastritis is also noted.

Clinical Presentation. Patients exhibit a spectrum of lesions, the mildest being erythema, a red face, or ruddy cheeks. Patients flush in response to triggers such as hot liquids, spicy foods, alcoholic beverages, sun exposure, vasodilator drugs, and emotional factors. Additional lesions include *papules* and *pustules* (but not comedones, the latter being more specific for acne). *Telangiectases* develop as a response to recurrent erythema and flushing. Facial edema can also result. In severe rosacea, *rhinophyma*, a thick, lobulated overgrowth of connective tissue and sebaceous glands of the nose, may ensue. Ocular complications include blepharitis, conjunctivitis, episcleritis, and, infrequently, iritis and keratitis.

Perioral Dermatitis

The cause of perioral dermatitis is unknown. Light sensitivity, rosacea, atopy, *Demodex* mite infestation, candidiasis, overgrowth of *Pityrosporum ovale*, and the use of fluoride or tartar control toothpaste have all been implicated, as have dental resins. Controversy exists as to whether the use of cosmetics and self-manipulation contribute to this disease. The condition can be replicated by prolonged use of fluorinated corticosteroid medications.

Patients present with an erythematous, scaling, papular, or papulopustular eruption around the mouth, chin, upper lip, and nasolabial folds. The lesions are usually bilateral and symmetric. Occasionally, papulopustular lesions are widespread. In the periocular variant, typical papules develop around the eyes instead of the mouth. Usually, perioral dermatitis is episodic, unlike rosacea, which tends to be chronic.

Periorbital Comedones

Favre-Racouchot syndrome presents as multiple, noninflamed, open comedones around the eyes, temples, and upper cheeks. The condition is related to a loss of elasticity in the skin of older patients. Actinically damaged follicles favor the accumulation of keratin and sebaceous materials. Comedones in the Favre-Racouchot syndrome recur more slowly than do the comedones associated with acne vulgaris.

DIFFERENTIAL DIAGNOSIS

The diagnosis is clinical. It is important to differentiate rosacea from other acneiform and erythematous diseases. Acne presents in a younger age group and features comedones in addition to papules and pustules. Rosacea can also imitate seborrheic dermatitis, *Pityrosporum* folliculitis, contact dermatitis, eczema, and drug-induced photosensitivity. Perioral dermatitis can look like rosacea, and some consider it to be a variant. Serious systemic diseases presenting similarly to rosacea include lupus erythematosus and sarcoidosis.

PRINCIPLES OF MANAGEMENT

Rosacea

Treatment involves removal of the exacerbating conditions that lead to flushing or vasodilation and the use of topical or systemic antibiotics.

Avoidance of Precipitants. Conditions to avoid include prolonged exposure to sunlight, extreme heat or cold, and ingestion of hot or spicy foods and beverages. Some medications, including vasodilators (aminophylline, hydralazine, niacin, nitroglycerine, papaverine), angiotensin-converting enzyme inhibitors, and simvastatin, have been reported to worsen rosacea. The patient should be cautioned against the use of topical fluorinated corticosteroids, which produce an initial response only to result in atrophy of skin and the development of permanent telangiectasia. Patients with rosacea should also select moisturizers or sunscreens formulated for sensitive skin. Protective ingredients such as dimethicone or cyclomethicone can help reduce irritation.

Topical Antibiotics. The mainstay of topical rosacea therapy is topical *metronidazole*. Alternatively, topical *sulfacetamide* with or without sulfur applied once daily can be of benefit. Other topical therapies, similar to those used for acne vulgaris, enhance skin turnover and restoration; these include topical *erythromycin, clindamycin, benzoyl peroxide*, and *retinoic acid*.

Systemic Therapy. Patients with papules, pustules, or ocular symptoms often need systemic treatment in addition to topical measures. The systemic antibiotics include *tetracycline, doxycycline, minocycline*, and *erythromycin*. These are initiated along with topical therapy and then tapered as the condition improves; topical therapy is continued for maintenance. For severe cases, *systemic isotretinoin* or *metronidazole* can be effective. Recent reports also detail the use of *ketoconazole* and *clarithromycin*. With all systemic therapies, side effects must be weighed against potential benefits. The tetracyclines can cause photosensitivity, and minocycline can cause pigmentation abnormalities, dizziness, and a lupuslike syndrome.

Flushing does not respond to the antiinflammatory properties of these systemic therapies and can be difficult to treat pharmacologically. Authors have mentioned the use of *anticholinergics* (e.g., glycopyrrolate), b-*blockers, clonidine*, and psychotropic medications to manage flushing. However, the side effects of these medications often outweigh their potential benefit.

Surgical Approaches include pulsed dye or *neodymium: yttrium-aluminum garnet* (Nd:YAG) laser for telangiectasias. Rhinophyma can be treated with *carbon dioxide laser, electrosurgery, excision*, or *dermabrasion*. Successful surgical management requires an experienced dermatologist.

Perioral Dermatitis

Patients with perioral dermatitis should avoid heavy cosmetics and topical products with a high proportion of oil. Some practitioners also advise patients to change toothpastes or mouthwashes. Topical acne preparations that increase skin turnover are useful but often inadequate if used alone. *Hydrocortisone cream* (1%) may promote rapid resolution of the dermatitis but should be discontinued promptly. Fluorinated corticosteroid creams should not be used. *Systemic tetracyclines* are consistently effective in controlling perioral dermatitis, as they are in controlling rosacea. If the tetracyclines cannot be tolerated, *erythromycin* may be used instead. Systemic treatment can be discontinued after resolution, usually within 4 to 8 weeks.

Periorbital Comedones

Periorbital comedones may be treated by *manual extraction* of the blackheads with a comedone extractor, but to avoid scarring, this must be performed by an experienced operator. Redevelopment of blackheads is somewhat slow, so that periodic extraction at 3- or 4-month intervals is adequate. Pharmacologic therapy with *retinoic acid* can aid in control of blackheads.

PATIENT EDUCATION

The major element of patient education is to explain that these conditions are common and treatable but may be chronic, with intermittent flares. Many patients are bothered by a single papule, whereas others can sustain the disfigurement of rosacea without complaint. A detailed review of aggravating factors is important for management and helps the patient to become a partner in the treatment of these stubborn conditions.

THERAPEUTIC RECOMMENDATIONS

Rosacea

- Begin oral tetracycline (500 mg twice a day) and continue for several weeks to months; the dosage is then gradually reduced to 250 mg every other day before cessation is considered. Prolonged low-dose therapy may be necessary. Alternatively, doxycycline (100 mg twice daily) or minocycline (50 mg twice daily) can be used.
- Begin topical metronidazole (0.75% twice daily or 1% once daily) along with systemic antibiotics, and maintain the patient on topical therapy after systemic therapy has been discontinued.
- If the patient cannot tolerate topical metronidazole, use topical sulfur and sodium sulfacetamide lotions twice daily.
- The patient should avoid sunlight and fluorinated steroids and limit systemic medications and foods known to exacerbate the condition.
- Consider a short-term course of a low-potency, nonfluorinated topical corticosteroid (e.g., 1% or 2.5% hydrocortisone cream twice daily) if erythema is refractory.
- Refer the patient for consideration of surgical management if rhinophyma or telangiectases are prominent.

Perioral Dermatitis

- Begin with tetracycline (500 mg twice daily) and gradually taper the dose during a period of weeks after resolution has occurred.
- The patient should avoid heavy cosmetics, creams, and fluoridated toothpastes.
- Consider a short course of hydrocortisone cream (1% or 2.5% twice daily).

Periorbital Comedones

- Refer for comedone extraction as needed.
- Initiate application of topical tretinoin (0.025% cream, 0.1% microsphere gel daily at bedtime) to the affected areas. Warn patients that tretinoin may cause irritation and that sunlight should be avoided while it is being used.
- For patients who cannot tolerate tretinoin, prescribe topical adapalene (0.1% solution or gel daily at bedtime).
- Prescribe sun protection with a noncomedogenic sunscreen.
- Consider referral for surgical approaches in severe cases.

CHAPTER 187 MANAGEMENT OF PSORIASIS

AMBER OWEN AND NICHOLAS J. LOWE

Psoriasis is a chronic skin disease that affects up to 2% to 3% of the U.S. adult population. It is characterized by discrete erythematous papules and plaques covered by a silvery white scale. Pustular and erythrodermic varieties are also seen, and arthritis sometimes complicates the condition. Patients presenting to their physician express concern about the cosmetic effects of the disease and request relief from itching and pain. The type of treatment selected should be based on the type of psoriasis present, the location of the disease on the body and its severity, and the patient's age and medical history.

The primary physician should be able to treat mild and localized forms of the disease and be knowledgeable about the treatment of more severe disease to ensure appropriate referral and collaboration with the dermatologist.

PATHOPHYSIOLOGY AND CLINICAL PRESENTATION

Pathophysiology. The epidermal turnover time it takes for a cell to travel from the basal cell layer of the epidermis to the granular layer is normally 14 days. In psoriatic skin, it is reduced to 2 days. Normal cell maturation cannot take place in this short time, and subsequent keratinization is faulty. Clinically, this is seen as scaling. Histologically, the epidermis is thickened, and immature nucleated cells are seen in the stratum corneum. An accompanying dilatation of the subepidermal blood vessels and infiltration with mononuclear cells account for the characteristic erythema. Neutrophils are often seen within the stratum corneum, forming characteristic micropustules.

The exact causes of this abnormal cellular proliferation and inflammation remain unknown, but current speculation is that genetically predisposed persons experience T-cell activation in response to antigen stimulation. Affected persons have an increased incidence of several HLA antigens, including HLA-B27 in patients with psoriatic arthritis. Psoriatic plaques are rich in activated T lymphocytes, which are capable of inducing both cellular proliferation and inflammation. The search for responsible antigens is ongoing.

Drug-exacerbated psoriasis offers some insights into disease mechanisms. Lithium is believed to act by enhancing the release of inflammatory mediators from neutrophils, b-blockers by decreasing cyclic adenosine monophosphate (cAMP)-dependent protein kinase (an inhibitor of cell proliferation), and NSAIDs by causing a buildup of the inflammatory mediator arachidonic acid. Antimalarials are also associated with an exacerbation of the disease. Drug-induced exacerbations can be unpredictable and severe and may occur months after the medication is first taken.

Clinical Presentation and Course. The onset of psoriasis is usually in early adult life, but the disease may appear in childhood or old age. It typically presents with well-marginated, erythematous, elevated *papules* or *plaques*; if not previously treated, these also show thick, silvery *scaling*. Removal of the scale reveals punctate bleeding points known as *Auspitz's sign.*. Nails often show punctate *pitting* and a characteristic discoloration of the surface that resembles a drop of oil. *Subungual collections* of keratotic material are also common, with distal separation of the nail from the nail bed. Mucous membranes are rarely involved. The *extensor surfaces* of the arms and legs are the most commonly affected sites; the scalp is another. Skin trauma increases the risk for involvement, but any epidermal surface can become involved, even the mucosa.

Other clinical types include *guttate psoriasis*, which presents with small, discrete, erythematous papular lesions. An *exfoliative* or *erythrodermic* form of psoriasis shows generalized erythema without any characteristic lesions of psoriasis. Localized pustular psoriasis with sterile pustules of the palms and soles may also be seen without other characteristic lesions. An uncommon but serious variant is generalized *pustular* disease, which is often accompanied by systemic symptoms and a risk for circulatory collapse. In patients with AIDS, a very extensive psoriasis may develop that is quite resistant to therapy.

The *arthritis* associated with psoriasis is often polyarticular and asymmetric, but it also may be monarticular. Classic manifestations include swelling and deformity of the distal interphalangeal joint in association with the characteristic nail changes. Juxtaarticular inflammation produces sausagelike swelling of the fingers. Radiologic features include interphalangeal joint erosion ("pencil-in-a-cup" appearance) and erosion of the distal tuft. Arthritis occurs in about 5% to 10% of patients. The skin disease usually precedes the joint disease by months to years.

The *clinical course* of psoriasis is characterized by chronicity and seasonal fluctuations, with improvement in the summer secondary to sun exposure and worsening in the winter as dry skin leads to epidermal injury.

PRINCIPLES OF MANAGEMENT

The basic approaches to therapy are direct reduction of the rate of epidermal proliferation and indirect reduction through inhibition of dermal inflammatory and immune responses. In addition, one seeks to protect the skin from drying and other forms of injury that may precipitate a flare. Approximately 75% of patients with psoriasis have relatively localized disease involving less than 20% of the body surface area. These patients are generally best managed with topical therapy as the first line of treatment. Certain overriding considerations, however, such as previous failure of topical therapy, inability to apply topical therapy, rapid relapse after previous therapy, or presence of severe psoriatic arthritis, may prompt the physician to choose systemic therapy instead.

Topical Therapies

Corticosteroids. For mild, limited plaque psoriasis, topical corticosteroids are the most commonly prescribed first-line agents because of their ease of use and convenience, short-term efficacy, broad range of potency, patient acceptability, and ready availability. A wide variety of delivery systems have been developed. Corticosteroids have antiinflammatory, antiproliferative, and immunosuppressive actions. Available formulations include ointment, cream, lotion, gel, impregnated tape, and aerosol. Factors to be considered include the anatomic site being treated, extent of involvement, age of the patient, potency of the product, application technique, duration of treatment, and any coexisting relevant conditions, such as preexisting atrophy or compromised adrenal reserve.

The classification of topical steroids is by relative potency, as determined by vasoconstrictive effect (see Chapter 184). Both the structure of the corticosteroid moiety and the type of vehicle delivery system used determine the potency and percutaneous transfer of the corticosteroid. Ointments are considered the most efficient delivery system because of the high solubility of corticosteroids in ointment bases and their relative occlusive action in comparison with other vehicles. The occlusion of localized lesions can enhance the effect of a topical corticosteroid of a given potency.

Adverse Effects and Their Prevention. Although topical corticosteroids can be highly effective in treating psoriasis, caution is advised in prescribing them because of their potential to cause local and systemic side effects. Common cutaneous side effects include *skin atrophy* and *acneiform eruptions*. Prolonged application of potent topical corticosteroids can cause *systemic steroid effects* (see Chapter 106). When potent topical therapy is discontinued, a *rebound* effect may occur, with the psoriasis becoming even more severe than the original, untreated condition. Also, a tendency toward conversion of "stable" to "unstable" (erythrodermic or pustular) disease may be noted.

To reduce the incidence of side effects, various *intermittent dosing schedules* have been developed, especially for potent topical preparations. " *Pulse therapy*" involves treating the psoriatic plaque with a superpotent steroid twice daily to initiate plaque regression; once improvement is noted, the steroid is applied on weekends only. The regimen can prolong psoriatic remissions and avoid adverse effects.

Tars

Topical *coal tar* preparations are among the oldest topical therapies for psoriasis. When used alone, they are no more effective than topical corticosteroids of low to intermediate potency, but they are effective in combination therapy. In the *Goeckerman program*, which combines topical tar with suberythemogenic *ultraviolet B* light, coal tar produces an enhanced effect. Patients with more than 10% of skin surface involvement are reasonable candidates. The treatment is associated with an 80% to 90% remission rate, and no significant evidence of an increased risk for skin cancer has been noted. Modifications of the Goeckerman program allow outpatient therapy in which less messy coal tar gels are used, followed in 2 hours by treatment with ultraviolet light. Treatment for 4 to 6 weeks is usually necessary to achieve maximum benefit.

Tar *shampoos* (Zetar, Sebutone, Pentrax, T/Gel) may be of benefit to patients with scalp psoriasis. The shampoo is massaged in thoroughly and left on for 10 minutes before water is added and the patient shampoos gently for several more minutes to remove scales. This is combined with overnight application of a moderate-strength topical steroid solution (e.g., Synalar solution) for maximum effect. Topical coal tars are messy and malodorous, which makes them inconvenient for patient use.

Anthralin

Anthralin is one of the more effective agents for topical treatment, acting to reduce epidermal inflammation and keratinocyte proliferation. Anthralin is as effective as a class II corticosteroid but causes unpleasant side effects, such as inflammation and staining of unaffected perilesional skin and clothing. These properties may make it unacceptable to patients. As a result of modifications to the once-traditional overnight anthralin therapy, the incidence of staining and side effects has decreased and application and removal have become easier, so that anthralin is now more acceptable to patients.

Short-contact application of newer anthralin cream formulations (e.g., Micanol cream) is an alternative to traditional overnight therapy. It appears that anthralin penetrates lesional skin faster than perilesional skin, so that a shortened contact time is possible without loss of efficacy in comparison with traditional therapy. The newer cream formulations cause less erythema, burning, and staining of skin and clothing and are more cosmetically acceptable than traditional anthralin, but of equal efficacy.

Vitamin D Analogues

Vitamin D analogues act via vitamin D receptors, which are members of the superfamily of steroid hormone receptors. They activate intranuclear transcription factors that bind to specific DNA sequences to modulate gene transcription activity, thereby affecting inflammation and control of epidermal growth and keratinization. Immune modulation results. The vitamin D analogues include calcitriol, calcipotriene (or calcipotriol in Europe), and talcacitol, which is not yet approved for use in the United States.

Calcipotriene (calcipotriol, Dovonex) has become a first- or second-line agent in the treatment of mild to moderate plaque psoriasis. The agent is a derivative of naturally occurring vitamin D and is highly effective in most patients for flattening plaque and decreased scale. The ointment formulation is more effective than short-contact anthralin cream in reducing psoriatic plaques, and it is more cosmetically acceptable. It also more effective than intermediate-strength topical steroids (e.g., betamethasone 17-valerate or fluocinonide ointment), with a considerably lower rate of relapse. Response begins within 2 weeks of treatment and continues to develop for 6 to 8 weeks. Patients experience improvement for up to 12 months of treatment, so that this agent is efficacious as both continuous and intermittent therapy. It is also used for intertriginous psoriasis.

Adverse Effects. The most common side effect (15% of users) is perilesional or lesional irritation and erythema. Dermatitis may also develop on the face after inadvertent transfer of the agent, so that hand washing immediately after application is necessary. *Hypercalcemia* and *hypercalciuria* can occur, especially if the topical dosage exceeds 100 g weekly, so that caution is needed, particularly when prescribing the agent for patients with renal compromise or in whom hypercalcemia or kidney stones are likely to develop. Patients with extensive psoriasis who may require a dose approaching 100 g weekly should be screened for hypercalciuria before treatment is begun.

Calcitriol (1,25-dihydroxyvitamin D_3) is a naturally occurring hormone that is a safe and effective treatment for plaque psoriasis; it reduces scale production, plaque thickness, and erythema without causing abnormalities in serum calcium levels, calciuria, or local cutaneous side effects. Compared with calcipotriene, calcitriol appears to cause only minimal irritation, even when applied to the face, and is associated with fewer changes in systemic calcium metabolism; however, it is less effective, especially when used in low doses for chronic plaque psoriasis. Higher doses are being studied for safety and efficacy.

Tazarotene

Tazarotene, a vitamin A derivative, selectively binds to retinoic acid receptors to cause negative gene regulatory effects specific to skin cells. The result is that it is less cytotoxic than other topical retinoids and produces less local irritation. Application for 2 weeks decreases keratinocyte proliferation, modulates abnormal keratinocyte differentiation, and decreases expression of inflammatory markers in the skin. The gel is effective in concentrations of both 0.05% and 0.1% applied either once or twice daily. The 0.1% tazarotene gel acts more rapidly than the 0.05% gel but is associated with a higher incidence of irritation.

Tazarotene gel (0.1% or 0.05%) applied once daily for a week is as effective as 0.05% fluocinonide cream, a topical corticosteroid, in reducing plaque elevation, but it takes longer to reduce plaque erythema. After 4 weeks of treatment, however, the overall treatment success rates are similar. Additionally, the relapse rate for 0.1% tazarotene gel is significantly lower than that for fluocinonide cream. An advantage of tazarotene over other topical agents is its sustained effect, generally within 20% of final treatment levels for up to 12 weeks after treatment. Furthermore, its onset of action is rapid, with decreased plaque elevation noticed by the first week, decreased scaling by the second week, and decreased erythema by the end of 6 weeks. Trunk and limb lesions generally respond more rapidly than thicker elbow and knee lesions. Tazarotene is also suitable for application to the face and scalp.

Combination Therapy

Because it is a chronic disease, psoriasis usually requires prolonged treatment, and although corticosteroids are often given as weekend therapy, their long-term side effects make them difficult to use as monotherapy in chronic cases. A new trend is to use combination therapy with *calcipotriene ointment* and *superpotent steroids*, such as halobetasol ointment, to induce greater improvement and reduce the side effects produced by either agent used as monotherapy. A combination of weekend therapy with corticosteroids and weekday therapy with calcipotriene ointment increases the duration of remission of psoriasis, and a combination of morning treatment with calcipotriene ointment and evening treatment with halobetasol ointment can enhance the effect of either agent used alone. Applying the agents at different times of day is recommended because the calcipotriene molecule has been shown to be relatively unstable and is rapidly degraded when directly combined with certain corticosteroid ointments.

Another effective combination program includes topical *corticosteroids* and topical *retinoids*. A protective effect against skin atrophy is noted when 0.1% tretinoin is added to betamethasone dipropionate. A combination of *tazarotene* and an intermediate- or high-potency *corticosteroid* achieved greater reductions in the severity of psoriasis than did a combination of tazarotene and placebo cream. Tazarotene and other topical agents in combination with ultraviolet B phototherapy is another potentially useful concept that is currently under study.

Systemic Treatment of Psoriasis

Systemic treatment is indicated only for severe or incapacitating disease. Indications include *generalized pustular psoriasis, generalized exfoliative psoriasis*, severe *psoriatic arthropathy*, topical treatment failure, *severe uncontrolled psoriasis* (generally involving more than 20% of the body surface area), and socially incapacitating disease. An additional indication is acute *guttate psoriasis*; the use of systemic therapy may prevent this form from becoming chronic.

Photochemotherapy

Photochemotherapy combines a systemic photosensitizing agent, *psoralens*, with long-wavelength (320 to 400 nm) *ultraviolet A light* (commonly referred to as *PUVA therapy*). PUVA therapy generally produces excellent results (80% to 90% remission) in patients with otherwise recalcitrant severe psoriasis. Acute side effects of PUVA therapy may include pruritus and nausea (15% of patients), and burning may also occur. Long-term side effects include premature skin aging and carcinogenesis. The risk for skin cancer is increased with both ultraviolet A and PUVA therapies, the most common type being *squamous cell carcinoma*. However,

some recent evidence suggests that patients undergoing long-term PUVA therapy are also at increased risk for the development of *melanoma*. Therefore, patients undergoing phototherapy must be given careful follow-up and regular skin checks. Patients at increased risk for skin cancer (fair skin, easily sunburned, previous radiation therapy to the skin) should not be given PUVA treatment, and PUVA treatment should be reserved for severe or recalcitrant psoriasis that is resistant to topical therapy.

Methotrexate

Methotrexate decreases the mitotic rate and DNA synthesis in the epidermis. However, it may exert part of its therapeutic effect via immunomodulation. It is effective in controlling severe disease, but the risk for serious side effects limits its use to chronic, refractory cases. Its use is also generally reserved for men and women past reproductive age because of its highly mutagenic potential. Oral regimens includeeither three doses at 12-hour intervals, given once weekly, or a single weekly dose. If nausea is significant, parenteral administration can be used.

Because of the potential of methotrexate to cause hematopoietic, hepatic, and renal toxicity, close monitoring and full patient compliance are essential. The patient's hematologic status and renal and liver functions should be normal before treatment is begun and monitored regularly during treatment. The monitoring program consists of weekly, followed by monthly, blood sampling. Evidence of bone marrow suppression may appear, but renal and hepatic injury are uncommon at the doses used for treatment of psoriasis. Hepatic fibrosis, however, may develop with prolonged use, so that most experts recommend consideration of pretreatment liver biopsy and repeated biopsy after a cumulative dose of 1.5 g.

Acitretin

Acitretin (Soriatane) is a systemic retinoid used in erythrodermic, pustular, and chronic plaque psoriasis. Although teratogenicity is a drawback in the use of most systemic retinoids, acitretin is rather rapidly cleared (not being lipid-bound or maintained in fat stores) and is thus safe for women of childbearing potential, provided that they use effective contraception while taking the drug and for at least 1 year after discontinuing it.

Side effects of acitretin include hyperlipidemia, dry lips, conjunctivitis, pruritus, alopecia, color blindness, and decreased night vision. The serum liver chemistries and triglyceride and cholesterol levels of patients should be evaluated before treatment is begun, and they should undergo laboratory monitoring at monthly intervals during treatment. Biopsy-proven hepatotoxicity has not been noted with long-term use of acitretin, so that the need for liver biopsy is obviated.

Acitretin and Phototherapy. Acitretin monotherapy is the preferred treatment for pustular psoriasis, whereas for plaque psoriasis, acitretin is best prescribed with adjunctive therapy, such as ultraviolet light phototherapy. The dose of acitretin and the total exposure to ultraviolet light can be reduced if they are used in combination. The dosing of ultraviolet light or PUVA, however, should be increased gradually and cautiously when patients are taking systemic retinoids because of their increased risk for ultraviolet light–induced erythema. After clearance of psoriasis has been achieved, patients can be maintained on either low doses of acitretin or PUVA alone.

Cyclosporine

Cyclosporine acts as a potent suppressor of T-cell activity and has effected significant improvement and even total clearing in more than two thirds of patients treated. However, relapse within several weeks of discontinuation of treatment is common. Moreover, hypertension, renal toxicity, hirsutism, and myalgias can occur with short-term therapy, and lymphoma with more prolonged use. Cyclosporine can be started at a low dose (2.5 mg/kg daily) and slowly increased to maintain efficacy. Once remission is achieved, the dose can be gradually decreased. There appear to be some differences in efficacy among available preparations.

PATIENT EDUCATION AND INDICATIONS FOR REFERRAL

For many, the social and psychological effects of severe or long-standing disease can be significant, leading to loneliness and depression. Regularly scheduled visits to reinforce the details of therapy and also to render support are appreciated. Knowing that disease severity can be reduced through appropriate treatment is reassuring. Informed advice about what works and what does not is essential. Concerns about contagion and genetic transmission of the disease need to be addressed. The chronic relapsing nature of psoriasis should be acknowledged, so that patient expectations will be realistic. Preventive measures should be stressed, such as keeping the skin well hydrated and avoiding sunburn and other forms of skin trauma. The safety and efficacy of most psoriatic regimens depend on strong patient compliance. Careful teaching that includes the rationale for a given practice is helpful, as are written instructions.

Patients with extensive, refractory, or acute pustular disease should be referred to a dermatologist for consideration of phototherapy, retinoids, antimetabolites, and immunosuppressive therapy. The development of generalized disease, especially if erythrodermal or pustular, requires hospitalization.

THERAPEUTIC RECOMMENDATIONS

- Treat localized, mild to moderate disease topically. Refer patients with more extensive (>20% of skin area involved) or refractory disease to a dermatologist.
- Emphasize the importance of keeping the skin well hydrated and avoiding sunburn and other forms of skin injury.
- Allow cautious sun exposure; avoid sunburn, and do not recommend sun exposure for those at increased risk for skin cancer (fair-skinned, easily burned, history of skin irradiation).
- Review medications for potential exacerbating drugs (lithium, b-blockers, NSAIDs); reduce dose or substitute if possible.
- Prescribe a topical steroid program for control of bothersome visible lesions. Begin with a "superpotent" preparation (e.g., Diprolene, Psorcon, Temovate, Ultravate), and change to a less potent preparation for maintenance. Use only milder steroids on the face and skin folds.
- Consider calcipotriene or tazarotene as alternatives to topical steroids.
- Recommend an ointment preparation for lesions with considerable scale, although a cream may be more acceptable for daytime use and suffice for plaques with minimal scale. A twice-daily regimen of steroid application achieves best results.
- For patients with excessive scale, recommend gentle removal by warm bathing.
- For mild scalp involvement, recommend nightly use of a tar shampoo. It is rubbed in gently, left on for 10 minutes, and then rinsed out gently. For more severe scalp disease, use of the tar shampoo is followed by gentle application of a topical steroid lotion (e.g., Synalar). Patients with marked scalp involvement may benefit from covering their head with a shower cap after steroid application and use of a superpotent topical steroid lotion (e.g., Diprolene), anthralin scalp preparation, Dovonex scalp lotion, or Tazorac gel.
- Refer patients who fail to respond and those with extensive disease to a dermatologist for consideration of methotrexate or other systemic therapies. Promptly admit to the hospital if generalized pustular or erythrodermal disease develops.

CHAPTER 188 MANAGEMENT OF INTERTRIGO AND INTERTRIGINOUS DERMATOSES

WILLIAM V. R. SHELLOW

Intertrigo is an inflammatory condition of body folds that presents as a moist lesion with erythema and scaling. It is more common in obese people and is exacerbated by warm weather. The areas of involvement are the axillary, inguinal, and inframammary folds and the toe webs. The primary physician should be capable of distinguishing intertrigo from other eruptions of the body folds, such as erythrasma, seborrheic dermatitis, psoriasis, and dermatophyte infections, and of rendering appropriate treatment.

PATHOPHYSIOLOGY AND CLINICAL PRESENTATION

Intertrigo presents as an erythematous exudative inflammation in the body folds. Patients may have soreness and itching, and with secondary infection, overt purulence may occur. The pathogenic mechanism is mechanical. Heat, moisture, and the retention of sweat produce maceration and irritation, an environment that promotes bacterial infection.

Early intertrigo is characterized by slight maceration and erythema. The moisture initially comes from eccrine sweat that cannot evaporate in the intertriginous areas because of reduced circulation of air. With time, redness becomes more intense, and the epidermis becomes eroded or even denuded. Subsequent inflammation causes exudation of serous fluid. Increased moisture may lead to bacterial colonization, which accounts for the odor that is sometimes associated with intertrigo. The groin and intergluteal areas may be colonized by gram-negative organisms. Incontinence of urine or feces may exacerbate maceration in the groin and gluteal areas.

DIFFERENTIAL DIAGNOSIS

Intertrigo in the Groin must be differentiated from *tinea cruris* and *candidiasis*. Tinea cruris is a fungal infection characterized by red, scaly patches. The lesions form circinate plaques with scaly or vesicular borders and central clearing. After scales are scraped and 20% potassium hydroxide solution is added, the finding of hyphae in specimens under low microscopic power serves to differentiate tinea cruris from intertrigo. Candidiasis produces deep, beefy red lesions with characteristic satellite vesicopustules outside the border of the primary lesion. Involvement of the scrotum is common, whereas in tinea the scrotum is usually spared.

The groin may be affected by sexually transmitted diseases such as *condyloma, herpes, scabies*, or *pediculosis*. These cause an erythematous and pruritic eruption with characteristics that point to the underlying diagnosis (see Chapter 141, Chapter 192, Chapter 193, and Chapter 195). In severe cases of intertrigo, an underlying disease such as lichen sclerosus et atrophicus should be considered. Long-standing intertrigo with scratching often leads to the development of lichen simplex chronicus.

Intertrigo in the Axilla needs to be differentiated from *candidiasis, tinea, erythrasma*, and *contact dermatitis. Candidal infection* presents with an erythematous eruption; tinea corporis in the axilla demonstrates an active border with scale; erythrasma has a reddish brown discoloration, and contact dermatitis usually spares the axillary vault. Erythrasma, caused by *Corynebacterium minutissimum*, will demonstrate coral red fluorescence under the Wood's light. A condition known as benign *familial pemphigus* should also be considered. If an axillary lesion is nodular or raised, Fox-Fordyce disease and *hidradenitis suppurativa* enter the differential.

Intertrigo of the Inframammary Region can occur with or without *candidal infection*.

PRINCIPLES OF THERAPY

Correcting Precipitants. The first principle of therapy is to alter the conditions that cause maceration and irritation of closely apposed skin. The goal is to *promote drying*, which can be accomplished by exposing the intertriginous areas to air. The use of a fan or electric bulb can promote drying. A hand-held hair dryer set to a cool setting is very effective. Addition of a nonmedicated *absorbent powder* that does not contain cornstarch is helpful. Zeasorb powder, made from corncobs, is useful. (Cornstarch is to be avoided because it serves as a food source and stimulates the growth of local bacteria). The patient should be instructed to wear loose-fitting cotton clothing. Bras that provide good support are also helpful. Hot, humid environments and clothing made of wool, nylon, or synthetic fibers can precipitate or worsen intertrigo. Nylon panty hose are a common offender. Men with groin involvement should be encouraged to wear boxer shorts rather than briefs, and women should wear cotton rather than nylon panties. Ointments and greasy preparations retain moisture and exacerbate the condition. Exudative lesions should be treated by the application of *compresses containing Burow's solution*, prepared by adding one package or tablet to a pint of water.

Treating Secondary Infection. Any secondary infection should be treated. Pustules or scales should be examined microscopically and cultured for evidence of bacteria, yeast, and dermatophytes, after which appropriate therapy should be instituted (see Chapter 190 and Chapter 191). There is no evidence that antibacterial soaps are more effective than ordinary toilet soaps. Medicated powders should not be used.

Topical Corticosteroids. As long as the area of intertriginous disease is uninfected, topical corticosteroids may be added to reduce inflammation. The strength of the preparation should match the severity of the condition. *Hydrocortisone cream* is an effective, safe, low-cost therapy for patients with mild to moderate inflammation. Fluorinated topical corticosteroids are useful when inflammation is more severe, but these should be applied only for short periods because intertriginous striae and atrophy are common complications of more prolonged use.

Combination Preparations. Some steroid preparations promoted for use in intertrigo contain an *antifungal agent* (nystatin or clotrimazole) in addition to *corticosteroid*. The rationale is concurrent treatment or prevention of secondary candidal or dermatophyte infection. Mycolog-II cream is a combination of triamcinolone (a low-potency corticosteroid) and nystatin. Its original formulation also contained sensitizing antibacterial agents and preservatives. In a randomized, controlled study comparing it with hydrocortisone, no difference in outcome was noted. Lotrisone combines medium-potency betamethasone with clotrimazole. Lotions with an alcohol base are quite drying and may sting. The popular combination formulations Vioform-Hydrocortisone (which contains the antifungal agent clioquinol) and Vytone (iodoquinol and hydrocortisone) stain clothing yellow.

Topical medication should be used sparingly to avoid retention of moisture. Concurrent medical conditions such as diabetes or obesity should be treated.

PATIENT EDUCATION

The patient must understand the mechanical effects of skin occluding skin and be encouraged to dress accordingly to ensure adequate aeration and absorption of moisture. Women with large or pendulous breasts might benefit from use of a support bra and the placement of soft cotton cloths, gauze pads, or lamb's wool between the breasts and the chest wall. The patient should be taught to inspect intertriginous zones to detect the development of erythema and maceration so that effective therapy can be instituted early. In elderly, immobile patients, the physician should educate the family or a friend to inspect intertriginous areas to prevent maceration and secondary infection.

THERAPEUTIC RECOMMENDATIONS

- Eliminate precipitating conditions. Carefully dry the area that separates folds with absorbent material, dust with drying powders, and recommend loose, absorbent clothing. In exudative lesions, a drying agent such as Burow's solution should be used as a compress.
- Advise avoidance of potential contactants in axillary eruptions.
- Treat areas with mild to moderate inflammation with topical hydrocortisone. For more severe cases, use a low- to medium-potency fluorinated topical

corticosteroid for short periods only.
- Treat any secondary bacterial or fungal infection with appropriate agents (see Chapter 190 and Chapter 191).

CHAPTER 189 MANAGEMENT OF CORNS AND CALLUSES

WILLIAM V. R. SHELLOW

Corns and calluses are common, vexing lesions that can interfere with daily functioning. They may not be a presenting complaint, but the primary care physician is frequently asked about them. The tasks in the primary care setting are to provide diagnosis, simple therapy, advice on prevention, and timely referral if symptoms are refractory or disabling.

PATHOPHYSIOLOGY AND CLINICAL PRESENTATION

Corns (helomata, clavi) and calluses (tylomata) have a common pathologic origin. Friction and pressure on the skin overlying bony prominences lead to hyperemia, hypertrophy of dermal papillae, and proliferation of keratin. Corns often have a central, hard core that is painful if the lesion is pressed. Ill-fitting shoes are the most common cause, and the pressure of shoes on a corn may produce pain during walking. The most common locations are on the lateral aspect of the small toe and over the metatarsal heads on the plantar aspect of the foot. Hard corns have a translucent, cone-shaped avascular core with interruption of normal skin markings. Soft corns appear as macerated white or gray lesions that may resemble dermatophytosis, but they are tender. The fourth and first interdigital web spaces are favored sites. Calluses, but usually not corns, may develop in persons who do not wear shoes. Calluses do not contain a central core and tend to occur across the area of the metatarsal heads; normal skin markings are preserved. Women are two and a half times more likely to be bothered by corns and calluses than are men.

DIFFERENTIAL DIAGNOSIS

Calluses are skin-colored or yellowish elevated, thickened plaques that are seen in areas of friction. Calluses can be confused with plantar warts but can be distinguished from them by the preservation of normal skin markings; with verrucae, these markings are interrupted. When corns are pared down with a scalpel, one does not see the small, dark brown to black dots that represent thrombosed capillaries and are characteristic of warts.

PRINCIPLES OF THERAPY

The primary physician's major contribution to therapy is to encourage *prevention* through *patient education*. The elimination of friction and pressure is the essence of prevention. Shoes must fit correctly, and pressure over the toes must be evenly distributed. Softer shoe materials and sandals are often helpful. Stockings must fit properly and should cushion the foot. Keeping the feet dry by using powder and changing shoes daily also reduces friction. Careful explanation of the rationale for such measures is essential to ensuring patient compliance.

Symptomatic relief of calluses can be achieved by *paring* hyperkeratotic lesions with a No. 10 or 15 scalpel blade. Keratin should be shaved off with the blade held parallel to the skin. Repeated strokes of the blade should be made in a direction least likely to cause penetration should the patient move suddenly. Proximal to distal movement is best. After a callus is removed, it is essential that previous weight-bearing trauma not be continued, or the callus will recur.

Patients can treat corns and calluses themselves by intermittent debridement with *keratolytic agents*. Salicylic and lactic acid combinations and 40% salicylic acid plasters are used to reduce the thickness of tissue. The patient should cut a piece of 40% salicylic acid plaster that is smaller than the lesion and apply it to the skin. It may be left on overnight or for as long as several days. The dressing should be removed and the foot soaked. The softened and macerated skin can be removed with a BufPed or pumice stone. The plaster may be carefully reapplied as often as necessary to keep the lesions flat and asymptomatic.

The treatment of soft corns involves reducing excess perspiration. Use of absorbent *lamb's wool*, soaking the foot in potassium permanganate (1:4,000 solution), and cauterization with silver nitrate have all been successful.

Intrinsic bone problems subject the foot to uneven pressure. Any pronation, flat foot, or medial or lateral imbalance should be treated. Padding of lesions with felt moleskin or lamb's wool may prevent uneven distribution of external pressure. If the lesion is surrounded with foam rubber, pressure is distributed around the lesion rather than directly on it. If underlying bony abnormalities are suspected, x-ray films of the foot should be obtained.

One investigational technique is the injection of medical-grade silicone under corns to cushion the skin from underlying bone. The technique has been one of the few approved uses for injectable silicone, but it is confined to a few investigators. Other investigators have injected cross-linked collagen between the corn and the bone.

INDICATIONS FOR REFERRAL

Referral to a podiatrist or orthopedic surgeon is indicated if simple measures and advice fail to reduce symptoms or recurrences. Latex, plastic, or silicone molds can be individually adapted to prevent localized pressure from producing corns or calluses. Shoes can be constructed by a podiatrist to redistribute weight and pressure. Occasionally, surgical removal of a subjacent bony prominence eliminates the source of abnormal pressure on the skin. Diabetics and others with impaired vascular systems should receive foot care from a podiatrist.

THERAPEUTIC RECOMMENDATIONS

- Advise the patient to avoid tight shoes with pointed toes, to wear shoes that fit properly, and to change them frequently. Socks should cushion the sensitive area.
- Corns and calluses may be treated by the patient with proprietary plasters. The physician or patient can apply a keratolytic agent to the lesion in the form of a 40% salicylic acid plaster for several days. After the lesion has improved, the use of circular pads may prevent recurrence.
- Consider paring down a large lesion. Patients can perform this procedure themselves, but instruct them never to pull loose skin. Protect the tender area with moleskin after paring.
- After the lesions have been removed or pared down, ensure that the foot is not subjected to the same pressures that originally produced the problem.
- Patients with refractory lesions and lesions caused by underlying orthopedic disease should be referred to a podiatrist or orthopedist for definitive treatment of the structural problem. A molded shoe insert device may be prescribed. Diabetics and others with an insufficient vascular supply to the foot should receive regular foot care from a podiatrist.

CHAPTER 190 APPROACH TO BACTERIAL SKIN INFECTIONS

WILLIAM V. R. SHELLOW

Part 1: Cellulitis

Cellulitis represents bacterial infection of the skin that involves the deeper subcutaneous layers. It must be differentiated from inflammatory skin changes caused by vascular insufficiency and phlebitis. Once cellulitis is identified, the primary physician has to decide who can be managed at home on oral antibiotics and who requires hospitalization.

PATHOPHYSIOLOGY AND CLINICAL PRESENTATION

Pathogenesis. Any process that causes a break in the integrity of the skin allows normal skin bacteria to invade the underlying subcutaneous tissue and initiate an inflammatory response. Trauma, stasis ulceration, ischemia, and chronic edema are common precipitants. Contiguous or hematogenous spread from other sites occurs uncommonly.

The organisms most commonly producing cellulitis are normal skin flora, with *Streptococcus* and *Staphylococcus aureus* predominating. Staphylococci produce disease through their ability to multiply and produce a host of extracellular enzymes, including a- and b-hemolysin, leukocidin, coagulase, hya-luronidase, and lipases. Streptococci produce more than 20 extracellular enzymes.

Conditions that impair the host response may predispose to skin infection by opportunistic organisms such as *gram-negative bacteria*. Skin infections with *Escherichia coli, Pseudomonas*, and *Klebsiella* are seen in immunosuppressed patients, diabetics, and alcoholics. Cellulitis in the perineum may be caused by enteric aerobic and anaerobic bacteria. Injury to mucosal surfaces predisposes to infection with *anaerobic organisms*. Anaerobic bacteria can produce hyaluronidase, proteases, neuraminidase, and extracellular enzymes, and they act synergistically with aerobic bacteria. Anaerobes play an important role in diabetic foot ulcers, abscesses, and traumatic wounds. Anaerobic infection also occurs in the setting of crush injuries. The degree of pain may be disproportionate to skin findings. A mixture of aerobic and anaerobic streptococci can cause fasciitis and cellulitis. Once connective tissue is involved, infection spreads along fascial planes.

In certain settings, cellulitis is caused by unusual organisms. In persons who handle fish, poultry, or meat, cellulitic infection with *Erysipelothrix rhusiopathiae* may occur. In patients with water-related injury and sometimes in those with immunosuppression, *Aeromonas hydrophila* can cause cellulitis. Animal bites or scratches, especially from cats, are associated with cellulitis caused by a *Pasteurella multocida* organism. *Vibric* species have been implicated in salt water-related injuries. Arthropod bites are portals of entry for conventional streptococcal or staphylococcal species, but one must also consider the unusual spreading cellulitis, a reaction to the toxin of a *brown recluse spider* or a *fire ant*. Another unusual cause of cellulitis simulating a septic thrombophlebitis is *Campylobacter* infection, often in the context of a concurrent enteritis.

Clinical Presentation. Cellulitis presents with local redness, heat, swelling, and tenderness that develops over a few days. Fever, chills, and rigors herald possible bacteremia. The clinical presentation does not allow delineation of the specific microbial etiology. Red streaks extending proximally in conjunction with tender lymph nodes indicate an associated *lymphangitis*. Crepitus indicates gas production and suggests anaerobic involvement.

Invasive strains of *group A streptococci* (M-types 1 and 3) cause not only the usual forms of invasive streptococcal disease (scarlet fever, erysipelas, necrotizing fasciitis, myositis) but also a toxic shock–like syndrome associated with mucosal or cutaneous infection. Mortality is as high as 30%. Onset is abrupt, with fever, diarrhea, rigors, and scattered pains. Bacteremia may be detected in 60%; hematogenous spread is common.

WORKUP

Cellulitis first needs to be distinguished from other causes of focal erythema, swelling, and tenderness. *Superficial thrombophlebitis* may present similarly, but the inflammatory response is usually centered in the involved vein, which is tender and palpable. The dependent rubor of *arterial insufficiency* is generalized, nontender, and associated with diminished or absent pulses and a cold extremity. *Erythema nodosum* is indicated by lesions that are typically multiple, exquisitely tender, and often pretibial in location. It is a secondary phenomenon, and the cause needs to be ascertained. It should be remembered that cellulitis may occur concurrently with phlebitis or arterial insufficiency.

History. Once it is established that cellulitis is present, predisposing factors should be identified. A history is obtained for diabetes, congestive failure, recent trauma, leg edema, claudication, previous infection, tinea pedis, and loss of sensation. One should ask about IV drug use, occupational exposure, and any recent bites and stings. A history of fever with rigors suggests bacteremia.

Physical Examination. Note is made of the temperature, area(s) of skin involved, lymphangitic streaking, proximal lymphadenopathy, heart murmur, peripheral edema, diminished peripheral pulses, decreased sensation, and any breaks in the skin, ulceration, or atrophy. Marking the borders of the lesion with an indelible pen allows objective and rapid assessment of progression and resolution. Crepitus or foul odor is suggestive of anaerobic infection. One palpates for fluctuance and inspects the viability of surrounding tissue. Any tinea, dermatitis, venous insufficiency, or previous injury should be noted.

Laboratory Studies. A *complete blood cell count* and *differential* are always helpful in gauging the severity of infection and the hematologic response. Because most cases of cellulitis are caused by streptococci or staphylococci, *bacterial culture of the skin* is not routinely performed. Moreover, it is difficult to culture the offending organism from unbroken skin. There is no evidence that aspiration from the advancing margin is superior to sampling from any other area of involved skin. Culture is indicated in patients who have open, weeping *wounds* or infection in unusual areas, such as the *perineum*. Material from such areas should be cultured both anaerobically and aerobically.

When rigors, fever, heart murmur, or lymphangitic spread is present or the patient is immunocompromised, two separate sets of *blood cultures* should be obtained before any antibiotics are administered. Blood cultures are positive in only 5% to 10% of cellulitis cases. If crepitus, fluctuance, or devitalization is present, obtain an x-ray film to look for gas production in soft tissue, which is indicative of gangrene. In diabetic or immunocompromised patients, or in situations of previous injury, radiography is important to be sure that osteomyelitis does not lurk beneath the cellulitis.

PRINCIPLES OF MANAGEMENT

The majority of patients can be treated as outpatients with oral antibiotics and supportive measures. Patients who are afebrile and in whom adenopathy and lymphangitis are absent may not even require antibiotics, but antibiotics are usually prescribed.

Antibiotics. The drugs of choice are either *penicillin* or a penicillinase-resistant *semisynthetic penicillin* preparation. There is little definitive evidence on which to base antibiotic selection. The high prevalence of streptococci, the sensitivity of some community-acquired staphylococci to penicillin, and the low cost of penicillin make it a reasonable choice. If after 24 to 48 hours the patient is still febrile or not improving, a penicillinase-resistant preparation can be substituted. The addition of probenecid as a morning dose can increase blood levels of oral penicillin. Antibiotic therapy should continue for 10 to 14 days, depending on the rate of clinical

resolution.

Supportive Measures include *elevation* of the affected part and scrupulous prevention of new trauma. *Heat* may help to resolve cellulitis by promoting blood flow to the area. In patients with underlying conditions such as congestive heart failure, stasis dermatitis, and vascular insufficiency, *control of edema* and maintenance of *skin moisturization* helps prevent recurrent episodes.

In patients with open wounds, the risk for tetanus should be considered. If a booster of *tetanus toxoid* has not been obtained within 5 years, it should be given. Patients who have not had an initial tetanus series should receive both tetanus toxoid and tetanus immune globulin (see Chapter 6).

INDICATIONS FOR REFERRAL AND ADMISSION

Abscesses should be drained and necrotic tissues should be debrided, so prompt surgical referral is necessary. Hospitalization and IV antibiotics are indicated for compromised hosts who are at risk for hematogenous spread of infection (e.g., patients with poorly controlled diabetes, alcoholics, IV drug abusers, HIV-infected persons). Other indications for prompt hospital admission and IV antibiotics include rapidly progressive or recurrent infection, cellulitis caused by group A streptococci, the presence of subcutaneous gas or necrotizing fasciitis, and cellulitis of the orbit, face, or perineum, especially when accompanied by fever and lymphangitis. Clinical signs that suggest a need for IV therapy include high fever, systemic symptoms, and pain more severe than the clinical appearance would indicate. In cases of progression despite the administration of oral antibiotics, the outpatient approach to treatment must be reconsidered. When patients appear unreliable and unable to care for themselves at home, admission is also indicated. Services that allow home administration of IV antibiotics and professional monitoring can help shorten a hospital stay.

PATIENT EDUCATION

When a lower extremity is involved, the patient should be instructed to rest in bed and elevate the limb. Getting up to go to the bathroom is allowed, but bed rest is mandatory. Exercises and anticoagulation may be needed to reduce the possibility of thrombophlebitis in patients at increased risk (see Chapter 35). It is crucial to protect the affected area and insist that the patient not scratch the involved skin. The importance of taking antibiotic therapy as instructed should be emphasized. The patient should be asked to report progress by telephone and to call if cellulitis fails to resolve within 5 to 7 days.

THERAPEUTIC RECOMMENDATIONS

- Hospitalize patients unable to care for themselves reliably at home, and also anyone with high fever, rigors, lymphangitis, rapid progression, compromised host defenses, or involvement of the face, orbit, or perineum.
- Treat the patient with mild, uncomplicated illness on an ambulatory basis. Begin with 500 mg of oral *phenoxymethyl penicillin* four times daily (1 hour before meals and at bedtime), and monitor closely during the next 48 hours.
- If inflammation and fever do not begin to resolve after 48 hours or if close monitoring is not possible, prescribe a penicillinase-resistant penicillin (e.g., 500 mg of *dicloxacillin* four times daily).
- For patients markedly allergic to penicillin (type I hypersensitivity), prescribe 500 mg of *erythromycin* four times daily. Cephalosporins, such as *cephalexin*, may be substituted if the allergy to penicillin is not well documented and was not anaphylactoid. The fluoroquinolones, such as *ciprofloxacin*, are effective against gram-negative cellulitis; however, they have only moderate antistreptococcal and antistaphylococcal activity in vitro and should be used cautiously in cellulitis.
- If anaerobes are suspected, then a fluoroquinolone plus *clindamycin* or *metronidazole* is indicated.
- Patients with an open wound but without a recent tetanus booster in the past 10 years should be given 0.5 mL of tetanus toxoid IM.

Part 2: Management of Pyoderma

The common cutaneous bacterial infections include impetigo, ecthyma, folliculitis, furunculosis, and erysipelas. They must be recognized promptly by the primary physician and treated effectively with antibiotics.

PATHOPHYSIOLOGY AND CLINICAL PRESENTATION

The clinical manifestations are a function of the causative organism, environmental factors, area of skin involved, and host resistance. Primary cutaneous bacterial infections develop on normal skin and are usually initiated by a single organism, such as coagulase-positive staphylococci or b-hemolytic streptococci. Secondary bacterial infection is infection superimposed on diseased skin. Cutaneous bacterial infections may also be classified according to the depth of infection and the propensity for scarring.

Impetigo, a common condition caused primarily by *S. aureus*, begins as a small, erythematous macular lesion that evolves into a vesicle beneath the stratum

corneum. The thin-roofed collection of fluid ruptures easily, leaving denuded, oozing areas. A honey-colored crust forms as the fluid dries and collects. Intense erythema at the base of the pustule suggests a b-hemolytic streptococcal component to the condition. New lesions appear in the same location, and they coalesce. When the honey-colored crusts are removed, the skin appears raw. Individual lesions usually do not exceed 2 cm in size. Impetigo is seen most frequently in children, but it also occurs in adults, especially those with poor hygiene. In adults, the condition is not as contagious as it is among infants. The face is the most common site of involvement. Ordinary lesions do not produce scarring but may leave erythematous marks for some time. Untreated infections may last for weeks.

Ecthyma is a deeper version of impetigo, usually caused by *streptococci*, but it is sometimes a sign of gram-negative sepsis or fungal infection. Erosion of the epidermis creates ulcerative, crusted lesions. The heaped-up crust conceals the underlying erosion. Healing is accompanied by some scarring because of the depth of the lesions. The legs are commonly involved, and children are more susceptible than are adults. Antecedent conditions include eczema, scabies, arthropod bites, trauma, and living in a hot, humid climate. The *brown recluse spider bite*, characterized by necrotizing ulcer and spreading ecthyma, is important to recognize because it requires specific therapy with dapsone.

Folliculitis is infection of the hair follicles, usually caused by coagulase-positive *staphylococci*, and may be divided into superficial and deep types. Superficial folliculitis consists of a small pustule pierced by the hair shaft. It may be seen on the scalp or other hairy portions of the body. Occupational exposure to cutting oils and the use of coal tar products or topical corticosteroids under occlusive dressings may precipitate folliculitis. Fungal folliculitis caused by *Pityrosporum ovale* may resemble bacterial folliculitis, but it is refractory to treatment with antibiotics. The diagnosis is made by the finding of yeastlike organisms on a potassium hydroxide wet mount, but a skin biopsy specimen stained for fungi is sometimes required. Rarely, small pustules with surrounding erythema caused by *Propionibacterium acnes* may develop around the occiput in male patients. *Pseudomonas folliculitis* has been described in association with bathing in hot tubs.

Furuncles and Carbuncles may develop from a preceding folliculitis and are limited to hairy areas. The erythematous lesions usually become fluctuant after 4 days. A yellowish, pointed area may be seen on the surface, and, if the lesion ruptures spontaneously, pus and necrotic tissue are extruded. The buttocks, axillae, neck, face, and waist areas are common sites of involvement. Predisposing systemic factors include diabetes, malnutrition, obesity, and hematologic disorders. Carbuncles are a coalescence of deep furuncles with multiple points of drainage.

Erysipelas, caused by b-*hemolytic streptococci* (mainly group A, but also groups G, C, and B), is characterized by a peripherally spreading, infiltrated, erythematous, sharply circumscribed plaque. The lesion is warm to the touch. The face, scalp, hands, and genitals are frequently involved. Rapid evolution of the lesions is seen, and some patients have constitutional symptoms such as fever and malaise. Poor hygiene and lowered resistance promote infection. Trauma may elicit infection, and recurrent erysipelas may lead to brawny edema and lymphostasis (*elephantiasis verrucosa nostra*) in the lower extremities.

DIAGNOSIS

Lesions are usually diagnosed and treated on the basis of clinical appearance, but microscopic examination of Gram's-stained material is a quick and inexpensive way to confirm a diagnosis. Culture and sensitivity testing are usually not necessary for superficial infections but are needed for more destructive lesions or cases that fail to improve.

PRINCIPLES OF THERAPY

Physical measures are used to enhance resolution and make the skin surface less amenable to colonization by bacteria, and antibiotics are given to treat responsible pathogens and prevent recolonization.

Physical Measures. The physical measures employed differ with the pyoderma being treated. The crusts of impetigo must be debrided to expose the skin surface where bacteria are present. The use of a washcloth for this purpose is recommended. Furuncles and carbuncles are treated with hot compresses to enhance drainage. Fluctuant lesions usually require incision and drainage. Sometimes, packing of the wound is necessary. With exudative lesions, drying compresses are required to remove detritus and desiccate the lesion. Saline solution, tap water, or Burow's solution may be applied for 10 to 20 minutes three to four times a day. Dehydration improves the appearance of the skin and destroys many organisms.

Antibiotics. *Topical antibiotics* are usually sufficient for impetigo and folliculitis, particularly when combined with cleansing and debridement. Most cases of pyoderma are caused by gram-positive organisms and respond to topical *erythromycin* or *bacitracin*. *Mupirocin* (Bactroban), a creamy antibiotic ointment, is so effective that it has supplanted the use of systemic antibiotics in many cases. It is cosmetically well tolerated, although it appears slightly shiny on the skin. Washing with *chlorhexidine* (Hibiclens) is a valuable adjunct because of its bactericidal properties. Patients should wash the areas with the liquid two or three times daily before mupirocin is applied. Antibiotic creams and ointments containing *neomycin* can be used, although neomycin is a known contact sensitizer. However, sensitization usually develops only after long-term use on areas that are denuded.

Reducing colonization is particularly important in the treatment of recurrent furunculosis. Frequent cleansing with soap, particularly chlorhexidine, is useful. Nails should be clipped and vigorously scrubbed. *Mupirocin* ointment should be instilled into the anterior nares. It can be used on a long-term basis to reduce bacterial carriage in the nares of patients in whom pyoderma repeatedly develops. Additional preventive measures include soaking the beard with hot water for 5 minutes before shaving, and discarding blades after each use. Alternatively reusable razor blades can be soaked in rubbing alcohol. Separate towels, sheets, and clothing should be used, and frequently laundered and changed. If vigorous reduction of colonization is unsuccessful, consideration should be given to replacement of pathogenic staphylococci with a less pathogenic strain.

Systemic antibiotics are indicated when constitutional symptoms are present or if the patient is uncooperative. Phenoxymethyl *penicillin* is sufficient for streptococcal infection; oral *erythromycin* is effective against most staphylococcal and streptococcal species that cause pyoderma. Azithromycin is a good alternative. Resistant staphylococcal species may require *dicloxacillin* or *cephalexin*. There is no evidence that antibiotic therapy prevents poststreptococcal glomerulonephritis. As noted, antibiotic selection may be based on clinical appearance, but microscopic examination of Gram's-stained material is quick and inexpensive. Culture and sensitivity testing are reserved for more destructive lesions or cases that fail to improve.

PATIENT EDUCATION AND INDICATIONS FOR REFERRAL

A primary consideration in the therapy of all cases of pyoderma is patient education. Teaching aggressive and regular use of cleansing and debridement is central to the successful resolution of the infection. In addition, careful review of preventive measures and antibiotic use is essential.

If aggressive hygienic measures and attempts to eliminate the staphylococcal carrier state fail to prevent recurrent infection, consider referral for replacement with nonpathogenic staphylococci or treatment with rifampin, which is effective for eradicating nasal carriage of pathogenic staphylococci.

THERAPEUTIC RECOMMENDATIONS

Impetigo

- Apply compresses soaked in Burow's solution for 20 minutes two to four times daily, then debride gently with a washcloth and cleanse with a chlorhexidine-containing agent.
- Lightly apply mupirocin to the area after drying. A nighttime application is also advised.
- Advise the patient not to cover the lesions and the family to avoid using the same towel or washcloth; keep children away from the patient with impetigo.

Folliculitis

- Treat with debridement and topical antibiotics, as for impetigo.

Furuncles and Carbuncles

- Treat with hot compresses until the lesions are fluctuant and spontaneous drainage occurs. Larger lesions may require removal of the core with a 4-mm biopsy

punch to facilitate drainage.
- Treat furuncles or carbuncles that are associated with cellulitis or fever or that are located on the face with oral antistaphylococcal antibiotics, either erythromycin (333 mg three times daily for 10 days) or dicloxacillin (250 mg four times daily for 10 days).
- Treat recurrent infection with a 10- to 14-day course of a systemic antibiotic and remove bacteria from potential sources, such as the skin, nares, nails, and razors and other fomites.

Erysipelas

- Treat with cool compresses and phenoxymethyl penicillin (500 mg four times daily) for 7 to 10 days.

Recurrent Pyoderma

- Eradicate the staphylococcal nasal carrier state. Prescribe oral dicloxacillin (500 mg four times daily for 10 to 14 days) in combination with topical mupirocin applied twice daily for at least 5 days.

CHAPTER 191 MANAGEMENT OF SUPERFICIAL FUNGAL INFECTIONS

WILLIAM V. R. SHELLOW

Although they are neither dangerous nor life-threatening, superficial fungal infections are prevalent, irritating, and often recurrent. They are easily diagnosed but commonly confused with nonfungal dermatoses such as impetigo (see Chapter 184). The primary physician should be capable of providing a definitive diagnosis, cost-effective therapy, and patient education for prevention.

PATHOPHYSIOLOGY AND CLINICAL PRESENTATION

Why some people resist these ubiquitous pathogens while others cannot remains unknown. Sometimes, a systemic disease such as diabetes is responsible. Hereditary factors may be involved. Dampness, darkness, and friction leading to skin maceration are important local precipitants.

Fungal infection occurs when one of these ubiquitous organisms invades the superficial layers of the skin. Dermatophytes do not invade below the level of keratin because a potent antifungal factor prevents deeper infection. Candidal infection produces inflammatory change through elaboration of an endotoxin-like substance.

Dermatophytic and candidal infections produce scaly, erythematous lesions with defined margins; these occur in characteristic areas of the body that promote the growth of fungi.

Tinea Versicolor (Pityriasis Versicolor) is characterized by brown, pink, red, or white scaly patches on the chest, back, and shoulders. During the summer, it may present as hypopigmented areas that are sometimes erroneously interpreted as vitiligo. The organism appears to prevent pigment transfer from melanocytes to epidermal cells. The diagnosis can be suspected if scratching a macular area raises a small amount of fine scale. Examination of the skin with a Wood's light reveals gold or orange-brown fluorescence. The infection is confirmed by scraping a scaly lesion and examining it with a drop of 20% potassium hydroxide for characteristic short hyphae and spores, sometimes referred to as "*spaghetti and meatballs.*"

Dermatophyte Infections are defined by the area of the body they affect. The most common is *tinea cruris*, which involves the groin and inner thighs and sometimes even extends onto the abdomen and buttocks. *Tinea pedis* is characterized by blisters and inflammation on the soles and interdigital areas of the feet. *Tinea corporis* affects other areas of the body, including the trunk and extremities. If the face is involved, the condition may be called *tinea faciei.* *Tinea capitis*, or scalp ringworm, occurs almost exclusively in children. *Tinea barbae*, involving the bearded area, has become very uncommon and therefore might be missed in the differential diagnosis of a facial rash. *Onychomycosis* is characterized by the accumulation of subungual keratin, which produces a thickened, distorted, crumbling nail. *Trichophyton rubrum*, *Trichophyton mentagrophytes*, and *Epidermophyton floccosum* are the most common infecting organisms. *Microsporum canis*, which is acquired by contact with infected pet cats and dogs, is another common pathogenic fungus.

Candida Infections of the skin occur principally in *intertriginous* locations, such as the axillae, groin, intergluteal folds, inframammary area, and interdigital web spaces. Crusted involvement of the labial commissures, known as *perlèche*, and involvement of the *glans penis* also occur. The presence of erythema on the glans penis and scrotum suggests a candidal rather than a dermatophyte infection. Lesions are pustular and thin-walled, located on a red base, and often produce burning and itching. Candidiasis may be clinically suspected in the presence of characteristic *satellite pustules* outside the margin of the primary lesion.

DIAGNOSIS

The finding of scaly, erythematous lesions with defined margins in characteristic areas of the body that promote the growth of fungi should raise suspicion of a superficial fungal infection. Satellite pustules suggest a candidal involvement. In intertriginous areas, fungal infection must be differentiated from intertrigo and erythrasma. Asymptomatic, slightly erythematous to light brown, finely scaling patches in the groin and upper thigh with little or no central clearing are characteristic of erythrasma (a corynebacterial infection). Early intertrigo is characterized by slight maceration and erythema. With time, the redness becomes more intense, and the epidermis becomes eroded or even denuded.

Potassium Hydroxide Preparation. When dermatophyte infection is suspected, microscopic examination of scrapings from an involved area of skin is required. To prepare a specimen for microscopic examination, the border of the lesion is scraped lightly with a No. 15 scalpel blade or the edge of a microscope slide. The scale is collected onto a clean microscope slide, and a coverslip is used to push all the scale into a small mound. One or, at most, two drops of 20% potassium hydroxide solution or potassium hydroxide with dimethyl sulfoxide (DMSO) are placed in the center of the mound of scale, and a coverslip is laid over it. If the potassium hydroxide solution does not contain DMSO, the slide must be heated lightly to improve "clearing" of the epithelial cells. If DMSO is present, heating is not required.

Under a magnification of 40× with reduced light, threadlike hyphae can be seen crossing cell walls. If budding spores and pseudohyphae are found, the diagnosis is candidal infection.The presence of branched, septate hyphae can be confirmed by using higher power (100x). This second step is necessary to make sure that artifacts are not being mistaken for hyphae. The wet mount should be examined within a few hours. Especially if potassium hydroxide with DMSO is used, the hyphae will dissolve after a period of time. Occasionally, a scraping must be planted on Sabouraud's dextrose agar for culturing to identify the fungal infection.

If candidal infection is identified or topical fungal infection is recurrent or extensive, one should check for conditions associated with immune compromise (e.g., HIV infection, diabetes, cirrhosis, lymphoma, steroid use, chemotherapy).

PRINCIPLES OF MANAGEMENT

Effective management requires attention to predisposing factors and proper use of antifungal agents. For example, systemically, diabetes control should be tightened and the use of immunosuppressive agents cut back. Locally, the *elimination of moisture* and *prevention of maceration* are priorities (see below and Chapter 188). Further drying of inflammatory or weeping lesions can be achieved with the application of compresses containing an astringent such as aluminum acetate, available as *Burow's* tablets or packets.

After predisposing factors have been reduced and the lesions dried, specific antifungal medication is appropriate. A host of effective agents are available. One should identify and use the least expensive, most effective agent that produces the fewest side effects. Patients with fungal infections have invariably tried over-the-counter remedies before they visit the physician. It is important to find out what they have used before prescribing the same product in its prescription version.

Antifungal Agents

Topical Agents. Four classes of topical antifungal agents are currently available (azoles, ethanolamines, allylamines, and polyene antibiotics). The over-the-counter preparations are the least expensive (although not necessarily inexpensive). New topical antifungal agents appear regularly and are usually the most costly (e.g., butenafine, terbinafine). Claims of unique efficacy are made for each one, but most within a given class provide similar cure rates. Most topical agents provide a cure rate of better than 85% for acute infections, but the rate is much lower for chronic infections. Topical lotions are more drying, less messy, and more useful for daytime application; a cream should be used at night.

Azoles comprise the largest class of topical antifungal agents; the older ones (*miconazole, clotrimazole, tolnaftate*) are available without prescription. Others include *econazole* (Spectazole), *oxiconazole* (Oxistat), *sulconazole* (Exelderm), and *ketoconazole* (Nizoral). In general, these are slightly less effective than the allylamines for

the treatment of tinea pedis, but the nonprescription preparations are considerably less expensive.

Ethanolamines. This class of agents is represented solely by *ciclopirox olamine* (Loprox). The drug is best at penetrating the nail plate, which makes it useful as an adjunct topical treatment of onychomycosis.

Allylamines. These agents include *naftifine* (Naftin) and *terbinafine* (Lamisil). *Butenafine* (Mentax) has a structure similar to that of the allylamines. The allylamines are unique in that they are both fungicidal and fungistatic. Cure rates are slightly better with these agents, but cost tends to be substantially higher.

Polyene Antibiotics. Topical *amphotericin* and *nystatin* represent this class of antifungals. They are primarily anticandidal.

Combination Therapy. If marked improvement of clinical lesions and symptoms is not seen within 3 weeks, it may help to try *combination therapy*, with an antifungal agent from one class used during the day and another from a different class applied at night.

Oral Drugs. Orally administered systemic therapy may deserve consideration if a patient's condition appears to be refractory to topical therapy and discomfort from the superficial fungal infection is sufficiently severe. The risks and benefits must be weighed carefully. Such therapy is most likely to be appropriate for patients who are immunocompromised (e.g., those with HIV infection, lymphoma, chemotherapy, cirrhosis). However, the systemic antifungal agents are potentially toxic to bone marrow and liver and must be used with care, especially if prolonged courses of therapy are needed. Rapid clearing of dermatophyte infection is likely to follow, but relapses are common and recurrent courses of therapy may be necessary. An awareness of the risks associated with the commonly used oral therapies helps inform clinical decision making.

Itraconazole (Sporanox) is an orally active azole. Common side effects include nausea and abdominal discomfort; hepatitis has been reported. The potential for important *drug–drug interactions* is considerable because itraconazole *inhibits hepatic microsomal cytochrome systems.* The concentrations of many hepatically metabolized drugs are increased substantially, including digoxin, terfenadine, astemizole, triazolam, sulfonylureas, cisapride, felodipine, and quinidine. *Fatal cardiac arrhythmias* (torsades de pointes) have occurred in patients taking *terfenadine* or *cisapride* concurrently. When itraconazole is taken concurrently with *oral hypoglycemics,* the risk for severe, prolonged *hypoglycemia* is increased. High doses can cause hypokalemia and hypertension, and thrombocytopenia and leukopenia have been reported.

Terbinafine (Lamisil), an allylamine also approved for oral use in onychomycosis, causes fewer drug–drug interactions than itraconazole does, but rare instances of serious *skin reactions* (e.g., Stevens-Johnson syndrome), symptomatic *hepatobiliary dysfunction*, and *ocular lens* and *retinal changes* have been reported. The drug is cleared by the liver, and clearance is reduced by concurrent use of cimetidine or terfenadine. Common side effects include headache (13% of patients), gastrointestinal upset (16%), rash (6%), liver enzyme abnormalities (3%), and taste disturbances (3%). Liver enzymes should be measured before treatment is begun and again after 6 weeks if a longer treatment course is contemplated. The complete blood cell count should also be monitored because of reported instances of severe but reversible neutropenia.

Griseofulvin, the original oral antifungal for onychomycosis, can cause leukopenia, so that periodic blood cell counts are necessary. Liver function also must be monitored because of the risk for hepatocellular injury. Bone marrow suppression and serious hepatocellular toxicity are uncommon complications.Headache, nausea, and abdominal discomfort are common side effects.

Ketoconazole (Nizoral). Immunocompromised patients with superficial fungal infection too widespread to be managed with topical therapy are candidates for systemic *ketoconazole.* For best results, ketoconazole should be taken with an acidic fruit juice to enhance absorption. Side effects include itching, rash, and dizziness. Serum testosterone is reduced, which may lead to gynecomastia in men and menstrual irregularities in women. Mild hepatocellar injury is common; severe impairment is rare. The risk for fatal idiosyncratic hepatotoxicity is nil when ketoconazole is taken for less than 2 weeks, but the drug should be stopped immediately whenever symptomatic hepatocellular dysfunction appears.

Fluconazole (Diflucan) is well tolerated and useful for candidal infections, but it can be teratogenic and in rare instances is associated with hepatic necrosis, Stevens-Johnson syndrome, and anaphylaxis. Gastrointestinal upset and rash are common. A few drug–drug interactions have been noted, including potentiation of phenytoin, anti-HIV agents (zidovudine, indinavir), warfarin, and sulfonylureas.

Treatment of Specific Conditions

Tinea Versicolor. For effectiveness, convenience, and least expense, a 2.5% suspension of *selenium sulfide* (Selsun) or a *pyrithione zinc* shampoo (Zincon, Head & Shoulders) can be applied with a rough washcloth. It should be allowed to remain on the affected areas for 10 minutes and then rinsed off. Daily application for 1 week is recommended. An 87% success rate at the end of 4 weeks was found with use of this program. In refractory cases, selenium sulfide suspension can be left on the skin overnight, with care taken to avoid the scrotal area. The topical antifungal agents are much more expensive but are useful in treating recalcitrant involvement of small areas. *Ketoconazole shampoo* is quite effective for treating tinea versicolor.

After treatment, patients should be reexamined for continued scaling, which suggests persistent activity. Patients with no signs of persistence or relapse should be advised that depigmentation may persist until they go back into the sun.

For immunocompromised patients with infection too widespread to be managed with topical therapy, systemic *ketoconazole* is worth consideration. A dose of 200 mg is prescribed daily for 7 to 10 days. For best results, ketoconazole should be taken with an acidic fruit juice. An alternative method is to take 400 mg once, then exercise to induce sweating. The patient is advised not to shower until the next day. This regimen is repeated 1 week later and can also be repeated monthly to prevent recurrence.

Other Diffuse Forms of Tinea. In moist intertriginous areas, the patient should dry oozing lesions by applying compresses soaked in *Burow's solution* for 30 to 60 minutes one to three times daily. A nonmedicated or antifungal *powder* may be used to absorb moisture. With very inflamed pruritic lesions of the groin and other intertriginous areas, the addition of a *topical corticosteroid* can help relieve the inflammatory component, and a topical corticosteroid is often prescribed in conjunction with topical antifungal therapy (see Chapter 188). Topical treatment suffices when glabrous skin is involved, but systemic drugs should be considered if hair sheaths are involved, involvement is widespread, or folliculitis develops.

Tinea Pedis. Athlete's foot is sometimes difficult to treat. The patient must be instructed to wear nonocclusive leather footwear or sandals and absorbent cotton socks, and to dry the feet frequently without rubbing, perhaps by using a hair dryer. *Topical antifungals* alone often suffice. The allyalmines are more effective than the azoles, but they are much more expensive than the nonprescription azoles and might be reserved for refractory cases. Naftifine cream used once daily is effective for tinea pedis and may yield better results than clotrimazole used twice daily. If widespread scaling with hyperkeratosis occurs ("moccasin-type" tinea pedis), *keratolytic agents* are required. The nightly application of Keralyt gel (6% salicylic acid) under occlusion, with antifungal creams used two to three times daily, may successfully treat this difficult problem.

Onychomycosis. Nail involvement by fungus is extremely refractory to treatment, although fingernail infections usually respond better than do toenail infections. Most topical agents cannot penetrate the nail plate, but *topical ciclopirox* (Loprox) may, and it can be tried nightly with applications under occlusion. Weeks to months of treatment may be necessary before improvement is noted. Often, topical therapy is insufficient, and the question of employing systemic antifungal therapy comes up. The value of the cosmetic benefit must be weighed against the cost and risks of prolonged systemic treatment. Even with successful therapy, relapse is common.

Itraconazole (Sporanox) is aggressively promoted for the systemic treatment of onychomycosis. Dosing can be continuous (200 mg daily for 6 weeks for fingernail infections and 12 weeks for toenail infections) or intermittent (pulsed). In pulsed dosing, 200 mg of itraconazole is given twice daily for 1 week each month. Fingernail infections are treated with two pulses and toenails with three to four. Clinical cure rates of 93% have been reported with pulsed dosing, versus only 80% with continuous therapy. In trials comparing itraconazole with terbinafine, another antifungal agent used to treat onychomycosis (see below), mycologic cure rates approached 65% with a 3-month course of once-daily therapy. The drug remains in the nails for up to 9 months after discontinuation of treatment. The nails will probably not be clear when the drug is stopped, and the patient must be told that continued clearing is to be expected during the next several months.

Terbinafine (Lamisil) is another heavily promoted agent for the treatment of onychomycosis. Mycologic cure rates of 75% to 90% at 1 year have been noted. In blinded comparison studies, results have been superior to those for itraconazole at 1 year. However, relapse rates are still in the range of 15%. This drug is taken once daily

(250 mg) for 6 weeks for fingernail infections and for 12 weeks for toenail infections. As noted above, in comparison with itraconazole, terbinafine causes fewer drug–drug interactions, but the complete blood cell count and liver enzymes should be monitored periodically because of the potential for bone marrow and liver injury.

Griseofulvin used to be the only available systemic treatment for onychomycosis. Treatment (250 mg two to four times daily) must be continued for 6 to 12 months until the infectedportion of the nail has grown out to the end. Sometimes, it is necessary to remove the affected nail. Use has declined with the advent of safer, better-tolerated oral antifungal agents. Even if a cure is obtained, reinfection is common.

Ketoconazole was formerly used to treat patients with severe disease who did not respond to griseofulvin or who could not tolerate it, but because the risk for hepatotoxicity is greatly increased during prolonged treatment, some authorities no longer recommend that it be used for this condition, especially now that less toxic alternatives are available (see above). Baseline liver function should be documented with testing and laboratory studies repeated at least monthly.

Fluconazole is an effective systemic antifungal agent. To date, it has not yet been approved for use in onychomycosis. Based on clinical trails, the expected dosing schedule will be 300 mg once a week for up to 9 months.

Cost. The oral antifungal agents used to treat onychomycosis of the toenails can be compared by cost. According to the average wholesale prices given in the 1999 Costs and Comparisons (red book), a 12-month course of Gris-PEG (250 mg four times daily) would cost $1,577, and a course of Fulvicin P/G (330 mg three times daily) would cost $1,467. Sporanox given as four pulses would cost $876; three pulses would cost $657. Twelve weeks of Lamisil would cost $613. Because these are wholesale prices, the patient would have to pay more.

Summary. The cosmetic effects of fungal nail infection and the enhanced efficacy of available systemic agents should be weighed against the considerable expense of such therapy, its potentially serious side effects, and the need for careful monitoring and frequent blood testing. Many patients will choose to live with their fungal nail infection, especially when it is limited to the toenails (use of separate nail clippers helps to prevent spread). Many women find that they can substantially reduce cosmetic unsightliness by filing down the hyperkeratotic nail and covering it with nail polish.

Candidal Infections. Treatment begins with attention to predisposing factors, such as the use of systemic corticosteroids, birth control pills, tetracycline, and other antibiotics and the presence of diabetes, Cushing's syndrome, and HIV infection. One proceeds to meticulous drying of the area, adequate exposure to air, and specific anticandidal therapy. Gentian violet or Castellani's paint are time-proven but quite messy remedies and have largely been abandoned. Imidazole creams or lotions (e.g., *clotrimazole cream*) should be used two or three times daily, but ointments should be avoided because they maintain a moist local environment. In highly inflamed infections, initiating therapy with the combination of a topical *corticosteroid* cream and a light application of *clotrimazole* (Lotrisone) is useful. *Fluconazole* (Diflucan) is an effective oral anticandidal agent for extensive or refractory infection.

Paronychial Infection is difficult to treat. Therapy consists of avoiding exposure to water and using rubber gloves with a cotton lining whenever contact with water is unavoidable. *Nystatin lotion* or amphotericin B (Fungizone) lotion should be applied two to four times daily to the affected area. In highly inflamed conditions, nystatin or clotrimazole with steroids may be applied overnight under a fingercot. Nails grow out normally after the paronychia has healed. Fluconazole should be given orally if local therapy fails but is quite costly for the patient.

Angular Cheilitis (Perlèche) requires combined treatment, including correction of the primary oral abnormality to prevent leakage of saliva through the corners of the mouth and treatment of a possible secondary infection. The combination of *nystatin* and *triamcinolone* acetonide as an ointment formulation is the most effective topical agent. It should be used sparingly three times daily. Dental procedures should be directed at restoring the seal at the angles of the mouth. For persistent cases, the depth of the grooves of the angles may be reduced with collagen implants. *Fluconazole* may be of value in treating persistent episodes.

INDICATIONS FOR REFERRAL

Referral to the dermatologist should be considered if a fungal infection proves refractory to conventional topical treatment and prolonged or repeated systemic therapy is being contemplated. Consultation for consideration of the risks and benefits can be quite worthwhile, as can a second look at the problem. Short courses of systemic therapy (2 weeks) entail little risk and often do not require dermatologic referral.

PATIENT EDUCATION

At the time of the first incident, patients with fungal infection should be instructed about appropriate measures to prevent recurrence.

Maintaining Dryness. Instructing the patient about how to keep the skin dry and prevent maceration is critical to both successful treatment and prophylaxis. Dryness is particularly important in tinea pedis, tinea cruris, and candidal infections. Preventive measures should be taken in areas that have shown a tendency to become infected. In addition, the patient should be told to apply powder liberally to naturally moist areas of the body and to wear cotton clothing and loose-fitting underwear. Also, patients with tinea pedis should always wear socks and avoid sneakers and rubber-soled shoes, and the physician should encourage exposure of the feet to the air as often as possible. Lastly, people who sweat profusely should change their clothing more frequently, shower, and apply nonmedicated talcum powder.

Other Advice. Fungal infections may be slow to clear. To ensure compliance, it is essential to instruct the patient carefully about appropriate application and duration of treatment. Patients should be told to call at the first sign of recurrence and to institute appropriate drying measures and specific therapy after physician consultation.

THERAPEUTIC RECOMMENDATIONS

- Prescribe a topical preparation approved for once-a-day use. This is cost-effective and is also likely to improve patient compliance.
- Avoid prescribing creams for intertriginous areas because patients may use too much medication and thereby increase maceration. Prescribe a lotion or solution instead.
- If clearing is incomplete after 2 to 3 weeks, the short-term use of a systemic antifungal should be considered.
- For patients with onychomycosis, the expense and potential for serious adverse effects of systemic agents should be carefully weighed against the cosmetic consequences of living with the untreated condition.

CHAPTER 192 MANAGEMENT OF CUTANEOUS AND GENITAL HERPES SIMPLEX

Herpes simplex virus is a ubiquitous virus that clinically affects humans. *Herpes simplex virus type 1* (HSV-1) is the prototypical infectious agent in cutaneous disease of the upper body; *herpes simplex virus type 2* (HSV-2) generally infects the genitals and lower body, but the two types share 50% of their genetic material and may be interchangeable clinically. They differ slightly in sensitivity to antiviral drugs and in their proclivity to cause specific disease in other organs. Serologic studies indicate a 22% prevalence for HSV-2 infection among adults in the United States.

Many patients seek confirmation of a suspected herpes infection or treatment of frequent and recurrent rashes and symptoms. The primary care physician must know how to obtain a prompt diagnosis, utilize the current approaches to prevention and treatment, and address the patient's concerns and negative social stigmata that often accompany genital infection.

PATHOPHYSIOLOGY AND CLINICAL PRESENTATION

The severity and duration of symptoms are a function of the patient's state of immunity to HSV. In primary infection, preexisting antibody protection is lacking, and symptoms tend to be more severe and longer-lasting than at other stages of the illness. With time, the frequency and severity of recurrences tend to decline, especially with HSV-1 infection. Some cross-type antibody protection is also afforded, so that when a person with a prior history of HSV infection of one type contracts HSV infection of another type (i.e., first episode of nonprimary herpes), the resulting clinical presentation is less severe than that of primary disease. Because of their inability to mount effective antibody responses, immunocompromised patients are at great risk for severe, sustained outbreaks (see Chapter 13).

Primary Infection

Primary infection is usually the most dramatic form of HSV disease, but the spectrum of presentations is wide, ranging from asymptomatic disease to a florid outbreak with systemic symptoms. The characteristic lesions are *erythematous papules* that evolve during 2 to 3 days to *vesicles* with clear fluid, then progress to *pustules* that erode and leave superficial, tender *ulcerations*, especially in moist areas. Healing occurs within 2 to 6 weeks. *Systemic symptoms* develop in one third of men and two thirds of women; fever, malaise, nausea, headache, and myalgias are all reported. *Meningeal irritation*, manifested by headache, stiff neck, and photophobia, can occur. *Regional lymphadenopathy* is characteristic of primary infection; the nodes are enlarged, firm, and tender.

Primary HSV-1 Infection usually goes unnoticed but may present as severe *exudative pharyngitis* or *gingivostomatitis*, with high fevers and tender lymphadenopathy. The illness often is mistaken for streptococcal disease, other bacterial infections of the oropharynx, or mononucleosis. Systemic manifestations of the illness may be more prominent than local symptoms. HSV-1 infection may also present as painful *genital lesions*, a consequence of oral–genital sexual activity and an unappreciated risk factor for neonatal herpes.

Primary HSV-2 Infection also may be missed or misdiagnosed. In its most overt form, an exudative, painful bilateral *vulvovaginitis* is seen in female patients and painful *penile ulceration* with tender inguinal nodes in male patients. The genital lesions are painful in 95% of men and 99% of women. *Cervicitis* develops in nearly three fourths of women with primary infection, manifested by vaginal discharge and intermenstrual spotting. Local symptoms increase during the first 6 to 7 days of illness and peak between days 8 and 10, gradually decreasing during the next week. Lymph nodes are enlarged, firm, and tender. Although suppurative lymphadenopathy does not occur, superimposed bacterial infections can produce this finding.

Primary genital infection usually takes place in adolescence, but it may be contracted at the time of birth. Fever and malaise occur in 67% of patients, dysuria (resulting from urethral involvement or urinary irritation of ulcers) in 63%, and tender adenopathy in 80%. In 20%, extragenital lesions appear on the hands or in the oropharynx. Complications include secondary *yeast infection* in 11%, *aseptic meningitis* in 8%, and *sacral autonomic neuropathy* leading to bladder or bowel dysfunction in 2%. *Cervical cancer* is strongly associated with HSV-2 antibodies or the presence of HSV-2, although no study or series has directly found HSV genetic material within these cancer cells. The association of HSV infection with cervical cancer may be epidemiologic rather than etiologic.

Uncommon Presentations of Herpes Simplex Viral Infection. An unusual form of primary infection results from implantation of virus into broken skin; this produces a *herpetic whitlow* characterized by pain, swelling, and erythema of the fingers with pronounced adenopathy. In wrestlers, *herpes gladiatorum*, a primary herpes infection, may develop on exposed parts of the body that are inoculated during the rough activity of wrestling.

First Episode of Nonprimary Disease

In most cases, a first episode of nonprimary disease represents new infection with HSV-2 in persons with clinical and serologic evidence of HSV-1 exposure earlier in life. Patients with a past history of fever blisters or cold sores note a new onset of painful genital lesions. The severity and duration of symptoms are characteristically intermediate between those of primary infection and recurrent disease—lesions are fewer in number, and healing takes place within 1 to 3 weeks. Cervicitis, urethritis, adenopathy, and systemic symptoms are minimal, if present at all.

Recurrent Infection

After primary infection, latent disease develops in all patients, with the virus residing in the associated dorsal root ganglion and circulating along the endoneural sheath to the skin if host defenses break down. Emotional or physical stress, sunburn, and skin trauma are among the reported precipitants. The result is a localized, self-limited form of illness with fewer lesions that resolve more quickly than in primary infection. Recurrent infection may begin with a prodrome of tingling or discomfort in the skin, and sometimes mild systemic symptoms are present, although they are not as severe as in primary disease. Genital disease may recur in a nongenital area (e.g., legs or buttocks) in about 10% of cases. If both genital and nongenital lesions are present at the time of primary infection, the chance of a nongenital recurrence is close to 50%.

Although pain without rash develops in some symptomatic patients, most patients experience the characteristic *maculopapular–vesicular* eruption. The lesions become turbid as interferon is produced in the vesicles and as lymphocytes stimulated by interleukin-2, interleukin-6, and other cytokines begin controlling the infection. During the initial 3 to 4 days, some patients inoculate themselves in other areas (hands, eyes, periorbital areas), but secondary infections are usually brief, mild, and self-limited, and disease is not established in new regions. Infections can recur in different distributions along the same ganglia, and heterogeneity characterizes the illness.

Eventually, reepithelialization of the skin occurs, usually without scarring. Secondary bacterial infections (caused by streptococci or staphylococci) can lead to cellulitis and lymphangitis and must be anticipated. The risk for transmission is greatest in the first 96 hours after the appearance of the rash. Even without evidence of disease, silent shedding occurs in 2% to 5% of patients, particularly those with recurrent genital disease.

Complications of local recurrent infections are few but can be clinically important, such as *hemorrhagic cystitis, dyspareunia*, and *sacral radiculopathy* (which leads to difficulty in voiding, fecal soilage, or both). Sacral disease is also associated with a risk for recurrent *aseptic meningitis*. Perirectal disease can cause *proctitis*. Disseminated disease is rare, even in immunocompromised patients, but lesions of autoinoculation may occur on the fingers or about the eyes. Recurrent disease sometimes takes the form of *erythema multiforme* without evidence of vesicles. In atopic persons, HSV can produce a devastating generalized *eczema herpeticum*. Chronic pain syndromes associated with infection but without lesions are being identified more frequently. *Post-herpetic neuralgia* caused by HSV-1 is described as a recurrent syndrome without clinical evidence of skin lesions. Vulvar burning alone may be an expression of HSV-2 infection. *Elsberg's syndrome* with radiculomyelopathy and acute urinary retention may also be secondary to clinically inapparent disease. HSV has been associated with an acute *retinal necrosis*

syndrome presenting as eye pain and visual loss.

Asymptomatic Disease

Most recurrences of genital herpes present as asymptomatic disease that is overlooked by both patient and physician, either because symptoms are very mild or atypical or because the only manifestation is truly asymptomatic shedding of virus. It is in this stage that the disease is most likely to be transmitted to sexual partners.

Neonatal Herpes

Neonatal HSV is most often the consequence of direct contact between the infant and HSV (both type 1 and type 2) during passage through the birth canal of an asymptomatic mother with active genital infection. Risk is estimated at 10% in women with recurrent or primary infection at 32 weeks and is several times higher if infection is present at term in the absence of antibody production. Congenital HSV infection frequently leads to death or severe neurodevelopmental problems. Acquisition of HSV infection early in pregnancy followed by a normal antibody response does not appear to compromise the outcome of pregnancy, but infection in the last trimester may not leave enough time for type-specific antibodies to form, so that the infant is at risk.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of genital ulceration in conjunction with inguinal lymphadenopathy includes *syphilis* and *chancroid* (see Chapter 141). Ulcerations may also be associated with noninfectious conditions, such as Behçet's syndrome and inflammatory bowel disease, or may simply represent excoriation and secondary bacterial infection caused by vigorous sexual activity. Syphilis serology should always be obtained in the setting of a genital ulcer, even one that is painful. Approximately 50% of ulcerative lesions in the genital area prove to be herpetic.

WORKUP

History. In most instances, the diagnosis is a clinical one, based on finding the characteristic lesions. However, atypical disease is common, particularly in the genital area, so that quick diagnosis is difficult. A detailed sexual history is essential (see Chapter 229) and must include inquiry about oral–genital sexual activity, as HSV-1 can also be a source of genital infection. Any history of genital redness, spotting, fissures, pain, and paresthesias, even in the absence of skin lesions, should raise suspicion of genital herpes. Any prior history of fever blisters or cold sores should also be noted because it indicates prior HSV infection and helps to identify patients with a first episode of nonprimary disease.

Physical Examination. Besides helping to identify early vesicular lesions as herpetic ("dew drop on a rose petal"), the physical examination is especially important for differentiating HSV infection from other causes of genital ulcer. Unlike the very tender ulcer of HSV infection, the ulcer (chancre) of primary syphilis is indurated and painless or only minimally uncomfortable. As in genital herpes, the base is clean, and tender, firm, nonfluctuant inguinal adenopathy may be present. These findings contrast with those of chancroid, which are characterized by very tender, soft, purulent ulcerations in conjunction with sore, fluctuant lymph nodes and erythema of the overlying skin.

Laboratory Studies. Unroofing a vesicle and performing a *Tzanck test* (see Chapter 193) can be helpful, but this is less specific than *viral culture*, which is also the most sensitive of the commonly available tests. The results (including typing) can be available within 2 to 3 days, which makes it of practical value. The best time to culture is within 48 hours after the onset of symptoms; the highest-yielding lesions are intact vesicles, pustules, and early moist ulcers. *Antigen detection* (by direct fluorescent antibody testing) is of limited sensitivity, and false-negative rates are high when it is used in populations with a low prevalence of HSV infection. Typing is not achieved. Only when used in settings of high HSV prevalence does the predictive value of a positive test result rise sufficiently to warrant its use. *DNA probes* are under development to provide a more sensitive, specific, and rapid approach to viral detection and typing. The use of *polymerase chain reaction* assays to detect the presence of specific DNA or RNA sequences offers the most sensitive and specific means for diagnosing active disease; cost is a consideration, but once these tests become widely available commercially, their cost should decrease, and they are likely to become the test of choice. Promising monoclonal and oligoclonal detection methods are also under development.

Serology can confirm prior infection, but such information is less useful in the evaluation of an ongoing episode because titers often do not rise sufficiently, and cross-reactivity between HSV-1 and HSV-2 occurs. *Western blot* assay promises to provide sensitive and specific type-specific antibody testing, but it is not yet widely available. Most commercial laboratories are presently unable to provide reliable type-specific antibody testing. Serology also has the disadvantage of not producing data while the patient is clinically affected, and patients, once exposed, carry titers forever, whether or not their infection becomes reactivated. Antibody testing could be used to identify persons at increased risk for primary infection (i.e., pregnant women with no antibody titers).

Genital herpes is a major cause of types II and III abnormalities on Papanicolaou smear and should be routinely sought if these changes are seen. It is important to differentiate this benign inflammatory abnormality from real metaplastic or anaplastic disease (see Chapter 107).

PRINCIPLES OF THERAPY

Because HSV infection is incurable and characterized by self-limited symptomatic recurrences and asymptomatic recurrences in which virus is shed, the goals of therapy center on reducing the duration of symptoms, the frequency and severity of recurrences, and the risk for transmission. Because treatment is either symptomatic or prophylactic, decisions regarding the use of antiviral therapy are customized to the physical and psychosocial needs of the patient. Treatment of symptomatic recurrences is most effective when initiated at the first sign of a relapse (during the prodromal phase); half of outbreaks can be prevented with an early start to antiviral therapy. Initiation of therapy after skin lesions have appeared is less effective, shortening the course of illness by little more than a day. Suppressive therapy can be offered to persons bothered by frequent recurrences and to those who want to decrease asymptomatic viral shedding and risk for transmission, especially to an antibody-negative partner.

The nucleoside analogues (acyclovir, valacyclovir, and famciclovir) are the principal antiviral agents available for use against HSV. They are effective for symptomatic treatment of primary and recurrent disease and can prevent recurrences and shedding of virus; however, they do not cure HSV infection. Emergence of resistant strains is very rare when antiviral therapy is used in immunocompetent persons, but it has been observed in those who are immunocompromised and take these agents for prolonged periods.

Acyclovir, the first of the nucleoside analogues, acts as a purine analogue substrate for viral thymidine kinase, which is uniquely activated in cells that are infected with HSV. Acyclovir is effective against both types of HSV, although HSV-1 is more sensitive. Oral acyclovir shortens viral shedding time and reduces the time to healing and crusting of lesions. The earlier the treatment is instituted, the better. Continuous use of acyclovir in patients with frequent recurrences reduces the number and severity of repeated episodes. Unfortunately, once the drug is discontinued, its effect on recurrence ceases. Long-term use is associated with slow adaptation of the virus to the drug, but clinically important resistance has not been reported. Cessation of use results in reversion to original sensitivity. One can readily treat for 12 months at a time without adverse consequences. Side effects include *nausea, headache,* and *vomiting*. Elimination is renal, and downward dose adjustment is required in the setting of azotemia. Half-life is less than 4 hours, so that frequent dosing is necessary.

The use of acyclovir for genital herpes in *pregnancy* appears to decrease dramatically the chance of fetal transmission in the last trimester, but safety remains to be established. Often, a cesarean section is advocated in these cases. IV acyclovir is indicated in *immunocompromised hosts* and in persons with disseminated disease, such as meningoencephalitis. IV acyclovir produces higher, more consistent blood levels than does oral acyclovir, which is only 15% absorbed. The oral vehicle is acceptable for mucocutaneous manifestations in immunocompetent hosts.

Topical acyclovir is of little use, although it has some limited efficacy in primary infection. Topical acyclovir is also of little use in keratoconjunctivitis, a dangerous illness; trifluorothymidine ointment plus oral or IV acyclovir should be used.

Famciclovir was developed to improve the absorption and effective half-life of acyclovir, so that higher serum levels could be obtained with less frequent dosing. Famciclovir is a nucleoside prodrug that is stable and well absorbed in the gastrointestinal tract and converted in the small bowel and liver to penciclovir, the active agent. The drug is effective in treating and suppressing recurrent infection and has also been used successfully for treating primary genital infection. No head-to-head studies have compared this agent with acyclovir. Adverse effects include nausea, dizziness, and headache. Drug–drug interactions are possible because the

conversion of famciclovir requires hepatic oxidative metabolism. Elimination is by renal tubular excretion, so that dose reduction is necessary in the setting of renal insufficiency and the concurrent use of such drugs as probenecid. No interactions with cimetidine have been observed.

Valacyclovir, a prodrug of acyclovir, is rapidly absorbed and converted to acyclovir in its first pass through the intestines and liver. Higher serum levels of acyclovir are attained than with oral administration of acyclovir. A regimen of 250 mg of valacyclovir four times daily provides the same serum levels as 800 mg of acyclovir five times daily. Efficacy is similar to or better than that of acyclovir and famciclovir. Side effects are nausea, vomiting, diarrhea, and headache. Interactions with cimetidine and probenecid are possible. The efficacy and safety of valacyclovir have not been established in immunocompromised patients and those with disseminated disease; thrombotic thrombocytopenic purpura and hemolytic/uremic syndrome have been reported in association with valacyclovir treatment in patients with advanced AIDS.

Adjuncts. Good local skin care and the use of drying agents to speed the transition from active vesicle to crusting are the essence of adjunctive therapy. Topical surfactants such as ether and chloroform seem to provide some additional relief. Some have advocated, with little evidence, the use of cimetidine because of research evidence suggesting that histamine2 antagonists have antiherpes activity. Vidarabine, ribavirin, bromodeoxyuridine, and ganciclovir sodium have shown some promise of antiviral activity. Care of skin lesions is especially important in the immunocompromised or eczematous host, in whom dissemination and autoinoculation can lead to serious consequences.

Some clinicians use *topical corticosteroids* to abort the progression of herpetic lesions. This empiric approach often works, although scientific evidence is lacking and there is a theoretical concern about spread. However, no evidence has been published to document this danger.

Over-the-counter preparations such as Blistex, Campho-Phenique, and Anbesol may provide minimal symptomatic relief but do not affect the course of the eruption. Considering the long history of ineffective therapy, physicians should remain skeptical about new remedies offered.

Vaccines. Evidence is growing that benign latency can be maintained by long-term modulation of the immune system with vaccines. Of particular interest is a vaccine against HSV-2 to reduce the risks for genital herpes and associated neonatal disease. Initial results were encouraging, but further studies have been less so. Work is ongoing.

PATIENT EDUCATION

Genital Herpes. Reassurance of the frightened patient with genital herpes (and partner) is critical. The primary care physician can help reduce the shame and suspicion that often accompany confirmation of the diagnosis. Herpes has acquired an unjustifiably vicious reputation in the media, not only as a risk factor for neonatal tragedy but also as a sign of sexual infidelity. Patients need to understand that genital herpes could have beenacquired decades ago and that asymptomatic shedding of virus is the most likely mode of transmission. Guilt can be assuaged by providing approaches to the prevention of transmission (e.g., safe sexual practices, suppressive therapy). Women of childbearing age appreciate knowing how neonatal herpes can be avoided and what they and their obstetrician can do to contribute to a safe delivery.

In educating patients about transmissibility, it is important to inform them about what constitutes a high-risk situation (e.g., unprotected sexual intercourse; oral–genital sexual activity between an infected patient and an antibody-negative partner, especially one who is pregnant). The concept of asymptomatic shedding must be appreciated by the patient. Transmission is less likely with the use of *condoms* but is still possible. If the presence of antibody in a sexual partner is confirmed, anxiety surrounding sexual relations can be reduced.

Pamphlets about the disease are available through the Centers for Disease Control and Prevention, the National Institutes of Health, and the American Social Health Association. These sources of information are superior to many of the lay-initiated hotlines, which tend to overplay the emotional problems. It should be emphasized that recurrent infection is far less likely to produce discomfort or pain than primary infection.

Facial Involvement. Facial lesions are always annoying and are embarrassing to some. Protection from sunburn and trauma should be urged, as should good local care, with use of drying agents to speed the transition from active vesicle to crusting. Patients are reassured by knowing that the risk for scarring is very small and that effective oral therapy is available for shortening severe episodes and reducing the risk for recurrence.

INDICATIONS FOR REFERRAL AND ADMISSION

Consult with an obstetrician regarding the safety and advisability of antiviral treatment in the third trimester versus cesarean section at the time of delivery to prevent HSV transmission to the fetus. Patients with suspected eye involvement should be referred urgently to an ophthalmologist for eye examination and treatment with trifluorothymidine and acyclovir. The immunocompromised person in whom disease appears to be disseminating requires prompt admission for IV therapy.

THERAPEUTIC RECOMMENDATIONS

Primary Infection and Nonprimary Initial Genital Disease

- Begin a 7- to 10-day course of oral acyclovir (200 mg five times daily), valacyclovir (1,000 mg twice daily), or famciclovir (250 mg three times daily). Titrate the dose according to response to treatment. Continue therapy until lesions have healed. Reduce dose for patients with renal failure. Provide a supply for use during recurrences, which are likely to develop several times in the first year after initial infection.

Recurrent Disease

- Treat bothersome symptomatic recurrences for 5 days with either acyclovir (200 mg five times daily or 400 mg three times daily), famciclovir (125 mg twice daily), or valacyclovir (500 mg twice daily). Begin treatment at the first sign of illness, preferably during the prodromal phase before skin lesions emerge.
- Consider long-term suppressive therapy for patients who have more than six to eight recurrences per year, want to minimize the risk for asymptomatic viral transmission, or are immunocompromised. Prescribe either acyclovir (400 mg twice daily), famciclovir (250 mg twice daily), or valacyclovir (500 to 1,000 mg daily). Titrate the prophylactic dose to the lowest level possible without reactivation and continue for up to 12 months at a time.
- After 12 months, halt suppressive therapy and reassess the need for continuation.

Additional Measures for All Patients

- Educate patients about the transmissibility of genital herpes, including the risk for genital infection associated with oral–genital sexual activity and with asymptomatic viral shedding; recommend the use of condoms when one partner is antibody-negative.
- Help the patient to keep the problem in perspective and address common misconceptions regarding the meaning of the infection.
- Watch for secondary bacterial infection and disseminated HSV disease. In patients who are immunosuppressed, dissemination may present as gangrenous ulcers or deep-seated eschars.
- Follow genital infections closely during pregnancy; consider monitoring antibody status in the latter part of pregnancy to determine susceptibility to primary infection and the need for extra precautions or the use of suppressive therapy in an infected male partner.

CHAPTER 193 MANAGEMENT OF HERPES ZOSTER

Herpes zoster (shingles) is a common viral cutaneous eruption estimated to affect 300,000 persons a year in the United States. Most cases represent reactivation of the varicella-zoster virus (VZV). The incidence increases with age and degree of host immunosuppression. A community-based study found 100 cases per 100,000 person-years between the ages of 15 to 35, with a rise each decade to 450 cases per 100,000 by age 75. The seasonal variation seen with varicella does not occur with zoster; shingles is rarely an epidemic illness. Shingles may present as a pain syndrome without vesicles and pose a diagnostic problem. The primary physician must recognize zoster, make the patient comfortable, and prevent complications.

PATHOPHYSIOLOGY AND CLINICAL PRESENTATION

Varicella, or chickenpox, usually affects people early in life; the virus then lies dormant in a nerve ganglion in a genomic state until reactivation occurs. The nerve root changes consist of necrosis and sometimes cyst formation. A decrease in *cellular immunity* may allow the latent virus to reactivate and spread along the nerve; clinical zoster is the result. Helper T cells and several lymphokines produced by other T-cell subsets usually protect the host from reactivation. The disorder occurs with increased frequency among immunocompromised patients and the elderly, probably as a consequence of defects in cellular immunity. Humoral immunity does not appear to be an important factor; even severely infected patients show significantly elevated antibody titers to zoster, and fewer than 5% of persons born in the United States do not possess varicella antibody. It has been suggested that every person who has had chickenpox harbors latent virus, that 50% of all people who live to the age of 85 will have an attack of zoster, and that approximately 10% will have at least two attacks. Occasional outbreaks may result from trauma to a nerve in which the virus is latent.

There is no evidence of an increased *risk of latent cancer* in persons with herpes zoster. The relative cancer risk is only 1.1 times that of the general population, although a tenuous suggestion of a somewhat higher-than-average risk for colon cancer has been noted. The *risk for transmission* is low despite the fact that zoster skin lesions contain large amounts of virus. However, immunosuppressed patients and those who have never had chickenpox are at risk for transmission from persons with zoster. Reactivation on exposure to zoster has even been observed in a few patients with a previous history of chickenpox.

Clinical Presentation is one of radicular pain followed by the appearance of tense, grouped vesicles on an erythematous base ("dew drops on a rose petal") in a dermatomal distribution. The pain too is dermatomal and may begin as an itch or tenderness that precedes the cutaneous lesion by 1 to 7 days. Patients describe sensations of burning, tingling, and sharp, knifelike pricking, or of deep, boring discomfort. More than half of patients have a unilateral involvement of one or more thoracic dermatomes. The cranial dermatomes account for approximately 15% of cases, and cervical and lumbar dermatomes each account for approximately 10%. Vesicles on the tip of the nose were formerly thought to indicate nasociliary involvement (putting the eye at risk), but a recent review of ophthalmic zoster does not confirm the validity of this clinical saw.

The cutaneous eruption becomes pustular within a few days; crusting and healing then follow during 14 to 21 days. The crust is often dark, almost black. Scarring and atrophy can occur if the lesions are deep.

Malaise, low-grade fever, and adenopathy accompany severe eruptions. The total length of the course is related to theduration of new vesicle development; vesicle formation for several days usually predicts a 2- to 4-week course, whereas vesicle formation persisting for more than a week predicts a longer course.

About one in eight patients experiences at least one complication. Major complications include post-herpetic neuralgia, uveitis, motor deficits, infection, and systemic involvement, such as meningoencephalitis, pneumonia, deafness, or dissemination. *Post-herpetic neuralgia* occurs most frequently in patients older than age 50. The pain is often excruciating and does not respond well to conventional methods of pain control.

The presence of more than 10 lesions outside a single dermatome of distribution is early evidence of *dissemination*. Patients with AIDS may have VZV infection as part of the AIDS-related complex. In most cases, VZV infection presents as a typical dermatomal illness; occasionally, it is disseminated and can be complicated by hepatitis, pneumonia, meningitis, or proctitis. In immunocompromised hosts, VZV and herpes simplex infections may present in similar and atypical fashion, sometimes without vesicles or in unusual distributions.

DIAGNOSIS

The diagnosis is generally not difficult if the characteristic dermatomal rash and pain are present. The most serious diagnostic problem occurs during the prodromal phase, when patients present with a pain syndrome. Periorbital headache, unexplained back pain, or chest wall pain may represent the prodromal period of herpes zoster. Prodromal zoster pain has been mistaken for myocardial infarction, cholecystitis, and appendicitis. The characteristic eruption may not appear until 2 to 5 days later.

In patients with the characteristic rash, a *Tzanck preparation* demonstrating the presence of *multinucleated giant cells* provides strong supportive evidence of zoster. The Tzanck preparation has proved superior to viral isolation in the diagnosis of early lesions. Culture, although slow, allows for confirmation. The diagnosis can also be confirmed by demonstration of a *rising antibody titer*, which requires two separate determinations, or by immunofluorescence. More rapid diagnosis is afforded by *polymerase chain reaction assays*, which detect DNA sequences of VZV. Herpes zoster can also be identified by host T-cell recognition of an immediate early integument protein (IE62) or glycoprotein I of VZV. Such rapid molecular diagnostic assays are expensive and best reserved for prompt diagnosis in severely ill persons who present with acute but nonspecific symptoms (e.g., meningeal infection).

PRINCIPLES OF THERAPY

The goals of therapy are to dry the vesicles, relieve pain, and prevent secondary infection and complications. Lesions are kept clean and dry by the application of a wet-to-dry compress soaked with *Burow's solution* three to four times a day. If purulence or erythema suggestive of secondary infection develops, antibiotics are indicated. No data are available to support the use of prophylactic antibiotics.

Relief of Discomfort. Pain relief can usually be achieved with a mild analgesic such as *aspirin* or *acetaminophen*, but one should not hesitate to use *codeine* if need be. Antiviral therapy (see below) often reduces pain within 72 hours and frequently alleviates the need for stronger pain relief measures. The pain of thoracic zoster can be reduced by splinting the affected area with a *tight wrap*. Trunk lesions are covered with a nonadherent dressing, and then the area is wrapped with an elastic bandage. Malaise reflects viremia and should be treated with rest. Severe local pain can be relieved with *intralesional* injections of *triamcinolone* (2 mg/mL) in lidocaine. There is little evidence to suggest that pain can be relieved or the rate of healing hastened by the use of *systemic corticosteroids*; however, such treatment may reduce the incidence of post-herpetic neuralgia (see below). Pruritus may be relieved by oral *antihistamines* (see Chapter 178) or by *calamine lotion*, which both reduces itching and dries the rash. *Topical capsaicin* has been tried, but with only minimal success. *Peripheral nerve block* is an invasive approach to reducing acute pain that does not respond to antiviral therapy; *sympathetic blockade* has also been tried in this setting with a modicum of success.

Shortening Clinical Course and Reducing Risk for Post-herpetic Neuralgia. The nucleoside antiviral agents *acyclovir, famciclovir*, and *valacyclovir* can reduce acute pain, shorten the course of illness, and reduce the risk for post-herpetic neuralgia. To be maximally effective, antiviral therapy must begin as early as possible and preferably no later than 72 hours after the onset of rash. Those who benefit most from antiviral therapy are persons who present early with severe pain, are older than 50 years, or have ophthalmic involvement. Because VZV is much more resistant to acyclovir than herpes simplex virus is, double-dose therapy is required (e.g., 800 mg of acyclovir five times daily for 10 days). The newer cyclovirs offer dosing regimens more convenient than those of acyclovir (e.g., 500 to 750 mg of famciclovir three times daily for 7 days; 1 g of valacyclovir three times daily for 7 days), cause fewer central nervous system side effects in the elderly (see Chapter 192), and demonstrate equal or better efficacy, often at lower cost. Response, manifested by a reduction in pain, typically occurs within 72 hours. For immunocompetent patients, valacyclovir is the least costly and most effective of these agents, but valacyclovir treatment in patients with disseminated VZV infection and advanced HIV

disease has been associated with case reports of thrombotic thrombocytopenic purpura and hemolytic/uremic syndrome, so that it must not be given to immunocompromised persons.

Because of the severity of post-herpetic neuralgia, its refractoriness to treatment, and reports of responsiveness to early use of *systemic glucocorticosteroids*, steroids have been prescribed prophylactically in conjunction with antiviral therapy, particularly in patients older than 50 years. Data regarding efficacy are limited, but recent randomized trials suggest that early therapy with high doses for a brief period is associated with a shorter duration of pain and a twofold to threefold reduction in the development of chronic pain. Steroid therapy is started at the same time as antiviral treatment. The best-studied regimen is a 3-week program of *prednisone*, in which 60 mg is given daily for the first week; the dose is then tapered to 30 mg/d during week 2 and to 15 mg/d during week 3. To minimize adverse effects, prednisone is taken in the morning with food (see Chapter 105). Persons over the age of 50 who present with severe pain and a large number of herpetic lesions are at greatest risk for post-herpetic neuralgia and are the best candidates for combination therapy.

Trials of several varicella *vaccines* have been completed, and vaccines should soon be available for adults who have not had chickenpox and for those at high risk for reactivation. It is hoped that the vaccine will stimulate T-cell subsets and cytotoxic killer T cells and make reactivation less likely. In studies of immunosuppressed persons, *interferon* and *vidarabine* have proved promising.

Treatment of Post-herpetic Neuralgia. *Tricyclic antidepressants* remain the first line of treatment (e.g., *amitriptyline* at a starting dose of 25 mg daily at bedtime); they provide significant benefit to about 50% of patients. Recently, the anticonvulsant *gabapentin* has been found to be similarly effective as a first-line agent (begun at 900 mg/d and titrated up to 3,600 mg/d) and better tolerated (dizziness and somnolence are the main adverse effects). The anticonvulsive drug *carbamazepine* has been used as a second-line agent. *Narcotics* are not well studied for long-term use in post-herpetic neuralgia, but they are often added if a first-line drug proves insufficient. Combination therapy has not been well studied but may prove useful if the agents utilized work by different pathways. Topical therapies are less effective; *capsaicin* is among the best, but efficacy is modest and a burning sensation may ensue with prolonged use.

INDICATIONS FOR REFERRAL

If any suggestion of visual compromise or other ocular involvement is present, prompt ophthalmologic consultation for herpetic eye care is essential to avoid scarring and permanent visual impairment. *Otic* involvement can lead to severe pain and otic nerve damage, so that referral to an ear, nose, and throat specialist is important. The patient with herpetic skin lesions and signs of meningeal irritation requires prompt hospitalization.

CHAPTER 194 MANAGEMENT OF WARTS

WILLIAM V. R. SHELLOW

Warts result from skin infection with human papillomavirus (HPV). Although a relatively harmless affliction, warts can be cosmetically bothersome and occasionally a source of pain. The primary care physician should be able to distinguish warts from other skin tumors, select effective treatment, and educate the patient in proper self-care and prevention.

PATHOPHYSIOLOGY, CLINICAL PRESENTATION, AND COURSE

Human papillomavirus is a DNA virus, with more than 80 types identified. It is epitheliotropic and causes tumors of the epidermis. At least five types are potentially oncogenic, with two implicated in cervical carcinoma (see Chapter 107) and three in squamous cell carcinoma (see Chapter 177). Warts can be transmitted by direct contact or by autoinoculation. Young people have a high frequency of warts. Healing can occur spontaneously, presumably through immunologic mechanisms. Approximately two thirds of warts disappear spontaneously within 2 years of their appearance, but if they are left untreated, additional warts may develop from the original ones.

Clinical Presentations vary according to site and viral strain involved. Morphologically, nongenital warts appear in three forms: the keratotic common wart, the filiform wart, and the flat wart. Most warts are asymptomatic; however, a plantar wart can be the source of considerable foot pain, acting as a foreign body during weight bearing. Anogenital warts may become friable, bleed, and cause discomfort. Periungual lesions may become fissured.

The Common Wart (Verruca Vulgaris) is associated with HPV-2 and HPV-4 infection. It appears flesh-colored or grayish white with a papillate, hyperkeratotic surface. The wart may be punctuated with black dots that represent thrombosed superficial capillaries, which are present in large numbers. The common wart may be seen anywhere but frequently affects the elbows, knees, fingers, and palms. The filiform wart is more delicate and threadlike. The *flat wart* (*verruca plana*), caused by HPV-3, is smaller than the common wart. Flat warts are tan to flesh-colored, slightly raised papules with a relatively smooth surface. Great numbers of them may appear on the hands, in bearded areas, and on the shaved legs of women.

The Plantar Wart (Verruca Plantaris) results from infection of the plantar surface of the foot with HPV-1 or HPV-4. It appears as a small skin nodule that produces grayish or yellow interruptions in the skin lines (dermatoglyphics) of the foot. It is less elevated than other warts because weight bearing presses it inward. These warts may be solitary, multiple, or confluent; if confluent, the term *mosaic wart* is used.

Genital Warts. In the genital area, four clinical morphologic types are seen: the cauliflower variety (*condyloma acuminatum*); smooth, flesh-colored papular lesions; flat warts; and keratotic genital warts, which can mimic seborrheic keratosis. *Anogenital warts* result from the sexual transmission of HPV-6, HPV-11, HPV-16, and HPV-18 and grow on mucous membranes. They range in appearance from pinpoint to cauliflower-like. Experienced clinicians have been able to correlate the elevated, lobulated papular lesions with HPV-6 and HPV-11, whereas the flat, hyperpigmented types are high-risk lesions associated with HPV-16 and HPV-18. Coexistent sexually transmitted diseases are common. Mucocutaneous warts may become refractory to appropriate therapy.

DIFFERENTIAL DIAGNOSIS

Common warts should be differentiated from *squamous cell carcinoma, seborrheic keratosis*, and from a *cutaneous horn* arising from an actinic keratosis (see Chapter 177). The differential diagnosis also includes *Gottron's papules* (seen on the dorsal aspect of the fingers in dermatomyositis), *granuloma annulare, lichen planus, molluscum contagiosum, skin tags*, and *lichen nitidus*. Multiple flat warts on the face should be differentiated from trichoepithelioma, syringoma, and the cutaneous lesions of sarcoidosis. Anogenital warts must be differentiated from the *condyloma latum* of syphilis and from *squamous cell carcinoma*. The differential diagnosis also includes *pearly penile papules, ectopic sebaceous glands*, and *nevi*. Bowenoid papulosis (associated with HPV-16) appears as pigmented wartlike lesions on the male and female genitalia and is a form of carcinoma in situ, although it has little biologic tendency to behave aggressively.

WORKUP

The appearance is usually sufficient to indicate the diagnosis, but early genital warts can be difficult to identify. Typically, a patient comes for evaluation because warts have been found in a sexual partner. In a male patient, the penis and upper portion of the scrotum should be carefully examined under magnification. If no visible lesions are present, acetic acid can be used. Soaking the penis for 5 minutes with a gauze moistened with 5% acetic acid (white vinegar) demonstrates early lesions not readily evident under hand lens magnification, but magnification alone usually suffices. For the gynecologic examination, early warts are best demonstrated when they are made white with acetic acid. The colposcope provides still higher magnification. However, one must remember that the use of acetic acid is very nonspecific; any disease or lesion that alters the stratum corneum will turn white with acetic acid.

PRINCIPLES OF MANAGEMENT

Not all warts need to be removed. The primary care physician should keep in mind the basic principle that warts are benign tumors that often regress spontaneously. Treatment should not be so aggressive as to produce permanent scarring. Simple and safe treatments should be employed.

Location, discomfort, cosmetic effect, and therapies available influence the decision to treat. Larger, long-standing warts and those involving the plantar, perianal, or periungual area are the most difficult to treat but among those that patients most want to have removed. The patient's occupation, skin pigmentation, and body area should be considered when therapy is designed. The goal is to destroy the epidermal tumor while minimizing damage to the underlying dermis. The greater the dermal injury, the greater is the risk for scar formation. Only minimal scarring should be expected or considered acceptable.

A host of measures are available; choice is based on efficacy, patient acceptability, and scarring potential of the therapy and on location, size, and type of lesion. Physicians will most likely be seeing a self-selected group of patients for whom over-the-counter remedies have failed.

Common Warts. Freezing the lesion with *liquid nitrogen* applied on a cotton swab is convenient, well tolerated, often effective, and associated with a low risk for serious scarring. Solid freezing of the lesion is usually achieved by the repeated application of liquid nitrogen with a cotton swab dipped into a Styrofoam cup containing the supercold liquid. It may be useful to watch for a 30-second thaw time. For larger lesions, a repeated freeze–thaw cycle may interfere with efficacy. The freezing injury separates the wart from the underlying dermis. The successfully treated wart then falls off within 2 weeks. Before freezing, the thickened keratin should be pared off, but care should be taken not to cut into the profuse collection of capillaries within the wart. It is best to freeze a few millimeters of the surrounding normal tissue to facilitate separation from the underlying dermis. The patient should be warned that the area may hurt for several hours after treatment, and occasionally hemorrhagic blistering develops, especially with vigorous treatment.

If not completely gone, the wart can be treated again within 2 to 3 weeks. In difficult areas or with large lesions, several treatments may be necessary. Cures are related to the total number of treatments and not to the interval between. Treatment with liquid nitrogen has the advantage of being quick, bloodless, and not too painful, but the liquefied gas evaporates quickly and requires storage in special containers. Commercial kits generating sticks of "dry ice" from compressed carbon dioxide gas are available, but because the sticks are not as cold as liquid nitrogen, they are not as effective and require the application of more pressure for a longer time.

Curettage with or without *electrodesiccation* is effective but time-consuming, and substantial scarring can result if treatment is too vigorous. Some practitioners worry about the presence of virus in the smoke caused by the electrodesiccation. *Chemical cautery* with *nitric acid* or *monochloroacetic, bichloroacetic,* or *trichloroacetic acid* is an older alternative to liquid nitrogen.

Plantar Warts. Nonsurgical methods are preferred to surgical removal because scarring in this location can cause permanent discomfort. The lesion should be pared and then treated with the application of 40% *salicylic acid plasters*; these are taped in place for 1 to 3 days, after which the macerated skin is scraped off. This procedure is used for 2 to 3 weeks and can be performed by the patient. A salicylic acid preparation suspended in a karaya gum that promotes absorption (TransVerSal) is a convenient way to apply the medication. The pad containing the suspension is cut to size after the wart is pared down with an emery board. A drop of water is placed on the wart and the pad is applied and left in place for 8 hours each day. A larger salicylic acid patch (Trans Plantar) is indicated for treating large plantar warts. The convenience of this method is offset by the expense, but it is appreciated by some patients. *Liquid nitrogen* can be used on plantar warts in non–weight-bearing areas.

Daily 10% *formalin* or 25% *glutaraldehyde compresses* are sometimes used for mosaic plantar warts. Occlusal-HP is a prescription salicylic acid–lactic acid combination that contains salicylic acid in a polyacrylic vehicle. It is quite effective for plantar warts and has also been used successfully for warts on the hands.

Flat Warts. Topical *5-fluorouracil* cream or solution and *retinoic acid* cream or gel are used effectively for flat warts, especially those on the face. With both of these topical agents, patients will probably experience irritation characterized by erythema, scaling, and burning. Patients must be counseled that irritation will occur. Men should switch to an electric razor if they are using a blade razor, as cutting facial warts spreads them throughout the beard area. Similarly, women with flat warts on their legs must switch to an electric razor or use depilatory creams. Alternatively, 6% salicylic acid gel (Keralyt) is sometimes effective in treating multiple flat warts on the legs.

Genital Warts. A preparation of 20% to 40% *podophyllin* in compound tincture of benzoin is used to treat *macerated genital warts*. It must be applied sparingly, only to the wart, and allowed to dry thoroughly before the patient dresses. The medication is washed off by the patient 1 to 4 hours after application. Repeated treatment is the rule. Podophyllin is contraindicated in pregnancy. *Podofilox* 0.2% (Condylox) solution and gel are available for the treatment of external genital warts in both men and women. Podofilox is a purified fraction of podophyllin resins and is the first prescription product for the treatment of warts that is safe for self-application at home. It is applied for 3 days consecutively, followed by 4 days of no treatment; treatment is repeated if the warts persist.

Heat has been reported to be useful in treating stubborn warts. The temperature needs to be 43°C. The patient can use a candy thermometer to determine the temperature of the water. The wart should be soaked for 15 minutes twice daily. *Imiquimod 5% cream (Aldara)* can be quite effective in the treatment of anogenital warts. The drug is an immune response modulator that is applied by the patient overnight three times weekly for up to 16 weeks until the warts clear. It is very expensive, but for patients with refractory anogenital lesions, it should be considered.

The *carbon dioxide laser* is quite useful in destroying large numbers of warts in the vagina or around the anus. The procedure is carried out in an operating room environment. Postoperative morbidity is much less than when conventional methods are used.

As noted earlier, evaluation for concurrent venereal disease is mandatory in patients presenting with genital warts (see [Chapter 125](#) and [Chapter 126](#)).

Refractory Warts. Sublesional *bleomycin*, diluted to 10 U/mL, has a distinct role in the treatment of refractory warts, both those on the hands and the plantar variety. Usually, 1 or 2 U injected beneath the wart is sufficient. Blanching occurs immediately, followed by blackening of the wart with subsequent clean sloughing. This treatment is less painful than liquid nitrogen for the most part, and causes no systemic effects.

Interferon alfa (both type 2a and type 2b) has been approved for the treatment of refractory genital warts. Intralesional injection is performed three times a week for 3 weeks. Lesions clear in fewer than 50% of patients, and this treatment has the disadvantages of being painful and expensive.

Immunostimulation is sometimes tried. *Dinitrochlorobenzene* (DNCB) sensitization followed by repeated applications of diluted DNCB has been used to treat resistant warts. This form of immunotherapy is sometimes effective, but DNCB has been shown to be a potential carcinogen in some studies. Autogenous wart vaccines appear no more effective than placebo.

The *carbon dioxide laser* has become an increasingly popular method for treating warts, although in many instances it is little more than an expensive method of causing tissue destruction. It is best reserved for certain situations, such as extensive vaginal or anal warts or refractory periungual lesions.

PATIENT EDUCATION

Prevention entails avoiding others with warts and having warts removed so that the viral reservoir is reduced. Although warts may initially have been acquired during contact with others,biting and picking at warts may result in the formation of additional lesions. Patients with periungual warts should be cautioned that biting the warts or pulling hangnails may result in the spread of lesions. Patients with genital warts can be reassured that warts do not develop in everyone who is exposed, but condom use should be urged.

The treatment of warts can be both time-consuming and expensive. Recurrences are seen in about one third of instances. The patient must be made to understand that warts are caused by a virus and that treatment usually does not eliminate the virus. Nonetheless, the patient can be reassured that in most instances the immune system will eventually prevent HPV from causing warts despite the continued presence of the virus. The length of treatment, cost, discomfort, risk for scarring, and possible failure of therapy should be candidly discussed before treatment is initiated.

INDICATIONS FOR REFERRAL

A Papanicolaou smear showing cervical dysplasia and evidence of HPV requires referral to a gynecologist for consideration of cervical biopsy. Women with extensive involvement by vaginal warts are also candidates for gynecologic consultation and possible laser therapy. Patients with truly refractory lesions who still insist on their removal may benefit from a dermatologic or surgical consultation. If topical treatment proves ineffective, electrocoagulation or surgical excision deserves consideration. Excision of large venereal warts that do not respond to podophyllin is indicated to rule out malignancy.

THERAPEUTIC RECOMMENDATIONS

- Use liquid nitrogen for initial treatment of common warts. Apply with a cotton swab to an area that includes a small rim of surrounding skin.
- Treat plantar warts by first paring them down carefully with a scalpel and then applying a piece of 40% salicylic acid plaster cut in the shape of, but slightly smaller than, the wart. Cover with occlusive adhesive tape and leave in place for 24 to 72 hours. Continue treatment at home, with gentle paring and reapplication of salicylic acid plaster as needed. Check progress regularly.
- Treat flat warts with topical 5-fluorouracil, retinoic acid, or Keralyt, a 6% salicylic acid gel.
- Treat moist anogenital warts with topical podophyllin; remind the patient to remove the medication after 4 to 6 hours. Consider topical podofilox for patient administration at home if repeated treatment is needed.
- Consider the use of imiquimod for anogenital lesions that do not respond to less expensive therapy.
- If these topical treatments prove ineffective or if the patient has extensive anal or genital involvement, then refer for consultation and consideration of more aggressive therapy, such as carbon dioxide laser treatment.

CHAPTER 195 MANAGEMENT OF SCABIES AND PEDICULOSIS

ALICE Y. LIU AND WILLIAM V. R. SHELLOW

Scabies and pediculosis are two arthropod parasitic skin diseases commonly seen in the primary care setting. Although accurate diagnosis, effective treatment, and preventive measures are available, infestations with scabies and lice are pandemic, affecting millions of patients worldwide. The primary physician should learn to recognize the manifestations of infestation quickly, and should be able to treat infestations effectively.

PATHOPHYSIOLOGY AND CLINICAL PRESENTATION

Scabies

Infestation with the human skin mite *Sarcoptes scabiei var hominis* leads to the disease scabies. Transmission is through prolonged close personal contact, either sexual or nonsexual. Persons of all socioeconomic levels, both sexes, and all age groups can be affected. Once contracted, scabies usually persists until specific therapy is instituted.

The scabies mite is an obligate arachnid human parasite, unable to live independently of its host. The mite measures 1/60 inch in length. The adult female attaches to and burrows into the horny layer of the skin. Copulation with a wandering male renders the female fertile for life. The female mite remains within her burrow for the rest of her 1-month life, laying two or three eggs a day. These eggs hatch within 3 to 4 days. Mature adults develop during the next 10 to 14 days. While in her burrow, the female feeds on epidermal cells. The average number of female mites on the body is 11.

Patients usually present with intense *pruritus*, which is often severe during the night. Pruritus also occurs when patients remove their clothing or become overheated. Eighty-five percent of infested persons have *burrows* on the fingers, interdigital areas, and wrists; these appear as linear marks a few millimeters in length, often with a dark dot at one end, which represents the female mite. Other common sites for burrows are the elbows, feet, ankles, penis, scrotum, buttocks, and axillae. Vigorous scratching may lead to excoriations, eczematous plaques, crusted papules, or secondary infection. In healthy adults, infestation is usually confined to skin below the neck. However, elderly or immunosuppressed patients may also present with head and neck lesions.

The mite is not necessarily found in all the cutaneous lesions. The rash and accompanying pruritus reflect a sensitivity reaction to the mite, eggs, or scybala (fecal droppings). In patients who have never been infested, the pruritic rash develops after a 2- to 4-week initial asymptomatic phase of infestation. In previously sensitized patients, the eruption can occur within a few days. Antiscabetic treatment kills the mite and ova but does not remove the sensitizing dead organisms or scybala from the burrow. Thus, pruritus may continue for a few weeks after treatment, until the contents of the burrow are shed with the natural turnover of skin. Persistent postscabetic papules may occur, especially on the penis, which may require intralesional injection of corticosteroids.

Crusted (Norwegian) scabies is an infrequent variant of the disease in which patients harbor a high mite load and present with hundreds of thick, keratotic papules. This form often affects patients with a decreased host defense, such as those with *HIV infection*, or without the ability to scratch, such those who have had a stroke. Crusted scabies is highly contagious because of the myriad of mites in the exfoliating scales.

Pediculosis

Human lice, which are obligate human insect parasites, are responsible for the diseases pediculosis capitis, pediculosis corporis, and pediculosis pubis. Transmission is through contact with infested humans, clothing, combs, or bedding. Body lice are most commonly found in people with poor personal hygiene or in indigent populations. Head lice are a public health problem among school children. Pubic lice are predominantly transmitted sexually. Human lice are the vectors for the transmission of typhus and trench fever.

The two species of these wingless, dorsoventrally flattened, blood-sucking insects are *Pediculus humanus* (subspecies *capitis* and *corporis*), which infests the head and clothing, and *Phthirus pubis* (crab louse), which infests the pubic area. These insects measure 3 to 4 mm in length, *Phthirus pubis* demonstrating a more rounded body in comparison with *Pediculus humanus*. Adult lice require a blood meal every 3 to 6 hours. The female insect lives 1 month and lays 7 to 10 eggs (nits) a day, which in turn hatch in about 8 to 10 days. The head louse lives on the scalp and lays eggs that are cemented onto hairs about 1 cm from the scalp. Body lice live and lay eggs in clothing, often in the seams. The crab louse prefers axillary, eyebrow, eyelash, beard, pubic, limb, and trunk hairs and lays its eggs on these hairs. Lice may be able to survive off the human host for 24 hours.

The head louse typically infests the occipital portion of the *scalp* and sometimes the postauricular region. Although few adults are present, many oval nits can be found cemented to the hair. Patients often complain of scalp *pruritus*. Cervical adenopathy may be present. Body lice cause pruritus, often representing a sensitivity reaction to lice excretions. Patients can have multiple excoriations over the trunk, and vertical excoriations are characteristic of infestation. Body lice and eggs can be seen in clothing. Pubic lice cause pruritus, often *nocturnal*. Characteristic asymptomatic, macular, blue discolorations called maculae ceruleae are sometimes seen on the trunk and thighs. Lice can be seen grasping pubic hairs, and specks of brownish feces can sometimes be seen.

DIAGNOSIS

Scabies

The diagnosis is suggested by finding the characteristic *burrows*. They should be sought on the hands, wrists, ankles, and genital areas, where the recovery rate is highest. A *scraping* is performed by shaving off the roof of the burrow with a scalpel, scraping the base to remove the contents, and placing the material on a microscope slide. Next, a drop of light mineral oil and a cover slip are added. The lowest-power objective should be used to view the specimen under a light microscope. The presence of adult mites, immature mites, ova, or tan-brown scybala confirms the diagnosis. In mineral oil, but not in potassium hydroxide, movement of the mite may be seen. In the absence of a scraping, presumptive diagnosis can be made based on the symptoms, appearance of the rash, and the history of contacts who also have symptoms of itching.

Pediculosis

The diagnosis is made by direct examination of the involved area. Few adult lice are found at the bases of the hairs, but many nits are typically seen. Both are usually visible to the naked eye, but a hand lens and bright light may help. Nits appear as gray or white specks attached to the hair. The examination should be performed with gloves to avoid infestation. The detection of head lice is facilitated by plucking a few hairs and identifying the full or empty egg cases about 7 to 10 mm up the hair shaft. Organisms may be found at the nape and behind the ears. Pyoderma of the nape or the occiput requires that pediculosis capitis be ruled out. Vertical excoriations on the trunk are a cardinal sign of body lice. The underwear of a patient infected with pubic lice is often speckled with blood.

PRINCIPLES OF MANAGEMENT

Elimination of the infestation and relief of pruritus are the goals of treatment.

Scabies

Because infestation is from person to person, close contacts of a scabies patient should be treated even if free of symptoms. After the mites and ova have died, but before they are shed from the skin, pruritus may continue for a few weeks following treatment. During this time, it may be necessary to use topical corticosteroids and oral antihistamines to help control the sensitivity rash and pruritus. Occasionally, systemic steroids are required (see Chapter 105). *Permethrin 5% cream*, which is synthetically derived from the natural compound pyrethrin, is currently the first-line treatment for scabies. Its toxicity in mammals is low because it is minimally absorbed and quickly reduced to inactive metabolites. Permethrin acts on the parasite nerve cell membranes and leads to paralysis. The 5% formulation is available with prescription in the United States.

Lindane (g-benzene hexachloride) lotion was formerly the agent of choice for the treatment of scabies. Because of reports of organism resistance and neurotoxicity in infants and persons with an extensively compromised epidermal barrier, lindane has been relegated to alternative-treatment status. It should not be used in children under 2 years of age, or in pregnant or lactating women.

Crotamiton 10% lotion is antipruritic but is usually less successful as a scabicide than is permethrin. The cure rate after five consecutive days of therapy is only about 55%. Malathion lotion is no longer available in the United States.

Ivermectin. The off-label use of ivermectin, a new antiparasitic medication, has been gaining popularity since it was introduced in the United States for the treatment of *Strongyloides* infestation. This macrocyclic lactone preferentially inhibits glutamate-gated chloride ion channels in invertebrate nerve and muscle. Its affinity for human channels is low, and penetration of the blood–brain barrier is minimal. Typically, a single dose of 200 μg/kg is given orally, and this has been reported to be extremely successful in treating infestation. Compliance is high because of the simplicity of treatment. Topical formulation is not yet available. Although many practitioners feel that one or two doses of ivermectin are safe, increased mortality of elderly patients treated with the medication has been reported. At the present time, it should not be administered to the elderly.

Although theoretically the scabies mite should not be able to live without its human host, most recommend that bed linens and underwear of all household members be washed thoroughly in hot water with detergent or dry cleaned to prevent reinfestation. Treatment of scabies is generally effective provided that all close contacts are treated simultaneously.

Pediculosis

Permethrin 1% cream rinse shampoo is the first-line treatment for pediculosis. The 1% strength is available without a prescription in the United States. Less than 2% is absorbed, and the drug is quickly reduced to inactive metabolites. The 1% preparation is effective for the treatment of pediculosis capitis. Most other nonprescription treatments for pediculosis combine the compound *pyrethrin*, a natural extract of chrysanthemum flowers, and a synergistic compound, *piperonyl butoxide*. The synergized pyrethrins have a wide safety margin because they are minimally absorbed through the skin. Because the nits have an undeveloped nervous system, none of these neurotoxic chemicals are completely ovicidal. Only permethrin has activity against eggs because it retains residual activity for 2 weeks and remains on the hair for 14 days after treatment. Thus, eggs that hatch after treatment can be killed. Some physicians still recommend that a second permethrin treatment be given 1 week after the first, for maximum cure rate.

Reports of resistance to standard treatment with 1% permethrin have engendered alternative strategies, including 5% permethrin cream overnight under a shower cap, ivermectin as described for scabies, oral trimethoprim/sulfamethoxazole, or physical methods such as *petrolatum* application. Eyelash involvement may be treated with petrolatum, which is nonirritating and nontoxic; the lice either suffocate or slip off the greased hairs.

To prevent reinfestation, *asymptomatic close contacts* should be treated simultaneously. Sheets and all clothing worn in the past 3 days should be laundered in hot soapy water or dry cleaned. Brushes and combs should be washed in hot water for 10 to 20 minutes. Floors, furniture, and play areas should bethoroughly vacuumed to remove hairs that may have been shed with viable eggs attached.

On occasion, secondary bacterial infection may occur, which can be treated with the application of topical mupirocin 2% ointment three times daily or the administration of appropriate oral antibiotics. As in scabies treatment, the use of *lindane* for the treatment of lice is no longer considered the first choice.

PATIENT EDUCATION

Patient education is essential. Treatment failure is usually the result of poor patient compliance. Written instructions are helpful. Review of the preventive measures outlined above is very important.

THERAPEUTIC RECOMMENDATIONS

Scabies

- Prescribe 5% permethrin cream, to be applied from the neck down (including all body folds and creases) and left on overnight for 8 to 12 hours. About 30 g is sufficient for the average adult. One treatment is usually adequate. Some practitioners are recommending application to the scalp also. Application beneath the nails may prevent reinfestation.
- Advise changing and cleaning of underwear and bed linen.
- Treat all household members.
- Only if reinfestation has occurred should a second course of treatment be necessary.
- Prescribe topical corticosteroids and oral antihistamines if rash and pruritus are bothersome; if severe, oral steroids can be considered.
- For crusted scabies, the use of a keratolytic agent (10% salicylic acid or 20% urea) can hasten shedding of the affected horny layer of skin. Subungual areas should be carefully coated with permethrin cream.

Pediculosis Capitis

- Have the patient routinely shampoo without medication and thoroughly dry hair. Excess water slows the neural activity of the insect, protecting it from the neurotoxic effects of permethrin. Sufficient permethrin 1% cream rinse should be applied to wet the hair thoroughly. It is left on for 10 minutes and then rinsed out.
- Alternatively, recommend a synergized pyrethrins shampoo, to be applied undiluted until the infested areas are entirely wet. After 10 minutes, the areas are washed thoroughly with warm water and then dried. Because it is less effective as an ovicide, this treatment should be repeated in 7 to 10 days to kill any newly hatched lice.
- Advise drying the hair with a clean towel after treatment with a pediculicide and removing any remaining nits with a fine-toothed comb. Nit removal is believed to reduce the chance of reinfestation.
- Recommend that combs, clothing, and bed linens be washed.

Pediculosis Corporis and Pediculosis Pubis

- Treatment is similar to treatment for pediculosis capitis. Permethrin 1% cream rinse or 1% cream can be applied to the body for 10 minutes before being washed off.
- The sexual partners of patients with pediculosis pubis need to be treated.
- Treat eyelash involvement with the application of petrolatum jelly up to five times a day for 5 to 7 days. Alternately, recommend physostigmine ophthalmic ointment 0.25%, applied to the lashes four times daily for three consecutive days.
- Clothing and bed linens need to be washed.

CHAPTER 196 MANAGEMENT OF SKIN TRAUMA: BITES AND BURNS

Part 1: Animal and Human Bites

ELLIE J. C. GOLDSTEIN

Five million animal bites, leading to 800,000 medical encounters, occur in the United States each year. Patients often present to the primary physician for advice and therapy. Patients may appear shortly after injury concerned about rabies, tetanus, or repair of a disfiguring tear. Sometimes they delay seeking care, only to present later with infection. The primary physician must provide first aid and tetanus prophylaxis, decide whether antibiotics are necessary, and estimate the risk for rabies. Human bites are less common but potentially more serious. Particularly treacherous are clenched-fist injuries, which result from striking the teeth. Occlusional bites and paronychial injuries may also result in infection.

PATHOPHYSIOLOGY AND CLINICAL PRESENTATIONS

Most bites result in minor trauma. Approximately 80% of patients neither need nor seek medical care. Bite wounds that produce a break in the skin allow the inoculation of bacteria that normally inhabit the skin or, more usually, the oral cavity of the biting animal. Conditions favoring infection include prior splenectomy, liver disease, immune compromise, crush injury, edema, wounds to the hand, and multiple punctures. Patients with established infection usually present more than 8 hours after having sustained an injury. Patients with preexisting edema (e.g., persons with congestive heart failure or chronic venous insufficiency, women who have undergone radical or modified mastectomy) are at risk for more severe infection.

Human bites, especially *clenched-fist injuries*, in which damage is inflicted while the tendons and other tissues of the exterior area of the finger are stretched to full length, the skin is broken, and the tendon and possibly the joint are exposed, are serious. As the fingers are straightened, the damaged parts relax, and infecting organisms are carried into the tissues, producing infection in wounds that may initially appear minor. If the joint capsule is penetrated, septic arthritis or osteomyelitis is a risk.

Bacteriology. In animal bites, the infecting organisms are usually the normal oral flora of the biting animal. *Pasteurella* species, including *P. multocida*, are present in 50% of animal oral cavities and in 50% of dog and 75% of cat bite wounds. Cat bites are more prone to infection than are dog bites and may lead to severe cellulitis. Cat-scratch disease is caused by *Bartonella henselae* and *B. quintana*, fastidious gram-negative rods; it often presents with fever and lymphadenopathy and is more frequently seen during the cold weather months. Any patient who has undergone splenectomy or has alcoholic liver disease is prone to sepsis with *Capnocytophaga canimorsus* (formerly DF-2).

The oral flora of humans is more abundant than in most animals and includes *Streptococcus viridans*, *Haemophilus influenzae*, *Eikenella corrodens*, *Prevotella* species, *Porphyromonas* species, anaerobic diphtheroids, fusobacteria, and spirochetes. Wounds may also be infected by *skin flora*, such as a group A b-hemolytic streptococci (*Streptococcus pyogenes*) or staphylococci (*Staphylococcus aureus*). If anaerobic bacteria are present, the infection is more severe and may lead to abscess formation. Human bites are responsible for most severe bite wound infections.

PRINCIPLES OF THERAPY

Principles of therapy include characterization of the injury, vigorous cleansing, elevation, tetanus prophylaxis, and administration of appropriate antibiotics.

Animal Bites

It is important to elicit a history of the circumstances surrounding the injury. If an animal bite occurred, the type of animal and its behavior need to be detailed, as well as whether the animal had been vaccinated, and whether the attack was provoked or unprovoked. The wound should be diagrammed in the chart, with proximity to bones or joints noted. Minor animal puncture wounds should be cleansed with *soap and water* and treated expectantly without antibiotics. Copious *irrigation* of wounds with normal saline solution is an important therapeutic adjunct. Animal puncture wounds that are small and clean require no other treatment.

Rabies. Since 1967, only one or two cases of rabies in humans have been documented each year in the United States. No cases of rabies have occurred in New York City or Los Angeles for many years. Raccoon rabies is epidemic in all states along the entire eastern seaboard. In most other states, skunks and bats are the most common rabid animals. Rabies is more prevalent in cats than in dogs in the United States. Rabies is a concern if the attack is unprovoked, occurs in a rural setting, or involves a raccoon, a bat, a skunk, or an animal that is behaving in a peculiar manner. The local health department provides data regarding the local incidence of rabies and should be notified for follow-up and documentation. If rabies is considered a possibility, *human diploid cell vaccine* should be given along with *rabies immune globulin* without delay (see Chapter 6). If a person is bitten by a pet, the animal should be watched at home by the owner for 2 weeks and the bite reported to the local health department.

Tetanus. It is important to determine whether the patient has had an initial series of tetanus shots and a booster within the past 10 years. Those who have not had an initial series should be given both *tetanus toxoid* and *tetanus immune globulin* (see Chapter 6). For persons who have had the initial series but no booster in 10 years, 0.5 mL of *tetanus toxoid* should be administered IM.

Tear Wounds. Therapy for tear wounds is problematic. No controlled trials of closure versus nonclosure, with or without antibiotics, have been undertaken. The principles of therapy are to cleanse and debride the wound cautiously. After the wound has been left open for 24 hours, the edges can be approximated with adhesive strips or sutured; 500 mg of *amoxicillin/clavulanate* is then given three times a day for 3 to 5 days. Secondary closures can be performed if it is apparent that no infection is present. Facial wounds may be closed and antibiotics given. It is useful to refer these patients to a plastic surgeon.

Infected Wounds. Patients who present with infection should receive debridement, drainage, cleansing, and antibiotics. *Penicillin/amoxicillin* can be used; the combination is often effective against *P. multocida*, streptococci, anaerobes, and *E. corrodens* but is ineffective against *S. aureus*. In penicillin-allergic patients, *doxycycline* is preferred because *P. multocida* is often resistant to erythromycin and cephalexin. *Amoxicillin/ clavulanic acid* is an effective but more expensive alternative. Only in vitro and anecdotal clinical data exist regarding the use of quinolones or oral second-generation cephalosporins for animal bites.

Human Bites

Human bites are usually located on an extremity. Wounds of the hand are the most serious. The same principles of cleansing, drainage, and debridement apply. Human bites should not be closed primarily, although edges can be approximated if the tear is severe. Antibiotics should be instituted after wound cultures are taken. *Penicillin* plus a *penicillinase-resistant penicillin* or *amoxicillin/clavulanic acid* should be administered pending culture results to cover b-lactamase–producing oral anaerobes and gram-positive cocci, particularly *S. aureus*. Infrequently, the presence of a gram-negative organism necessitates a change in antibiotic regimen. All patients previously immunized who have not had a booster in 5 years should be given 0.5 mL of *tetanus toxoid*. Follow-up is essential because of the potential for late serious infection. A small risk exists for the transmission of viral pathogens such as hepatitis A, B, and C viruses and HIV.

Clenched-fist Injuries usually require specialized care. Radiographs should be taken to rule out fractures and provide a baseline for future assessment of osteomyelitis. Extension and flexion of digits should be carefully checked and sensation tested. The third metacarpophalangeal joint is most often affected. The integrity of the joint capsule must be determined, and this may require an experienced surgeon. If the capsule is intact, the hand is cleaned, debrided, immobilized,

and elevated. *Penicillin* plus a *penicillinase-resistant penicillin* or *ampicillin/sulbactam* or *cefoxitin* is started and *tetanus toxoid* administered. Patients seen within 8 hours of injury with intact joint capsules can be managed as outpatients with careful follow-up. Those with torn capsules need to be admitted for surgery and treatment with IV antibiotics. Patients who present after 8 hours should be admitted for observation to determine whether the capsule is intact or interrupted.

THERAPEUTIC RECOMMENDATIONS AND PATIENT EDUCATION

- Clean all wounds vigorously with soap and water. Copiously irrigate with normal saline solution. A needle and syringe can be used to generate a high-pressure jet to cleanse puncture wounds.
- Immunize patients who have previously been immunized but have not had a booster in the past 5 years against tetanus with 0.5 mL of IM tetanus toxoid.

Animal Bites

- Animal puncture wounds that are trivial and clean, without crush injury and not involving the hand, often require no other treatment.
- Treat moderate or severe fresh, *uninfected* animal tear wounds with cleansing, debridement, and *phenoxymethyl penicillin* (250 mg four times daily), followed by secondary closure in 24 to 48 hours if no signs of infection are present.
- Treat *infected* animal bite wounds with debridement, drainage, and cleansing. Culture the wound, delay wound closure until infection subsides, and begin *penicillin* (500 mg four times daily). Add a penicillinase-resistant penicillin (e.g., 500 mg of *dicloxacillin* four times daily) if erythema appears to be spreading or if *S. aureus* is suspected. *Amoxicillin/clavulanic acid* (875/125 mg twice daily) may be used as a single agent, as may *cefuroxime* (500 mg twice daily), especially for an infected cat bite. If the patient is allergic to penicillin, use *doxycycline* (100 mg twice daily) for initial antibiotic therapy.
- Treat for 7 to 10 days for an uncomplicated cellulitis.

Human Bites

- Treat all human bites initially with both penicillin and a penicillinase-resistant agent (e.g., *dicloxacillin*). Delay closure of the wound.
- Elevate affected limb until the swelling declines, usually after 3 to 5 days.
- Immobilize clenched-fist injuries and obtain hand surgery consultation promptly.
- Instruct the patient to watch the wound for signs of infection, such as pain, redness, warmth, swelling, or purulent exudate.

Part 2: Management of Minor Burns

Accidental minor burns are common. The majority of the estimated 2 million annual burn victims can be treated as outpatients. The primary physician is often asked for advice about immediate care and should render definitive treatment for localized, partial-thickness burns.

PATHOPHYSIOLOGY AND CLINICAL PRESENTATION

Burns represent direct thermal injury to the cells of the skin and underlying structures. The clinical presentation depends on the degree of damage, which is a direct function of the intensity of heat and duration of exposure.

First-degree Burns involve just the superficial layers of the epidermis. The skin is painful, red, and swollen. It blanches with pressure and shows little or no edema. Ultraviolet radiation, scalding, low-intensity exposure to steam, or brief contact with a hot object are common causes. Complete recovery usually occurs within a week, often with peeling and sometimes with postinflammatory hyperpigmentation.

Second-degree Burns involve the epidermis and dermis; a broad distinction is made between superficial and deep burns, based on the amount of dermis involved. Deep second-degree burns involve the entire papillary dermis, with penetration to some or all of the reticular dermis. Second-degree burns present as painful red blisters or broken epidermis exposing a weeping, edematous surface. They are most often caused by scalds or brief exposure to a flame. Recovery requires 2 to 3 weeks; sometimes scarring occurs.

Third-degree Burns involve all layers of the epidermis and dermis, with penetration into underlying fat and muscle. They usually result from prolonged contact with steam, hot objects, or flames and present with ulceration and tissue necrosis. They are painless because nerve tissue in the area has been destroyed. Deep tissue destruction can occur in electrical or chemical burns that may not become evident for several days.

Sunburn and Photosensitivity Reactions. Sunburn is one of the most common types of burn seen by the office-based physician. It represents ultraviolet injury to the skin. There are two phases: an immediate, initial, erythematous phase, which generally fades within 30 minutes after exposure, and a delayed response—what patients call sunburn—that occurs 3 to 6 hours after the exposure to the sun and peaks in 12 to 24 hours. Sunburn is characterized by erythema, pruritus, and tenderness but may proceed to edema, vesiculation, and even blistering. Repeated severe sunburns at an early age increase the risk for melanoma and other skin cancers later in life (see Chapter 177). Long-term excessive exposure to ultraviolet light leads to sustained elevations in skin matrix metalloproteinases, which can degrade skin collagen and contribute to premature skin aging.

Sun-related eruptions may also occur as a result of photosensitizing medications. The primary culprits are thiazide diuretics, sulfa-containing agents, tetracyclines (particularly demeclocycline), griseofulvin, phenothiazines, and nalidixic acid. Topical substances, particularly furocoumarins (found in parsley, celery, carrots, certain perfumes, and aftershave lotions as is St. John's wort) are also photosensitizing.

PRINCIPLES OF THERAPY

The first task is to assess the depth and extent of injury. Treatment of burn wounds is based on the depth and surface area of skin involved. The surface area of burns has traditionally been based on the "rule of nines." Each arm is considered to be 9% of the body surface area, each leg is 18%, the anterior and the posterior trunk are each 18%, the head is 9%, and the perineum and genitalia are 1%.

With the use of these classifications, the treatment of burns can proceed in an organized fashion. All second-degree burns involving more than 5% to 10% of the body surface, all third-degree burns, any burns associated with an electric current, and all burns of the ears, eyes, face, hands, feet, or perineum should be treated immediately at a major hospital familiar with burn care. A history of prolonged contact with scalding liquids, flaming clothing, or high-voltage electric current portends full-thickness damage and the need for referral, as does dry, parchment-like skin with a loss of hair follicles and sensation.

First-degree burns and second-degree burns involving less than 5% of the body surface can be treated on an outpatient basis by the primary physician with adequate wound care and follow-up, provided the patient is reliable and the home situation amenable.

The goals of therapy are to reduce inflammation, prevent infection, relieve pain, and promote healing.

First-degree Burns

First aid to minor burns involves immediate application of *ice packs* or *cold compresses* of water, milk, or oatmeal. Cold reduces discomfort, edema, and hyperemia and may diminish the extent of injury. The application of cold should continue until the burn is pain-free. *No dressing* is required, just skin lubricant and instructions to return if blistering occurs. Prophylactic antibiotics appear to have little or no effect.

Pain can usually be relieved with aspirin or acetaminophen. Aspirin has the advantage of suppressing inflammation and is particularly helpful in sunburn.

In cases of extensive sunburn, a topical corticosteroid lotion or spray may provide symptomatic relief. Systemic corticosteroids do not reduce the edema associated with sunburn and are not indicated.

Second-degree Burns

If the skin is broken, the wound requires protection so that healing can occur without infection. This involves gently *washing* the area of the burn with water and a mild antiseptic soap, such as one containing chlorhexidine. Washing is followed by gentle *irrigation* with sterile isotonic saline solution and application of a sterile *occlusive dressing*. With chemical burns, the involved area is placed under running water for at least 15 to 30 minutes before cleansing or debridement is started. A syringe or water pick can be used to help irrigate and remove embedded debris. Devitalized tissue should be debrided (see appendix to section 12). Patients complaining of pain or who appear anxious should be given an analgesic or a sedative before the injured area is manipulated. Adherent tar can be removed after being hardened by the application of ice or softened with a topical antibiotic such as polysporin or mupirocin (Bactroban) ointment. *Tetanus prophylaxis* is indicated and includes administration of tetanus toxoid booster to previously immunized patients (see Chapter 6).

Management of Blisters is somewhat controversial. Some argue that blisters provide an excellent burn dressing and protective barrier, but others suggest that the trapped fluid can become a culture medium for bacteria. Small, thick-walled blisters probably should be left intact, whereas those that are larger, thin-walled, located on hairy skin that is prone to infection, or located in areas where movement is likely to cause rupture should be removed. Removal should be complete because needle aspiration simply negates the protective barrier while retaining the potential culture medium for infection.

Prophylaxis against Infection is provided by the topical antibiotic preparation *silver sulfadiazine* (Silvadene). The cream is easy to apply and provides softening in addition to an antibacterial effect. It is contraindicated in persons allergic to sulfa and in pregnant and nursing women. The agent should be applied with a tongue depressor or glove in a layer thick enough to prevent the burn from being visible. Pain can be minimized by keeping the cream refrigerated. Silver sulfadiazine should be removed daily or every other day and reapplied. *Systemic antibiotics* are indicated only for established infection and are not appropriate for prophylaxis or outpatient use.

Dressings are prepared by applying a nonadherent, fine mesh gauze soaked in sterile saline solution to the burn. This is then covered with a bulky dressing into which fluid can drain without passing through (see appendix to section 12). The patient should be examined in 2 days for pain, adenopathy, and fever, and the dressing should be checked. If no evidence of infection is seen, the dressing may remain for 5 to 7 days, after which the area is reexamined to determine the need for a dressing change.

Pain Relief is an essential part of management, and usually aspirin or a nonsteroidal agent such as ibuprofen suffices. Short courses of agents containing codeine or oxycodone are appropriate for painful burns. Topical anesthetics may provide symptomatic relief but are not justified because of the risk for sensitization. In cases of extensive sunburn, topical corticosteroid sprays may provide modest symptomatic relief, but a short course of systemic steroids may be more effective.

Moisturization is important but often overlooked. After the burn heals, the new epithelial layer tends to dry and crack, and this problem can be reduced by the application of a moisturizing cream such as Eucerin or aloe vera for 4 to 8 weeks after apparent resolution.

INDICATIONS FOR REFERRAL AND ADMISSION

Referral for surgical consultation and hospitalization is indicated if burns exceed 10% to 15% of body area or full-thickness burns exceed 3%. Prompt admission and surgical consultation should be considered for circumferential or full-thickness burns; involvement of the eyes, ears, other organs of sensation, hands, or perineum; evidence of inhalation injury; or serious concurrent medical conditions such as diabetes and immunosuppression. Patients who are unreliable or unable to care for themselves may also require inpatient treatment.

PATIENT EDUCATION

Patient education is critical to successful recovery from a burn. The patient and caretaker should be instructed to keep the wound clean and note erythema or inflammation, which are signs of infection. Instruct the patient to note numbness, tingling, or a change in skin color or temperature, which may suggest that the dressing is too tight and circulation is being impaired. Explicit (often written) instructions on the removal of dressings, cleansing of the wound, reapplication of topical sulfadiazine, and treatment of dried skin are important. Patients with healed burns should be instructed to avoid exposure to direct sunlight because of increased sensitivity during the year following a burn injury. A burn provides a good opportunity to reinforce the importance of sunscreen use and to educate the patient about the warning signs of skin cancer (see Chapter 177).

The occurrence of a burn, even a minor one, is a good opportunity to reinstruct patients on the importance of burn prevention. The obvious caveats are not to smoke and to keep flammable material and matches away from children. Specific instructions on the use of pot holders, careful puncturing and removal of plastic wraps from food heated in the microwave oven, and controlling the temperature of hot tap water are all helpful. Reminders about the importance of smoke detectors and maintaining an approved fire extinguisher are important. A written burn prevention checklist is a useful aid.

THERAPEUTIC RECOMMENDATIONS

- For first-degree burns, immediately apply cold and keep the area cold until it remains free of pain even when the cold is withdrawn.
- If the skin is broken, cleanse with a mild soap and water before applying cold water or ice.
- No dressing or antibiotic is indicated for first-degree burns. Emollients such as Eucerin or aloe vera should be used if blistering does not occur after several days.
- For severe sunburn, prescribe a gentle topical corticosteroid lotion for symptomatic relief. Aspirin or ibuprofen provides analgesia and helps limit inflammation. Consider a brief course of systemic steroids for extensive sunburn.

- For second-degree burns, spread silver sulfadiazine (Silvadene) over the involved area in a thickness sufficient to prevent the burn from showing through. Refrigerating the sulfadiazine minimizes pain. Wrap the area with six or seven layers of gauze for protection.
- Prescribe systemic antibiotics, usually dicloxacillin, for any secondary cellulitis. Prophylactic oral antibiotics should not be used for fear of selecting out resistant gram-negative organisms.

CHAPTER 197 MANAGEMENT OF SKIN ULCERATION

WILLIAM V. R. SHELLOW

Skin ulceration can be a troublesome, disabling, and potentially dangerous problem. Cutaneous ulcers commonly encountered in medical practice include leg and pressure ulcerations. Approximately 1% of the population is affected by venous leg ulcers. Diabetics and others with arterial insufficiency are at increased risk for ischemic ulceration and limb-threatening infection. About 20% of geriatric patients have pressure ulcers, with an associated fourfold increase in mortality. The primary physician who recognizes and effectively treats early skin changes can prevent many of the debilitating consequences.

PATHOPHYSIOLOGY AND CLINICAL PRESENTATION

Skin ulceration most commonly results from venous or arterial insufficiency or from prolonged, excessive pressure. Infectious and malignant causes are also encountered, especially in immunocompromised persons.

Venous Insufficiency. The initial manifestation of venous insufficiency is edema, usually absent on arising and severe at the end of the day. Incompetent venous valves can be associated with age, thrombophlebitis, or a hereditary tendency to the development of venous varicosities. In all three conditions, abnormally high venous pressure during ambulation causes fibrinogen to leak from the engorged capillary bed. A precapillary fibrin layer develops and interferes with oxygen and nutrient exchange. Pigmentation, induration, dermatitis (*stasis dermatitis*), and finally ulceration may develop. The rupture of delicate venules releases hemoglobin, which changes to hemosiderin, producing pigmentation. Scaling and oozing develop when the skin is scratched. Vesicles may indicate a contact dermatitis caused by a topical medication. Secondary bacterial invasion occurs and may lead to cellulitis.

Stasis ulcerations develop within areas of dermatitis or indurated cellulitis. They occur most often above the medial malleolus because of its poor vascular supply and sparse subcutaneous tissue. Minor trauma can precipitate ulceration. The stasis ulcers vary in size from small erosions to an ulcer that encircles the ankle. They may or may not be painful. The base of the ulcer is usually moist, with exuberantgranulation tissue. Purulence indicates secondary infection.

Arterial Insufficiency. The most common cause of arterial insufficiency is *atherosclerotic disease*. The leg is cold and appears pale or cyanotic (although dependent rubor may be present), and peripheral pulses are lost or reduced. The ulcers are initially small, punctate, and superficial, but with worsening ischemia, they become larger and deeper. Typically, they occur on the sides of the feet, the heels, the toes, and the nail beds.

Ischemic ulcers are also associated with *hypertensive disease* and *vasculitis*. Those occurring in the context of hypertension characteristically develop over the lateral malleoli. They begin as painful, blue-red plaques that soon ulcerate. A purpuric halo may surround the ulceration. Vasculitic ulcers occur in the context of connective tissue disease, hematologic and malignant conditions, and hypersensitivity reactions, beginning as palpable purpuric lesions or hemorrhagic vesicles (see Chapter 179).

Decubitus Ulcer

The pressure sore or decubitus ulcer is common in bedridden or semiambulatory patients. It may present as nonblanchable erythema, soft-tissue loss, blisters, or eschar over bony prominences. Pressure ulcer severity is reflected by the stage of the lesion. Stage 1 lesions are manifested by nonblanchable erythema of intact skin. Stage 2 ulcers involve only the epidermis and dermis. Stage 3 ulcers extend into the subcutaneous tissues and undermine the surrounding skin. Stage 4 lesions extend through deep fascia to involve muscle and may extend to the bone.

Factors contributing to the development of pressure sores include shearing forces, friction, and moisture. Decubitus ulcers usually occur over bony prominences. The pressure gradient occludes lymphatic vessels and overloads the microvascular system, so that waste products accumulate and ultimately necrosis ensues. The lower part of the body and sacrococcygeal area are the predominant sites, with the hip, malleolus, and heel being other important areas.

Pressure sores can lead to cellulitis, bacteremia, osteomyelitis, and even meningitis. The microbiology of decubitus ulcers is polymicrobial, and the organisms that cause the most problems, including life-threatening bacteremias, are *group A streptococci*, *Staphylococcus aureus*, *Escherichia coli*, and *Bacteroides fragilis*.

PRINCIPLES OF MANAGEMENT

Many of the principles of ulcer management are similar, regardless of cause or location. Important objectives are to restore circulation (see Chapter 34 and Chapter 35), improve local factors, reduce pressure, remove necrotic tissue, maintain cleanliness, and prevent further injury.

Leg Ulcers

Regardless of cause, treatment of the leg ulcer begins with washing the leg and ankle with a mild soap. Emollients are used to prevent drying (xerosis). In leg ulcers with a clean base, application of an Unna's paste boot or an occlusive wound dressing may encourage healing and reepithelialization. An *Unna's boot* is a flesh-colored gauze roll bandage impregnated with zinc oxide, calamine, glycerin, and gelatin. Topical enzymes and hydrophilic beads are sometimes useful adjunctive agents in leg ulcers or pressure ulcers.

The bewildering array of commercially available *occlusive wound dressings* includes polyurethane films (Opsite, Tegaderm, Bioclusive), polyethylene oxide hydrogel (Vigilon, Spenco 2nd Skin), foam dressings (Lyofoam, Allevyn), laminate dressings (Biobrane), alginate dressings (Sorbsan, Kaltostat), and hydrocolloid dressings (DuoDerm). The dressing is replaced every 3 to 7 days, or sooner if it begins to leak. The patient must be warned to expect an unpleasant odor, caused by a buildup of fluid, when the dressing is removed. The optimal occlusive dressing for wound healing remains to be developed. DuoDerm is readily available and convenient to use.

Occlusive dressings are promoted as being capable of shortening the healing time, although they often prove no better than simple *wet-to-wet dressings*. Wet-to-wet dressings, along with cleaning and gentle debridement with gauze sponges several times daily, are useful. Dilute hydrogen peroxide can be used to clean the ulcerated area. Occlusive dressings do offer greater convenience and some pain relief. Occlusive dressings should not be used on wounds complicated by cellulitis.

Treatment of Stasis Dermatitis. Stasis dermatitis of any degree should be attended to because it can lead to further ulceration. Venous insufficiency and edema should be treated (see Chapter 35). *Topical corticosteroids*, creams or ointments, are useful to reduce the inflammatory component and itching. Corticosteroids should not be applied within an ulcer because they may delay wound healing. Oozing dermatitis requires wet dressings (compresses) and bed rest with leg elevation. Acute exudative dermatitis can be soothed and dried with cool *Burow's compresses*. Scratching, use of over-the-counter medications, and placement of adhesive tape on involved areas should be avoided and prohibited.

Secondarily infected dermatitis should be treated with *oral antibiotics* active against staphylococcal infection, such as dicloxacillin, amoxicillin/clavulanate (Augmentin), or erythromycin. *Topical antibiotics* may be used in mild cases. Top-ical mupirocin is effective against a wide range of staphylococci, including methicillin-resistant organisms, and appears to be nonsensitizing. However, its use should not be continued beyond 14 days because of the risk for emergence of resistant species with longer use. Preparations containing neomycin should be avoided because of its tendency to induce contact sensitization and dermatitis. Even

the dual antibiotic ointments containing polymyxin and bacitracin have induced contact dermatitis.

External *compressive bandages* or *stockings* should be used to reduce venous pressure in the lower extremities, and compression has been shown to promote healing. Graduated compressive surgical stockings are expensive but can be helpful (see Chapter 35). The patient should apply the compression in the morning before getting out of bed. Prolonged standing should be avoided, weight loss emphasized, and periods of leg elevation encouraged. Intermittent pneumatic compression has been used successfully as an alternative to elastic compression in refractory cases to speed ulcer healing.

Decubitus Ulcer

Nutritional repletion is important to reverse catabolism and to correct all factors that affect the oxygenation of tissue, such as anemia, edema, and vascular problems. *Reducing pressure* on the affected area is critical. In some cases, an alternating-pressure air mattress may be indicated. The basic principle of debridement is to use *wet-to-wet dressings* or an occlusive dressing. A variety of biochemical agents that dissolve debris are purported to promote healing, although double-blind evidence of their efficacy is generally lacking. Occasionally, grafts are required to close the ulceration.

If decubitus ulcers are complicated by infection, the antibiotic program should include anaerobic in addition to aerobic coverage. Even a shallow ulcer may hide a deep infective sinus or a tunnel to an osteomyelitis. A roentgenogram may be useful to detect chronic osteomyelitis.

Further measures include the use of laser sterilization, growth factors, allografts, and platelet aggregation inhibitors. The best treatment remains primary prevention.

PATIENT EDUCATION

With most ulcers, prevention is the key. Patients and family must be educated to look for pre-ulcerative changes in stasis dermatitis and use compensatory measures before ulceration occurs. In patients with chronic vascular disease, advice about cutting nails, treating sores early, and seeking medical care at the first sign of a break in skin is important. For people confined to bed or a chair, the family should be educated about preventing prolonged pressure on a bony prominence.

INDICATIONS FOR REFERRAL AND ADMISISON

Failure of ulcers to heal despite good management and a compliant patient indicates the need for surgical consultation. Surgical debridement and split-thickness or full-thickness skin grafting may be necessary. If fever or other signs of bacteremia develop, then IV antibiotics and prompt hospitalization are needed. Mortality risk is high, especially with associated anemia and hypoalbuminemia.

THERAPEUTIC RECOMMENDATIONS

Venous Insufficiency and Stasis Dermatitis

- In all patients with changes of stasis, control edema with rest, elevation, diuretics, avoidance of dependency, and external compression with stockings or bandages.
- Treat any concurrent nutritional deficiency, hypertension, diabetes, or congestive heart failure.
- Treat pruritus with intermediate-potency topical corticosteroids (e.g., 0.1% triamcinolone acetonide). Ointments are indicated if the area is dry and scaly, and creams should be used if the area is moist. Avoid application near or on an ulcer because corticosteroids may delay wound healing.
- Treat acute exudative dermatitis with cool Burow's compresses (1:40 dilution) two to three times daily for 30 to 60 minutes.
- Scratching and use of over-the-counter medicaments should be discouraged.

Cutaneous Ulceration

- Prescribe application of wet-to-wet dressings, followed by cleaning and gentle debridement with gauze sponges several times daily. Dilute hydrogen peroxide can be used to clean the ulcerated area.
- Occlusive dressings are worth a trial because they may ease pain, debride ulcers, and lead to healing without the need for surgical intervention.
- In the clinical setting of secondary infection, culture for aerobic and anaerobic bacteria, and treat accordingly with oral or IV antibiotics.
- In cases of mild skin infection, topical antibiotic creams such as mupirocin can be considered for short-term use (<2 weeks), but preparations that contain neomycin should be avoided.
- In cases of persistent deep ulcers, underlying osteomyelitis should be considered. A roentgenogram may be useful.
- Refer for surgical consultation patients whose ulcers prove refractory to proper conservative management. Pinch grafting is a relatively simple approach that can be performed in the office. Culture-derived human skin-equivalent grafts (Apligraf) have been quite successful but are very expensive. Becaplermin (recombinant human platelet-derived growth factor BB) gel (Regranex) has been shown to be clinically effective in healing ulcers but is also very expensive to prescribe.
- Surgical debridement and split-thickness or full-thickness skin grafting may be necessary.
- Alternative medicine has been shown to be of some value in the healing of wounds.

PART 13 OPHTHALMIC PROBLEMS

CHAPTER 198 SCREENING FOR OPEN-ANGLE GLAUCOMA

CLAUDIA U. RICHTER

Open-angle glaucoma affects approximately 2.25 million Americans aged 45 years or older and is the third leading cause of blindness worldwide, causing 3 million people to be bilaterally blind. The condition represents a group of diseases characterized by optic neuropathy with characteristic optic nerve findings and visual field loss. Among adults, primary open-angle glaucoma is the most frequent type, presenting asymptomatically until visual loss is advanced. Although the underlying disease process is neither preventable nor curable, visual loss can be prevented or minimized if the patient is identified early and the intraocular pressure is controlled.

EPIDEMIOLOGY AND RISK FACTORS

The prevalence of glaucoma increases with age, with whites aged 70 and older having a prevalence of 3.5% and African-Americans, 12%. Population-based surveys have demonstrated that African-Americans have a prevalence of glaucoma three to four times that of whites.

The strong risk factors for the development of glaucoma include elevated intraocular pressure, age, African descent, and family history. Other risk factors that are less strongly correlated are myopia, diabetes, and migraine and vasospasm.

Elevated intraocular pressure is one of the most important risk factors and is currently the only modifiable risk factor. Additionally, studies have demonstrated that lowering intraocular pressure can stop or slow the progression of glaucomatous damage.

PATHOPHYSIOLOGY, NATURAL HISTORY, AND EFFECTIVENESS OF EARLY THERAPY

The essential pathophysiologic feature of glaucoma is loss of ganglion cell axons with the development of optic nerve cupping and visual field loss. The exact mechanism of optic nerve damage has not been established and is probably a combination of factors. Ischemia of the optic nerve, caused by elevated intraocular pressure and increased vascular resistance or small blood vessel disease, can result in loss of ganglion cell axons. Increased intraocular pressure can also interfere with axoplasmic flow in the ganglion cell axons, causing cell dysfunction and death. The lamina cribrosa, the sievelike structure through which axons pass when leaving the eye, may lose support for the ganglion cell axons, resulting in interference with axonal function. Apoptosis may also play a role in the development of glaucoma. These different mechanisms of axonal damage, and others still unelucidated, are of variable importance in different patients, but the final result is loss of ganglion cells and their axons, optic nerve cupping, and visual field loss.

The relationship between intraocular pressure and visual loss (as manifested by field defects) is highly variable among individuals. The mean duration of intraocular pressure elevation before development of field defects has been estimated to be 18 years. The incidence of glaucomatous field defects among patients with ocular hypertension is 5 to 10 per 1,000 per year.

Glaucomatous visual field loss is irreversible. Although incurable, optic nerve damage and visual field loss can be delayed or prevented by lowering intraocular pressure. Early diagnosis and treatment are important because the optic nerve becomes increasingly vulnerable to further damage once initial damage has occurred.

SCREENING METHODS

Tonometry. Tonometry has been the most widely used screening test for glaucoma, with 21 mm Hg the cutoff point for referral. However, half or more of those patients with glaucoma will have screening intraocular pressures below this value (low sensitivity). Conversely, many individuals with intraocular pressure repeatedly more than 21 mm Hg do not have and may never develop glaucomatous damage. Elevated intraocular pressure repeatedly measured in the high twenties or higher has been demonstrated to be a strong risk factor for the development of glaucomatous damage. However, there is no level of intraocular pressure above which damage to the optic nerve and visual loss always occurs or below which glaucomatous damage never occurs.

Ophthalmoscopy. Changes in the contour of the optic cup in the center of the optic disc provide the first definitive evidence of glaucomatous damage. The usual cup has a round regular contour. The cup in early glaucoma becomes notched on the superotemporal or inferotemporal rim. Later changes include an increase in the depth and width of the physiologic cup, nasal displacement of the central retinal vessels, and progressive pallor of the optic nerve head. Other disc changes associated with glaucoma are asymmetric discs and disc hemorrhages. The preferred technique for optic nerve evaluation involves magnified stereoscopic visualization (as with a slit-lamp biomicroscope) through a dilated pupil.

The value of ophthalmoscopy for screening is not clear. Even among acknowledged glaucoma specialists, there is wide variability and poor agreement in the assessment of optic nerve status. The need for highly trained personnel and the possible need to dilate the pupils to allow adequate visualization are additional drawbacks. The use of sophisticated techniques such as computer-assisted optical imaging of the optic nerve may improve on the validity and reliability of traditional cup-to-disc ratio estimates, but expense, immobility, and complexity of use make these techniques inappropriate for mass population screenings.

Visual Field Testing. Visual field testing is inadequate for mass glaucoma screening because of the time and technical difficulty in performing an adequate examination and the low sensitivity of manual visual field techniques and the low specificity of automated visual field methods.

Nerve Fiber Layer Analysis. Computer-assisted nerve fiber layer analysis may detect glaucomatous optic nerve damage before optic nerve cupping is visible or visual field defects are detectable. However, nerve fiber layer analysis has a high rate of false-positives and false-negatives for glaucomatous damage and is expensive and immobile and therefore not currently practical for screening examinations.

CONCLUSIONS AND RECOMMENDATIONS

- Glaucoma is highly prevalent in the older adult population and is a major cause of blindness.
- Risk factors for glaucomatous visual loss include elevated intraocular pressure, a family history of glaucoma, advancing age, and African-American heritage.
- Treatment early in the course of the disease is more effective and more likely to prevent visual loss than that which is delayed until onset of symptoms. Early treatment necessitates detection of the asymptomatic patient.
- Frequency of screening depends on the risk factors of each patient. Asymptomatic African-Americans should be screened every 3 to 5 years between the ages of 20 and 39, every 2 to 4 years between ages 40 and 64, and every 1 to 2 years at age 65 and after. Other asymptomatic patients need to be screened less than every 3 to 5 years between ages 20 and 39, every 2 to 4 years between ages 40 and 64, and every 1 to 2 years at age 65 and after.
- Screening for ocular hypertension by a Schiotz tonometer by the primary physician has not been demonstrated to have adequate specificity or sensitivity in detecting glaucoma to be valuable.
- Funduscopic examination, with attention to the appearance of the optic cup, is an important component of the screening evaluation and should be performed by all primary care physicians.
- Automated perimetry or nerve fiber layer analysis may be a valuable screening adjunct in the future, but cost is too great, false-positives too frequent, and the

equipment too immobile to recommend these at present.

CHAPTER 199 EVALUATION OF THE RED EYE

ROGER F. STEINERT

The red eye is the most common eye problem encountered by the primary care physician. Most cases represent benign self-limited disorders that can be expeditiously diagnosed and treated by the primary physician; however, because redness of the eye may signal serious disease that threatens vision, the physician must be aware of the differential diagnosis and conduct a proper initial evaluation.

PATHOPHYSIOLOGY AND CLINICAL PRESENTATION

Redness of the eye and the periocular tissues reflects *inflammation* or *hemorrhage*. Causes of inflammation include bacterial, viral, chlamydial, and fungal infections; allergic responses; immune disorders; elevated intraocular pressure; environmental and pharmacologic irritants; foreign bodies; and trauma. Hemorrhage may be due to laceration, contusion, coagulopathy, or concomitant infection. Much less commonly, eyelid redness may be the presenting sign of benign or malignant eyelid *neoplasms* or be due to local dermatoses or systemic immunologic disease.

The pattern of conjunctival injection provides important clues in differential diagnosis. Corneal or intraocular inflammation produces "*ciliary flush,*" dilatation of the fine capillaries around the corneal border producing a red-violet halo. Larger deep episcleral vessels may also be engorged. Primary conjunctivitis induces diffuse vessel engorgement on the palpebral and bulbar conjunctiva, without a ciliary flush. The clinical presentations of various causes of red eye are distinctive (Table 199.1).

Table 199.1. Some Important Causes of Red Eye

A red eye may be due to pathology in the conjunctiva, cornea, uveal tract, eyelids, or orbit.

Conjunctival Pathology

Conjunctivitis is the most common cause of a red eye. Discharge, conjunctival erythema (especially of the peripheral bulbar segment), normal vision, lids stuck together in the morning, and absence of photophobia are the major manifestations. The etiology may be infectious, allergic, or chemical.

Bacterial conjunctivitis is characterized by a mucopurulent discharge and usually occurs unilaterally without preauricular adenopathy. The eyelids have a thick crust on them after a night's sleep. *Pneumococcus* is most commonly the infectious agent in temperate zones and *Haemophilus aegyptius* in tropical climates. Grossly purulent conjunctivitis suggests *Neisseria infection*, which may scar or perforate the cornea or lead to systemic dissemination. Chronic conjunctivitis is often due to *Staphylococcus aureus* or *Moraxella lacunata*. Concomitant sterile marginal corneal ulcers are common with chronic staph infection.

Chlamydial conjunctivitis, transmitted from the genitourinary tract, occurs as bilateral "inclusion conjunctivitis" in sexually active young adults. Exudate is profuse, and preauricular adenopathy is common.

Trachoma is a major cause of blindness worldwide but is rare in the United States except among Native Americans in the Southwest. However, the rapidly increasing rate of chlamydial cervicitis (see Chapter 115) among young women raises the risk of trachoma in a much wider population of newborns.

Viral conjunctivitis is characterized by watery sometimes mucoid discharge, often beginning in one eye but spreading to the other eye several days later. Preauricular adenopathy is common. It may be associated with fever and pharyngitis (pharyngoconjunctival fever), particularly in children. Epidemic keratoconjunctivitis is a highly contagious adenoviral infection that may be accompanied by corneal epithelial defects in the first week and subepithelial infiltrates in the second week, with some diminution of vision. Pseudomembranes or scarring of the conjunctiva may occur and sometimes is painful.

Allergic conjunctivitis may be associated with seasonal allergies and atopic dermatitis and is characterized by bilateral itching and clear tears. Vernal keratoconjunctivitis is a chronic recurrent hypersensitivity reaction that may lead to the formation of corneal ulcers.

Bilateral sterile conjunctival inflammation occurs in acne rosacea, Reiter's syndrome, and Stevens-Johnson syndrome.

Hypersensitivity to eye medications may cause erythema of the external lids, especially at the lateral canthus. *Angioneurotic edema* of the lids may occur bilaterally as an allergic response to a systemic allergen, often food, or unilaterally secondary to exposure to local allergens such as topical chemicals, poison ivy, and insect bites; it develops rapidly and resolves in 1 to 2 days. Edema without erythema suggests allergy.

Pinguecula is a yellow harmless nodule of the scleral conjunctiva, usually found on the nasal side, causing only mild discoloration. However, a related disorder, *pterygium*, is vascularized. It causes redness and encroaches on the cornea. The condition is most common in patients heavily exposed to strong sunlight.

Subconjunctival hemorrhage usually occurs secondary to trauma, although the patient may be unaware of the minor trauma involved. In patients receiving anticoagulant medications, spontaneous subconjunctival hemorrhage may be a sign of overdosage. Massive subconjunctival hemorrhage accompanied by proptosis and limited extraocular movements, usually after trauma, signals orbital hemorrhage, which may compromise the optic nerve and retinal circulation.

Foreign body on the bulbar conjunctiva or under either the upper or lower lid may result in copious tearing, conjunctival injection, and a sensation that something has gotten "into" the eye. On occasion, the foreign body may be well tolerated, with the eye remaining white and quiet.

Episcleritis is usually a benign inflammation of superficial episcleral vessels. The conjunctiva manifests areas of circumscribed nodular inflammation, seen in association with collagen disease, gout, allergic conditions, and such skin diseases as psoriasis. The patient complains of tender irritated eyes. Vision and lids are normal, the corneas are clear, and the conjunctivae show local raised areas of redness.

Scleritis, often associated with rheumatoid arthritis and other immune disorders, is a potentially destructive inflammation of the collagen in the deep episcleral

vessels and the sclera. The eye is sometimes painful. Fortunately, scleritis is rare. An experienced observer is required to make the diagnosis.

Corneal Disease

Keratitis presents with a perilimbal ciliary flush, accompanied by clear tears and photophobia. Corneal ulcers detected by fluorescein staining may be sterile or caused by bacteria, viruses, or fungi. Particularly distinctive is the "dendritic" figure of herpes simplex keratitis, in which the epithelium stains in a fine branching pattern. Herpes simplex and zoster may also cause broader "geographic" defects. *S. aureus* may cause a sterile infiltrate in the corneal limbus.

Corneal abrasions stain with fluorescein but have no infiltrate unless they are untreated for several days. *Hyphema* (blood layering in the anterior chamber) indicates severe trauma and requires ophthalmologic consultation. *Recurrent erosion* presents as an epithelial defect at the site of an abrasion that occurred months or years before and was often caused by organic material (e.g., tree branch, fingernail). It may also occur in corneal dystrophies. In both instances, it is due to a defect in epithelial adherence to the underlying stroma. A *corneal foreign body* may cause tearing and hyperemia with little sensation of a foreign body. This is particularly true of rust rings left by ferrous foreign bodies. Dry eyes can cause intense reactions secondary to superficial keratitis, as does overwearing of contact lenses (corneal hypoxia) and ultraviolet keratitis. *Corneal laceration* with perforation is suggested by a shallow or absent anterior chamber, markedly decreased intraocular pressure, and eccentric pupil with iris prolapse into the wound.

Chemical keratoconjunctivitis is a common industrial injury due to a splash of an irritant solution. The conjunctiva is uniformly red, the pupil constricted, vision decreased, the cornea hazy, and the eye painful because of spasm of the iris.

Uveal Tract Disease

Uveitis refers to inflammation of the uveal tract, including the iris, ciliary body, and choroid. The diagnosis is suggested by pain, photophobia, redness, and ciliary flush. Iritis presents with eye pain, photophobia, redness, and pupillary contraction. It may be unilateral or bilateral; if unilateral, the pupil is smaller than that of the other eye because of spasm. Flashlight examination shows a slightly cloudy anterior chamber. Slit-lamp examination discloses cells in the anterior chamber and "flare," representing increased aqueous humor protein. Inflammatory cells, called "keratic precipitates," may collect in clusters on the posterior cornea.

Iritis and uveitis are usually idiopathic but may be associated with a large number of systemic and ocular diseases. *Ankylosing spondylitis, sprue, granulomatous colitis, tuberculosis, sarcoidosis,* and *juvenile rheumatoid arthritis* are sometimes associated with uveitis. The HLA-B27 tissue antigen is strongly associated with iritis, often accompanied by ankylosing spondylitis or *Beháet's disease.* Secondary iritis occurs in response to blunt trauma or corneal inflammation.

Eyelid and Orbital Disease

Blepharitis connotes inflammation involving the structures of the lid margin with redness, scaling, and crusting. Examination of the lid margin may reveal inspissated sebaceous ma-terial. *Staphylococcal blepharitis* causes anterior lid margin findings, including dry scales, lash loss, and sometimesconjunctivitis and corneal limbal infiltrates. *Seborrheic blepharitis* is associated with anteriorly located greasy scales. Meibomian gland dysfunction is characterized by dilated vessels at the posterior eyelid margins, blocked and pouting meibomian glands, and abnormal meibomian secretions. *Meibomian gland dysfunction* is frequently associated with seborrheic dermatitis and acne rosacea. Blepharitis tends to be chronic with acute flare-ups and is more common in fair-skinned people. Table 199.2 lists other causes of eyelid inflammation.

Table 199.2. Other Causes of Eyelid Inflammation

Hordeolum is an acute staphylococcal infection of the meibomian glands (internal hordeolum) or of the glands of Zeis or Moll around the lashes (external hordeolum or sty). It may present as diffuse redness, tenderness, and edema, localized only by an inspissated meibomian gland. An internal hordeolum may point either to the skin or conjunctival side of the lid, whereas an external hordeolum always points to the skin. Hordeolum may produce a diffuse superficial lid infection known as "preseptal cellulitis."

Chalazion is a sterile granulomatous inflammation of the meibomian gland, which may be tender and mildly inflamed or a quiet discrete mass.

Acute dacryocystitis is a tender, warm, localized infection of the tear ducts over the lateral nose; purulent material may be expressed from the tear duct on the application of pressure.

Hemorrhage in the lids or forehead, either spontaneous or traumatic, may rapidly dissect along the tissue planes of the lids and cause an impressive generalized ecchymosis, greatly alarming the patient.

Orbital cellulitis is usually caused by gram-positive organisms that enter the orbit either directly from the sinuses or through venous channels. It presents as swollen red eyelids with chemosis, exophthalmos, pain, fever, and leukocytosis. If it progresses, it may lead to paresis of the third, fourth, and sixth cranial nerves or the ophthalmic division of the fifth, signs of the very serious complication *cavernous sinus thrombosis.*

Intraocular Disease

Acute glaucoma is an ocular emergency that presents as a painful red eye with prominent ciliary flush. The pupil is mid-dilated and fixed, and the cornea is cloudy secondary to edema. Intraocular pressure exceeds 40 mm Hg and may reach 70 to 80 mm Hg. The patient reports cloudy vision, colored rings around lights (due to corneal edema), and unilateral headache, often accompanied by nausea and vomiting, occasionally leading the physician to consider an acute abdomen. Acute glaucoma is usually due to closure in eyes with narrow angles but may be due to inflammatory cells or red blood cells in the anterior chamber, neovascularization of the iris (rubeosis iridis), or peripheral anterior synechiae.

DIFFERENTIAL DIAGNOSIS

The causes of red eye can be divided anatomically into the categories of conjunctival, corneal, uveal, eyelid-orbital, and intraocular disease (Table 199.1). Differentiation can usually be made on clinical grounds (Table 199.3).

Table 199.3. The Red Eye

	Conjunctivitis			Corneal Injury or Infection	Iritis	Acute Glaucoma
	Bacterial	Viral	Allergic			
Vision	–	–	–	↓ or ↓↓	↓	↓↓
Pain	–	–	–	+	+	+++
Photophobia	–	–	–	+	++	+
Foreign body sensation	–	±	–	+	–	–
Itch	±	±	++	–	–	–
Tearing	+	++	+	++	+	–
Discharge	Mucopurulent	Scant	–	+	–	–
Preauricular adenopathy	–	+	–	–	–	–
Pupils	–	–	–	NL or small^a	Small	Mid-dilated and fixed
Conjunctival hyperemia	Diffuse	Diffuse	Diffuse	Diffuse and ciliary flush	Ciliary flush	Diffuse and ciliary flush
Cornea	Clear	Sometimes faint punctate staining or infiltrates	Clear	Depends on disorder	Clear or lightly cloudy	Cloudy
Intraocular pressure	NL	NL	NL	NL^c	↓, NL, or ↑	↑↑

^a In herpes keratitis.
^b Indicates secondary iritis.
^c May be ↑ in perforating trauma.
NL, normal.

WORKUP

History is directed toward ascertaining the duration of redness, rapidity of onset, the patient's activity at the time, and the degree and quality of symptoms. Ophthalmologic history and medications should be noted. Key symptoms include visual changes, pain, itching, crusting in the morning, tearing, mucoid or purulent discharge, photophobia, and foreign body sensation. Although usually helpful, the history can be misleading, because viral conjunctivitis may be accompanied by itching or a foreign body sensation or the patient may ascribe the symptoms of herpes simplex keratitis to a "chemical in the eye" because the symptoms were first noted after, for example, a home hair permanent.

Physical Examination. Accurate measurement of visual acuity, preferably at a distance, is essential. If it is abnormal, it is important to check for uncorrected optical abnormality by use of a pinhole. Any patient with reduced vision not readily explained by a preexisting or obviously harmless condition needs to be immediately referred to an ophthalmologist. Mucus and tearing may reduce vision one or two lines at most. Corneal lesions may further reduce vision, with only partial improvement on pinhole testing; a central epithelial abrasion typically maintains vision at about 20/100 or better. Preauricular nodes should be palpated. A complete examination of the eye and fundus is important. The lid margins should be inspected for crusting, ulceration, inspissations, and masses and the conjunctiva for distribution of redness, ciliary flush, foreign bodies (including lid eversion), and, if a slit-lamp is available, follicles and papillae. Corneal clarity is noted with a flashlight, and a direct ophthalmoscope set at about +15 diopters can be used to magnify corneal details.

If *fluorescein stain* is available, it can be used in conjunction with a blue filter to visualize the cornea for infection and other injury. However, if there is any suspicion of corneal injury, referral is needed quickly for slit-lamp examination.

Intraocular pressure should be determined if glaucoma is suspected. Depth of the anterior chamber of the other eye can be assessed by a flashlight aimed parallel to the iris (coronal plane) from the temporal side. A shallow anterior chamber is usually convex and will cast a shadow on the nasal iris.

Laboratory studies are usually the responsibility of an ophthalmologist. The primary practitioner may attempt *conjunctival smears*, which show polymorphonuclear leukocytes in acute bacterial conjunctivitis, lymphocytes in viral or late bacterial conjunctivitis, and eosinophils in allergic reactions. This is time consuming and generally not necessary. Purulent discharges should be *cultured* on blood agar and, if *Neisseria* is suspected, plated on chocolate agar and Gram stained. Scrapings for inclusion bodies in suspected chlamydial and viral disease are usually unrewarding, and scraping and culture of an infected corneal ulcer require an ophthalmologist.

White blood cell and differential counts are indicated, as are *blood cultures*, in suspected cellulitis. Clotting studies for subconjunctival hemorrhage are not indicated unless other evidence of coagulopathy is present (see Chapter 81) or the patient is being treated with anticoagulants (see Chapter 83).

PRINCIPLES OF MANAGEMENT AND INDICATIONS FOR REFERRAL

Red eye problems associated with eye pain, visual disturbance, or corneal damage require immediate referral, as does acute glaucoma. In most other situations, the primary physician can provide symptomatic relief or at least first aid. A nonophthalmologist should never prescribe topical steroid or steroid–antibiotic combination drops, because infection may worsen and a corneal ulcer may rapidly form and cause perforation.

Conjunctival Disease. Conjunctivitis, in the absence of photophobia, eye pain, or change in visual acuity, can be managed by the primary physician.

Viral Conjunctivitis is contagious, and live virus is shed in the tears for up to 2 weeks. The patient should be instructed to refrain from rubbing the eye and transmitting infection to the other eye or to another person. Treatment is expectant, because the condition is self-limited, usually clearing within 2 to 3 weeks. Cases that fail to improve spontaneously should be referred to the ophthalmologist.

Bacterial Conjunctivitis responds well to *erythromycin ophthalmic ointment* (prescribed four times a day) or *polymyxin/trimethoprim (Polytrim) drops* (prescribed four times a day). Improvement is usually noted in several days. Bacitracin ophthalmic ointment and sodium sulfacetamide are alternative antibiotics. Neomycin causes allergic keratitis in 5% of patients treated topically and should be avoided if possible. More potent topical antibiotics such as the aminoglycosides and fluoroquinolones are not recommended for routine conjunctivitis.

Allergic Conjunctivitis in seasonal allergies is relieved by *cool compresses* and *decongestant-antihistamine drops* (Vasocon-A, Naphcon-A, Albalon-A), antihistamine (Livostin), and mast-cell–stabilizing topical medications (Opticrom, Patanol, and others) up to four times daily. Long-term use of decongestant drops is not recommended, because marked rebound vasodilation may develop. *Acular (ketorolac) ophthalmic drops* (a nonsteroidal antiinflammatory agent) may also help alleviate allergic symptoms. Oral *antihistamines* are another alternative. Severe allergic conditions may require *topical steroid therapy*; management of topical steroids by an ophthalmologist is mandatory because of the risks of steroid-induced glaucoma and cataract.

Subconjunctival Hemorrhage usually requires only reassurance. Compresses (initially cool, then warm) and erythromycin ophthalmic ointment or a lubricating ointment may reduce discomfort in cases with marked swelling.

Conjunctival Foreign Bodies are usually easily removed with a cotton swab or fine forceps; erythromycin ointment three times a day for 2 days is adequate for healing.

Eye Lid and Orbital Disease. Topical therapies are often helpful, at times supplemented by oral antibiotics.

Blepharitis usually responds to lid hygiene measures and topical antibiotics. One can instruct the patient to dilute Johnson's *baby shampoo* 50:50 with water and use a cotton ball to scrub the lids well with the eyes closed. After rinsing with water, a hot compress is applied to the closed lids for 5 to 10 minutes and then *erythromycin* or *bacitracin ophthalmic ointment* is instilled in the inferior fornix. The excess is rubbed into the eyelash base. Carrying out this procedure as many as three to four times daily will improve most cases. After improvement is obtained, the lids can be maintained by nightly lid hygiene and warm compresses. An occasional stubborn case will require nightly antibiotic ointment as prophylaxis.

Chronic blepharitis and meibomian gland inflammatory disease may be due to acne rosacea. In addition to topical therapy, institution of systemic treatment for the rosacea is indicated. Traditionally, this has consisted of long-term suppressive therapy with a *low-dose tetracycline*-family antibiotic (e.g., tetracycline 250 mg, doxycycline 50 or 100 mg, or minocycline 50 mg once daily). Recent evidence implicating *Helicobacter pylori* in the pathogenesis of acne rosacea has led to a therapeutic regimen of a 7- to 14-day course of double- or triple-antibiotic therapy (e.g., amoxicillin, metronidazole, bismuth subsalicylate; see Chapter 68).

A Hordeolum may respond to this treatment or, like chalazia, may require incision and curettage by an ophthalmologist.

Mild cellulitis of the lid margin (preseptal cellulitis) responds to topical treatment plus oral antibiotics. *Dicloxacillin* (250 mg four times a day) is a good first choice. *Erythromycin* (250 to 500 mg orally three times a day) is an effective alternative for patients who are penicillin allergic. *Orbital cellulitis* and orbital cellulitis complicated by *cavernous sinus thrombosis* are medical emergencies that require immediate hospitalization for intravenous antibiotics.

Acute Dacryocystitis. Warm *compresses* and oral antibiotics are also indicated, but persistent localized abscess requires *incision* and *drainage* by an ophthalmologist.

Mild Hypersensitivity Reactions of the lids respond rapidly to discontinuation of the offending agent and application of cool compresses. Systemic antihistamines are useful in moderate reactions, and steroids are useful in severe reactions.

Traumatic Lid Ecchymoses are minimized by cool compresses and ice packs applied early. Later, warm compresses speed resolution.

Corneal Disease. The prompt attention of the ophthalmologist is usually required, but a number of conditions can be treated by the primary physician in the initial stages.

Corneal Ulcers require intensive emergency evaluation and treatment by an ophthalmologist. Patients with typical herpes simplex dendritic keratitis may be started on Viroptic drops up to nine times a day or Vira-A ointment five times daily and erythromycin ointment twice daily if an ophthalmologist is not available.

Corneal Abrasions heal rapidly with *erythromycin ointment* and a tight *sterile patch* that prevents lid motion for 24 to 48 hours. If the initial abrasion was sizable (roughly 25% of the cornea or more), healing should be checked after removal of the patch. Lesions of this size also require cycloplegia for relief of painful secondary iritis during healing (see iritis treatment). After reepithelialization occurs, ointment applied three times daily for 4 days helps complete the healing process.

Foreign Bodies are treated with vigorous *irrigation*. Rust rings are treated like abrasions once the foreign body has been washed away. Foreign bodies that do not wash away with irrigation can be removed with a *cotton swab*, a sterile "golf stick," or an 18-gauge needle with a syringe as a handle, but such removal should not be attempted by the nonophthalmologist unless specifically trained to do so. Rust on the surface is easily debrided, but scraping is prohibited because it will damage Bowman's membrane and cause permanent scarring. Left untreated, rust may be irritating but will surface and slough in 1 or 2 weeks.

Contact Lens Overwear and Ultraviolet Keratitis respond to brief cycloplegia, erythromycin ointment, and sterile pressure patching for 24 hours. The associated pain often requires codeine.

Suspected Corneal Laceration and Perforation are ophthalmic emergencies. A protective metal shield ("Fox shield") should be placed over the eye; no medication should be instilled.

Uveal Tract Disease. An ophthalmologist must evaluate and treat *primary iritis*, but initial cycloplegia by tropicamide 1% four times a day or cyclopentolate 1% four times a day will prevent posterior synechia formation and relieve pain. *Iritis* secondary to corneal abrasion may be treated with these medications, or in an eye that will be patched for 1 or 2 days, several drops of scopolamine 0.25% will provide longer cycloplegia. The nonophthalmologist should avoid atropine because its effects persist for 1 to 2 weeks.

Intraocular Disease. *Acute glaucoma* should be treated by immediate administration of acetazolamide, 500 mg intravenously, and glycerol, 120 mL orally in orange juice. Pilocarpine 2% should be begun with instillation as frequently as every 15 minutes to break the attack. Immediate attention by an ophthalmologist is necessary because the only definitive treatment is laser or surgical iridotomy.

CHAPTER 200 EVALUATION OF IMPAIRED VISION

CLAUDIA U. RICHTER

Patients with decreasing or blurred vision often refer themselves directly to an eye specialist, but at times they first present to their primary physician. Sudden visual loss is a medical emergency. Gradual diminution of sight raises the specter of eventual blindness and inability to function independently. Paradoxically, some elderly patients may not volunteer that their vision is decreasing because they consider it a natural part of aging. Consequently, the primary physician needs to screen elderly patients for treatable causes of decreased vision. In addition, one should be capable of distinguishing visual impairment due to refractive error, cataracts, glaucoma, retinal disease, and trauma to provide proper initial care and appropriate and timely referral.

PATHOPHYSIOLOGY AND CLINICAL PRESENTATION

Vision is impaired when there is a change in the refracting surfaces of the eye, opacification of the transparent ocular media, damage to the photoreceptor cells of the retina, or a lesion of the optic nerve, its radiations, or the visual cortex. Anatomic orientation provides a framework for considering the pathophysiology of visual difficulties, beginning with the cornea and working inward.

Refractive error is the most common cause of decreased visual acuity. It results from the inability of the eye to focus light precisely on the retina and may be due to an abnormality in the cornea, lens, or size of the globe. Myopic patients commonly present during their teens and early twenties. Patients in their forties may report decreased visual acuity but in fact simply cannot accommodate to near distances and require reading glasses. Early cataracts can increase myopia before they opacify and block transmission of light. Uncontrolled diabetes mellitus can produce swelling of the lens and myopia, which resolves with control of the blood sugar. Sulfonamides, thiazides, and anticholinergic agents may induce myopia causing blurred vision.

Eyelid Disease. Occasionally, sudden visual loss results from eyelids being closed by swelling due to trauma, insect bites, cellulitis, or angioneurotic edema. Acute blepharospasm secondary to ocular surface pain may be described as inability to see.

Corneal Disease. The cornea is the major refracting surface of the eye, and any change in it can lead to visual disturbances. A corneal abrasion, herpes simplex virus keratitis, or ulcer causes irregularity of the corneal epithelium and opacification of the normally clear cornea. Acute glaucoma causes sudden visual loss by producing corneal edema. Corneal dystrophies or degenerations result in a more gradual reduction in visual acuity, often progressing over a period of years.

Anterior Chamber Disease. The anterior chamber may be opacified by inflammatory cells resulting from *iritis* or red blood cells resulting from a *hyphema. Cataracts*, opacifications of the lens, are a leading cause of gradual vision loss in older patients. The usual history is one of a painless slow deterioration of eyesight. However, a traumatic cataract may develop over a period of hours to days.

Vitreous opacification occurs most often from hemorrhage and less commonly from inflammation or infection. Proliferative diabetic retinopathy, a retinal hole or detachment, trauma, sickle cell retinopathy, hypertension, and clotting abnormalities may cause vitreous hemorrhage. A *vitreous floater* may transiently blur vision or may be called a blind spot.

Glaucoma may damage nerve fibers at the optic disk and cause visual field defects. Most visual loss due to glaucoma is gradual and progressive (see Chapter 207). Four types of visual field defects occur: paracentral scotomas occurring along the distribution of the arcuate nerve fiber bundle, arcuate scotomata, sector-shaped defects, and nasal steps. As the disease progresses, these visual field defects enlarge. Central vision remains intact until late in the disease, but even this may be lost. The optic cup becomes enlarged and irregular (see Chapter 198). Acute angle-closure glaucoma produces a red eye, fixed pupil, hazy cornea, eye pain, and acute impairment of vision. Acute angle-closure glaucoma accounts for less than 5% of all glaucoma cases.

Retinal Disease. Degeneration, inflammation, trauma, detachment, or ischemia may compromise the retina, causing visual loss.

Age related macular degeneration occurs in patients over age 55 and is a leading cause of legal blindness. Central vision is impaired, whereas peripheral vision remains intact. Funduscopic examination may show loss of the foveal reflex, macular drusen, atrophy of the retinal pigment epithelium with prominent choroidal vessels, subretinal edema or hemorrhage, or a central fibrous scar. Some 15% of patients with senile macular degeneration have treatable disease, presenting with early visual symptoms and a subretinal neovascular net that can be obliterated with laser photocoagulation. They need to be seen promptly to maximize their chances of effective treatment. Those at particular risk of developing exudative senile macular degeneration have drusen or a disciform scar in one macula. They should screen their central vision daily with an Amsler grid (see Chapter 206).

A host of other retinal problems may lead to loss of vision. *Central serous retinopathy* is an idiopathic spontaneous detachment of the retina in the macular area. Patients range in age from 20 to 50 years old. Central vision is reduced, but recovery is usually spontaneous within a few months.

Retinal inflammation of the retina and choroid, such as histoplasmosis, toxoplasmosis, cytomegalovirus, or herpes virus infections, can involve the macula or produce a vitritis, decreasing vision. *Cytomegalovirus retinitis* is of concern in HIV-infected patients and important to recognize because it is treatable. Patients with CD4 counts less than 200 are at significantly increased risk of developing cytomegalovirus retinitis. Spread to the eye is hematogenous. Ocular symptoms include new floaters and loss of vision. Funduscopic manifestations include perivascular yellow-white retinal lesions presenting as a focal white granular infiltrate with or without hemorrhage, expanding in a "brushfire" pattern.

Trauma may cause decreased visual acuity by producing *macular edema* or a *choroidal* rupture. *Macular edema* resolves within a few days and visual acuity improves. A choroidal *rupture* causes permanent decreased visual acuity.

Retinal detachment may cause decreased visual acuity when it is extensive or may be noted as a minor field defect when it is small. Flashing lights and a shower of vitreous floaters may presage a retinal detachment. As a detachment extends, the patient may note that the visual field defect progresses like a shade being drawn. A detached retina appears ballooned forward with undulating folds.

Systemic diseases may involve the retina and cause decreased vision. Vascular injury is the most common mechanism, as occurs with hypertension, diabetes mellitus, and systemic lupus erythematosus. Infiltrative disease may also affect the retina.

Vascular Disease. The vasculature of the retina or optic nerve may be compromised, leading to sudden visual loss. The vascular diseases involving the arteries include central retinal artery occlusion, giant cell arteritis, and anterior ischemic optic neuropathy. In *central retinal artery occlusion*, there is sudden painless loss of ability to perceive light or hand movements. The patient may have had previous episodes of amaurosis fugax with fleeting blindness lasting 10 to 15 minutes. Ophthalmoscopy reveals a pale optic disc, attenuated arterioles, "boxcar" veins, hazy edematous retina, and a cherry-red spot in the macula. Occasionally, an embolus may be seen at a bifurcation of a retinal arteriole. The most common embolic sources are an atheromatous plaque in the ipsilateral carotid artery or a vegetation from a cardiac valve leaflet.

Giant cell or temporal arteritis, a granulomatous inflammation of the medium and large arteries in elderly people, may cause sudden visual loss (see Chapter 161). These patients may have premonitory visual symptoms similar to amaurosis fugax and may have symptoms of polymyalgia rheumatica. The fundus examination may reveal a swollen optic disc, a normal optic disc, or a central retinal artery occlusion.

Anterior ischemic optic neuropathy is produced by ischemia to the anterior portion of the optic nerve. The patient notes decreased visual acuity or a visual field defect,

usually involving the superior or inferior visual field and the macula. The optic disc initially appears edematous, sometimes in just one portion, with a few flame-shaped hemorrhages. Optic atrophy follows the disc edema. The most common etiology is thrombosis of an arteriosclerotic vessel. The patients tend to be younger than those affected by giant cell arteritis and have hypertension or diabetes mellitus.

Central or branch retinal vein occlusions cause a sudden painless decrease in visual acuity. In central retinal vein occlusion, the fundus has a classic "blood and thunder" appearance: The veins are tortuous and dilated and the retina is edematous and covered with flame-shaped hemorrhages. The optic disc margin is blurred. The fundus changes in branch retinal vein occlusion are similar but limited to the distribution of the involved vein. Decreased visual acuity is due to macular edema and ischemia. In central retinal vein occlusion, 20% of patients have preexisting chronic open-angle glaucoma and 50% of men have preexisting hypertension. In branch retinal vein occlusion, 75% of patients have preexisting hypertension.

Optic Nerve Disease. *Optic neuritis*, inflammation of the optic nerve, presents with a relatively acute impairment of vision in young persons (ages 15 to 40). It is usually idiopathic, but 20% to 50% eventually develop clinical *multiple sclerosis*. Clinically, there is progressive loss of vision over hours to days, typically unilateral with pain on eye motion, and improved visual function in the second to third week. Examination reveals an afferent pupillary defect, globe tenderness, visual field defects, and impairment of color vision. The optic nerve may appear normal.

Infiltrative or compressive lesions of the optic nerve, such as pituitary adenomas, meningiomas, gliomas, or internal carotid artery aneurysms, cause gradual visual field loss. It is unusual for lesions posterior to the optic chiasm to present with decreased visual acuity because of the decussation of fibers in the optic chiasm. Unilateral lesions, such as a tumor or a cerebrovascular accident, cause a homonymous hemianopsia or related visual field defect. Bilateral central nervous system lesions may cause profound visual loss.

Many patients complain of blurred vision at night. Rarely, these patients may be found to have true *night blindness* caused by *retinitis pigmentosa or vitamin A deficiency*. More commonly, no etiology is found; a slight decrease in visual acuity at night is common and normal.

Psychogenic pathology sometimes presents as visual loss or compromise. Characteristically, the eye examination and objective measures of visual function that do not require the patient's report are intact. Hysteria and malingering account for most psychogenic cases.

DIFFERENTIAL DIAGNOSIS

The causes of visual impairment can be logically considered in terms of anatomic site affected (Table 200.1). The leading causes of blindness include cataracts, open-angle glaucoma, and macular degeneration.

Eyelids
 Edema
 Blepharospasm
Cornea
 Abrasion
 Infection
 Edema
 Degeneration
Anterior chamber
 Inflammatory cells (from iritis)
 Hyphema
Lens
 Cataract
 Swelling (e.g., poorly controlled diabetes)
Vitreous
 Hemorrhage
 Floaters
Retina
 Age-related macular degeneration
 Central serous retinopathy
 Inflammation
 Trauma
 Detachment
 Diabetes
 Hypertension
Vasculature
 Central retinal artery occlusion
 Giant cell (cranial or temporal) arteritis
 Anterior ischemic optic neuropathy
 Retinal vein occlusion
Optic nerve
 Compression (glaucoma, tumor)
Psychiatric
 Hysteria
 Malingering
Refractive error

Table 200.1. Causes of Impaired Vision

WORKUP

History. A thorough history is most important in evaluating a complaint of visual loss. It is essential to establish the onset, duration, clinical course, and pattern of visual loss. Any associated visual phenomena should be ascertained, as well as any pain. The presence of premonitory symptoms is helpful. Acute loss is suggestive of a vascular event or retinal detachment. Preceding episodes of amaurosis fugax indicate central retinal artery occlusion or giant cell arteritis. A sudden flurry of flashes of light (photopsia) and vitreous floaters may herald a retinal detachment. Scintillating scotomata may herald migraine. Progressive visual loss points to a chronic disturbance, such as cataract, macular degeneration, or glaucoma. Previous episodes of decreased visual acuity with halos around lights and pain indicate angle-closure glaucoma. A foreign body sensation indicates a corneal abrasion, foreign body, or herpes simplex keratitis. The presence of other diseases such as diabetes mellitus, hypertension, heart disease, or sickle cell anemia may be contributory. A history of trauma is important to note, as is smoking, an important independent risk factor for age-related macular degeneration.

Physical Examination and Laboratory Studies. *Visual acuity* testing should be done formally, one eye at a time. If the patient complains of pain, a topical anesthetic such as proparacaine should be used to allow testing. If the lids are tightly swollen, it may be necessary to pry them apart forcibly. The patient should wear his or her distance glasses. A *Snellen eye chart* with its standardized letter sizes is most convenient. If letters cannot be read, the distance at which the patient can accurately count fingers or identify hand motions is noted. If targets cannot be seen, it is important to determine whether the eye can perceive light. Vision is rechecked with the patient looking through a pinhole to eliminate any residual refractive error.

The *pupils* should be examined carefully, noting size, direct and consensual reactions to light, and presence of any afferent pupillary defect. An afferent pupillary defect may be found in optic neuritis, central retinal artery occlusion, giant cell arteritis, and extensive retinal diseases. A fixed pupil in conjunction with a red eye is indicative of acute angle-closure glaucoma.

The *conjunctiva* is examined to determine whether the eye is red and inflamed or white and quiet. With the exception of trauma, acute glaucoma, and infection, the diseases that cause sudden visual loss do not cause a red eye (see Chapter 199). The cornea normally is clear with a crisp light reflex and no fluorescein stain. If a tonometer is available, the intraocular pressure should be measured.

Ophthalmoscopy is important; it should first be noted whether the fundus can be visualized or if a dense cataract or vitreous opacity is present. If the fundus can be visualized, the *optic disc* is examined for papilledema or atrophy. The *macula* is examined, looking for a cherry-red spot, hemorrhages, and scars. The *retinal vessels* are examined, with attention paid to the caliber and the presence of visible emboli. Patients over age 50 with sudden visual loss should have a careful check for temporal arteritis, which includes palpation of the *cranial arteries* for tenderness, enlargement, and loss of pulsation and determination of the *erythrocyte sedimentation rate* for marked elevation (see Chapter 161).

If a patient is a malingerer or hysterical, the examination of the eye will be normal, including opticokinetic responses, stereoscopic vision, and visual fields. One can quickly check opticokinetic responses by passing the front page of a newspaper before the eyes of the patient.

Vision Screening in Primary Care Practice. Adults with gradual onset of visual impairment often do not recognize or complain of their deficit. In addition, many patients being cared for by primary care physicians (especially hypertensives, diabetics, and the elderly) are at increased risk for potentially serious eye disease that may compromise vision. Yield for detection of important eye pathology can be high when persons at increased risk are screened by a brief ophthalmologic history complemented by Snellen chart testing of visual acuity. Findings indicative of benefit from ophthalmologic referral include age over 65 years; history of diabetes, glaucoma, eye trauma, eye infection, or other eye problem; and vision worse than 20/40 by Snellen testing or a difference of greater than two Snellen lines between eyes. Diabetics are particularly well served by referral for a screening ophthalmologic examination.

SYMPTOMATIC MANAGEMENT

Patients with sudden visual loss need immediate ophthalmologic consultation. If an ophthalmologist is not immediately available, appropriate emergency measures should be taken.

If a *central retinal artery occlusion* exists that is less than 24 hours old, it is reasonable to attempt heroic measures to salvage vision. The goal is to encourage the embolus to break apart or at least to move distally. First, one can gently massage the globe with the fingers to attempt to dislodge the embolus. Next, have the patient breathe a mixture of 5% CO_2 and 95% O_2; this will cause the retinal vessels to vasodilate and allow delivery of a high PO_2 to any viable retinal cells. If this mixture is not available, have the patient breathe into a paper bag. Next, give the patient 500-mg intravenous acetazolamide to decrease the production of aqueous humor and to lower intraocular pressure.

If *giant cell arteritis* is suspected, the patient should be started at once on high-dose glucocorticosteroids (e.g., prednisone 60 mg/d) and considered for temporal artery biopsy. Some vision may be salvaged in the affected eye, and the other eye is protected (see Chapter 161).

Acute angle-closure glaucoma should be treated at once with topical pilocarpine 2% in both eyes and acetazolamide 500 mg intravenously. The pilocarpine acts therapeutically in the involved eye and prophylactically in the uninvolved eye. Other topical medications that may help lower intraocular pressure include topical beta-blockers (timolol, betaxolol, levobunolol, etc.), a-agonists (brimonidine, apraclonidine), and carbonic anhydrase inhibitors (dorzolamide, brinzolamide). Pain medication and antiemetics are appropriate. If available, osmotic agents such as intravenous *mannitol* or oral *glycerol* should be used. All patients with acute angle-closure glaucoma need a laser iridotomy or peripheral iridectomy to prevent further attacks.

INDICATIONS FOR REFERRAL

All patients with acute loss of vision should be seen immediately by an ophthalmologist. Individuals suspected of having glaucoma, macular degeneration, retinal vein occlusion, or an infectious etiology and those in whom the cause of impaired vision is unclear should have early ophthalmologic consultation. Diabetics should be referred, even if asymptomatic, because screening and early diagnosis and treatment can prevent vision loss. Type 1 diabetics require annual ophthalmologic examination starting 5 years after onset of disease. At the time of diagnosis, type 2 diabetics should be referred for a detailed retinal examination and then annually. Patients with refractive error should be referred to an eye specialist for proper refraction. Refractive surgery may be considered for patients who have difficulty with glasses and/or contact lenses.

CHAPTER 201 EVALUATION OF EYE PAIN

ROGER F. STEINERT

Pain in the eye is most often produced by conditions that do not threaten vision. However, at times the discomfort may result from corneal or intraocular pathology that is capable of compromising eyesight. The first responsibility of the primary physician is to determine promptly if there is an immediate threat to vision that requires urgent therapy or quick referral to the ophthalmologist; minor problems can be treated symptomatically in the office.

Ocular pain is usually not the only presentation of injury or disease. Several distinct pain categories can be identified that, when combined with assessment of inflammation (see Chapter 199) and vision (see Chapter 200), allow the primary physician to categorize the nature of the problem and make appropriate disposition.

PATHOPHYSIOLOGY AND CLINICAL PRESENTATION

The external ocular surfaces (lid, conjunctiva, and cornea) and the uveal tract are richly innervated to detect pain. Localization within these structures is relatively less precise. The orbit and sinuses may give rise to pain localized to the eye. Pathology confined to the vitreous, retina, or optic nerve is rarely a source of pain.

Eyelids. Inflammation of the eyelid causes tenderness and foreign body sensation. Common causes are hordeolum (stye), trichiasis (inturned lashes), and tarsal foreign bodies. Redness and edema may accompany the pain.

Conjunctiva. Viral and bacterial conjunctivitis cause mild burning and foreign body sensation, whereas allergic conjunctivitis primarily elicits itching (see Chapter 199). Toxic, chemical, and mechanical injuries are commonly responsible for unilateral disease.

Cornea. The cornea is densely innervated by pain fibers, so that even a minor injury may result in considerable discomfort. Pain arises from exposure of nerve endings in the epithelium; the patient complains of a burning or foreign body sensation. Reflex photophobic lacrimation may accompany the discomfort. Blinking exacerbates the pain, which is generally relieved by a pressure patch holding the lid shut.

Keratitis (inflammation of the cornea) occurs with trauma, infection, exposure, vascular disease, or decreased lacrimation. Contact lens use has become an important source of microbial keratitis. Cellular infiltration and loss of corneal luster ensue. If blood vessels invade the normally avascular corneal stroma, vision may become cloudy. Severe pain is a prominent symptom; movement of the lid typically exacerbates symptoms. Fluorescein stain reveals the epithelial defects quite well and allows identification with a penlight.

Sclera. Compared with disease of the eyelids, scleral problems are more likely to cause dull deep pain. If the condition involves the anterior sclera, it may be readily visible as an area of redness. The blood supply to the sclera is not extensive, and its metabolism is relatively inactive. Consequently, inflammatory conditions of the sclera tend to be rather torpid; many are associated with connective tissue disease.

Uveal Tract. Anterior uveitis or iritis is accompanied by a dull ache and photophobia due to the irritative spasm of the pupillary sphincter. Posterior uveitis without anterior involvement may be painless or cause deep-seated aching. Profound ocular and orbital pain radiating to the frontal and temporal regions accompanies sudden elevation of pressure, as in acute angle-closure glaucoma. Vagal stimulation with high pressure may result in nausea and vomiting. Often the patient gives a history of mild intermittent episodes of blurred vision preceding the onset of an attack of throbbing pain, nausea, vomiting, and decreased visual acuity; halos about lights are sometimes noted. A fixed midposition pupil, redness, and a hazy cornea may be present (see Chapter 207).

Orbit. Inflammation and rapidly expanding mass lesions may cause deep pain. Displacement of the globe and diplopia may ensue. One important etiology is *optic neuritis*, a condition of younger patients (aged 15 to 40 years). Onset is acute. Eye movement may cause sharp pain due to meningeal inflammation (the extraocular rectus muscles insert along the dura of the nerve sheath at the orbital apex). Most cases are idiopathic, but 10% to 15% are associated with multiple sclerosis and as many as 20% to 50% eventually develop multiple sclerosis. Symptoms include pain on eye movement, abnormal color vision, and some loss of central vision. In most instances, the optic disk appears normal, but occasionally there is edema. A central scotoma may be found.

Sinusitis may also cause secondary orbital inflammation and tenderness on extremes of eye movement. In orbital cellulitis there is proptosis, limitation of extraocular movement, injection, and diminished vision.

Other Sources. Mild headache referred to the orbit is associated with refractive error, ocular muscle imbalance, sinusitis, and other causes of nonocular headache, such as tension headache, temporal arteritis, and the prodromal phase of herpes zoster. Severe aches in the eye cannot be attributed to refractive error, nor can aches about the eye that are noted on awakening in the morning.

DIFFERENTIAL DIAGNOSIS

The causes of eye pain can be considered anatomically (Table 201.1).

Table 201.1. Important Causes of Eye Pain

WORKUP

The initial task is to ensure there is no threat to vision. Most intraocular conditions that cause eye pain may compromise vision and should be carefully checked for, as should corneal injuries.

History. The quality of the pain needs to be considered. Deep pain is suggestive of an intraocular problem; a foreign body sensation makes it likely that the problem is on the surface of the eye. The patient should be asked about any change in visual acuity or color vision, because any report of deteriorating vision requires urgent

ophthalmologic consultation. A history of diplopia and displacement of the eye raises the possibility of an orbital problem. Ascertaining the aggravating and alleviating factors can aid diagnosis. Pain exacerbated by lid movement and relieved by cessation of lid motion is suggestive of a foreign body or corneal lesion. Pain worsened by eye motion may be due to retrobulbar optic neuritis, especially if accompanied by loss of central vision and a normal-appearing optic disc. Photophobia is often prominent in acute anterior uveitis. Localization of a extraocular lesion by history is often difficult, because most of the time the foreign body sensation is felt in the outer portion of the upper lid, regardless of the lesion's location. In considering causes of conjunctival irritation, it is important to ask about occupational exposures, trauma, sun, sun lamp, and other forms of ultraviolet radiation (e.g., arc welding), as well as foreign body contact. History of sinusitis and headaches should be noted.

Physical Examination. An ophthalmoscope, penlight, ability to perform lid eversion, and use of fluorescein stain can be very helpful for assessment. First, visual acuity, color vision, and extraocular movements should be tested and recorded. The eye, lid, and conjunctiva are inspected for masses and redness, the pupil for reactivity, the cornea for clarity, and the fundus for any abnormalities of the disc. A *cloudy cornea* in conjunction with a fixed midposition pupil is consistent with acute glaucoma; the eye may be red. A *constricted pupil* in the presence of an eye that is tearing excessively suggests anterior uveitis; in severe cases, the eye also may be reddened and the anterior chamber hazy. Finding a *central scotoma* should raise suspicion of retrobulbar neuritis; a normal-appearing disk supports the diagnosis. The upper lid should be inverted with a cotton-tipped applicator to check for a foreign body or chalazion. The penlight can then be used to survey the cornea for gross injury; examination is facilitated by use of a small hand lens. The iris should be examined for evidence of dilated vessels around the limbus; this *ciliary flush* is characteristic of intraocular inflammation and occurs in anterior uveitis. Often the flush cannot be seen without the aid of a slit lamp.

Fluorescein Staining. All but very small corneal epithelial lesions can be detected without the use of a slit lamp if fluorescein staining and a cobalt blue filtered light are used in the eye examination. Because of the ease of bacterial (particularly pseudomonal) contamination of the fluorescein, it must be instilled by means of either a single-dose container or sterile fluorescein strips wetted with sterile saline. The strip is touched to the inferior cul de sac while the patient looks upward; the patient is then asked to blink once. The fluorescein stains into denuded areas of corneal epithelium, producing a bright green color when viewed by normal light. The intensity of staining is enhanced if the eye is illuminated with a cobalt blue light. Among the lesions that can be identified by fluorescein staining are the dendritic ulcers of herpes keratitis, abrasions, small foreign bodies, and punctate defects caused by irradiation.

Intraocular Pressure. If pain is not clearly related to the external eye or adnexa, the intraocular pressure should be measured to rule out glaucoma, provided there is no infection and the globe is intact without external or penetrating foreign bodies.

INDICATIONS FOR REFERRAL

Significant loss of vision always requires prompt ophthalmic evaluation. Progressive pain, redness, or discharge that fails to respond to conservative treatment must be evaluated. Care must be taken not to mistake penetrating trauma for a simple abrasion. An eccentric pupil or shallow chamber may indicate loss of aqueous humor. One should never instill antibiotic ointment if there is a possibility of a perforation. Under such circumstances, patch the eye with a metal or plastic shield, which protects the eye, and arrange referral; do not place any pressure on the globe.

SYMPTOMATIC MANAGEMENT

Most serious causes of eye pain require prompt ophthalmologic referral, but some foreign bodies and abrasions can be managed in the office setting.

Foreign Bodies. Irrigation with normal saline from a squirt bottle, syringe without a needle, or intravenous tubing may flush out foreign material. If irrigation fails, no further attempt should be made by the nonophthalmologist to remove the foreign body if it is firmly embedded in the cornea. Use of a dry cotton-tipped applicator will only remove much normal corneal epithelium. Use of a cotton-tipped applicator or needle for foreign body removal requires topical anesthesia, good visualization, and specific training.

Abrasions. Superficial epithelial abrasions usually heal well with prophylactic antibiotic medication (e.g., erythromycin ointment) and a tight pressure patch for 24 to 48 hours.

For management of conjunctivitis and glaucoma, see Chapter 199 and Chapter 207, respectively.

CHAPTER 202 EVALUATION OF DRY EYE

DAVID A. GREENBERG

The normal tear film provides important protection to the eye. Defects in tear production are uncommon but often occur in conjunction with systemic disease. The primary physician must decide if systemic disease does exist, provide symptomatic relief, and know when referral is needed.

PATHOPHYSIOLOGY AND CLINICAL PRESENTATION

The ocular tear film performs a host of functions, including maintenance of the corneal and conjunctival epithelium, lubrication of lid motion, delivery of oxygen and uptake of CO_2 from the cornea, carriage of antimicrobial defenses, clearance of foreign matter and tissue debris, and smoothing of the anterior ocular surface for clear vision. The tear film is inherently unstable, depending on the interaction of its three components for stability.

The outermost layer of the tear film is lipid, excreted by the lid meibomian glands. This layer retards evaporation and counters gravitational forces on the aqueous layer. The middle layer is aqueous, secreted by the lacrimal glands and accounting for most of the tear film. The innermost layer is mucinous, primarily secreted by conjunctival goblet cells and attaching to the corneal epithelium. This converts the corneal surface from a hydrophobic to a hydrophilic one. Each blink redistributes and replenishes the tear film. Dry eyes ensue from a defect in maintenance of the tear film.

Aqueous Deficiency. A defect in production of the aqueous phase by lacrimal glands causes dry eyes or *keratoconjunctivitis sicca*. The condition most often occurs as a physiologic consequence of *aging*, commonly exacerbated by the desiccating effect of dry environmental conditions. It also may develop in the setting of *connective tissue disease, anticholinergic drug* use (e.g., phenothiazines, tricyclic antidepressants, antihistamines), and neurologic disease.

In *Sjögren's syndrome*, the lacrimal glands become involved in immune-mediated inflammation. The condition may occur in the context of other rheumatoid diseases or as an isolated event. Women outnumber men by 9:1. Onset is typically after age 50. The condition may present as an isolated focal problem (*primary disease*) or in the context of ongoing rheumatoid disease (*secondary disease*). Characteristic features of focal disease include dry eyes and dry mouth. Patients complain first of burning eyes and a sandy, gritty, foreign body sensation, particularly later in the day. Increased eye debris and mucus are noted. Secondary bacterial infection develops in severe cases. There also may be facial telangiectasias, parotid enlargement, altered taste, lip fissures, dental caries, and difficulty with phonation. Secondary disease manifestations include polyarthritis, fatigue, Raynaud's phenomenon, and a vasculitic rash (see Chapter 146). A seronegative form of the condition has been described in males with AIDS.

Mucin Deficiency. Mucin production may decline in the setting of *vitamin A deficiency*, which causes primary goblet cell deficiency. When this is combined with protein deficiency (as occurs in underdeveloped parts of the world), *keratomalacia* results. Secondary loss of goblet cells and mucin deficiency follows chemical *burns*, benign ocular *pemphigoid*, and *trachoma*. With loss of main and accessory lacrimal production, a combined mucin-aqueous deficiency ensues. Dry eyes linked to problems in mucin production have been noted in patients using the antiacne preparation *isotretinoin* (Accutane).

Eyelid Defects. Compromised lid function may affect the entire tear film because of impaired rewetting. Incomplete blinking, fifth or seventh cranial nerve palsy, exophthalmos, and exposure during sleep are among the conditions that result in drying of the inferior interpalpebral cornea. Lid movement may also be hindered by scar formation.

Neurogenic hyposecretion is a potential consequence of such uncommon conditions as basal skull fracture or the Ramsay-Hunt syndrome.

Patients with dry eyes are more likely to report grittiness, itching, burning, soreness, difficulty in moving the eyelids, or the sensation of a foreign body present with that complaint. When ocular irritation stimulates excess reflex tearing, the patient may present paradoxically with watery eyes. In rare instances, a corneal ulcer or red eye may ensue.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of dry eyes can be organized pathophysiologically (Table 202.1). As noted, the most common cause is the generalized diminution of lacrimal secretion associated with aging, followed by systemic conditions and anticholinergic drugs. Keratoconjunctivitis sicca secondary to a mucin or lipid abnormality is less common. Environmental factors contribute. In a population-based assessment of the elderly, medication side effects proved to be the predominant etiology, accounting for 62% of cases. Risk was particularly high when three or more drugs with known drying side effects were used concurrently (e.g., tricyclics, anxiolytics, antihypertensives).

Lacrimal Gland Dysfunction
   Age
   Systemic disease (Sjögren's syndrome, sarcoidosis, Hodgkin's
      disease)
   Anticholinergic drugs (atropine, antihistamines, tricyclics)
Compromised Eyelid Function
   Fifth or seventh nerve palsy
   Exophthalmos
   Scar formation
Mucin Deficiency
   Chemical burns
   Hypovitaminosis A
   Isotretinoin (Accutane)
   Benign ocular pemphigoid
   Trachoma
Environmental Factors
   Excessive dryness
   Excessive exposure (e.g., exophthalmos, Bell's palsy)
Lipid Abnormalities
   Chronic blepharitis
   Meibomitis

Table 202.1. Principal Causes of Dry Eyes

WORKUP

History. The workup should begin by noting the duration and frequency of symptoms and particularly if onset is related to dry environmental conditions. Symptoms of keratoconjunctivitis sicca are usually more pronounced as the day progresses and are frequently exacerbated by tobacco smoke. The physician should ask if tears are produced with crying and if the patient finds strands of mucus from the inner canthi on awakening (a very suggestive symptom). It is important to note any associated dry mouth, joint pains, prior ocular disease, infection, or surgery. A detailed drug history is essential, especially in the elderly, who may be taking several drugs that together may be the source of the patient's difficulty (e.g., tricyclics, anxiolytics, antihypertensives). Any prior history of rheumatoid disease or its symptoms should be sought.

Physical Examination. Attention is paid to frequency and completeness of blinking and note taken of any lid pathology. Blepharitis and meibomitis are evident as lid margin crusting and engorgement of the meibomian glands, respectively. Other physical findings may include thick yellow mucous strands in the lower fornix, hyperemic and edematous bulbar conjunctiva, and corneal dullness. It is mandatory to check for completeness of lid closure and position of eyelashes. The corneal

reflex is checked if there is concern about a neuroparalytic keratitis or facial nerve palsy. Skin and joints should be examined for signs of rheumatoid disease (see Chapter 146).

Studies. The *Schirmer test* diagnoses aqueous deficiency by measuring the wetting of a filter paper strip (Whatman No. 41 filter paper, 5 × 35 mm). A folded end is hooked over the lower lid temporally and the patient is instructed to keep the eyes lightly closed during the test. In the Schirmer I test, wetting is measured after 5 minutes; less than 5 mm is usually abnormal. A basal Schirmer test using topical anesthetic to prevent reflex tearing caused by the paper strip is no longer performed.

Testing for Sjögren's Syndrome. Evidence by history or physical examination of *Sjögren's syndrome* or rheumatoid disease should trigger serologic testing that begins with an *antinuclear antibody* determination (95% sensitive in Sjögren's; specificity low) and a *rheumatoid factor* (75% sensitive; specificity low). If these screening serologic tests are positive, then follow-up testing for the more specific *anti-Ro* and *anti-La* antibodies (60% to 70% sensitivity, more than 90% specificity) is worth considering; see Chapter 146). *Lip biopsy* is the definitive test but often not necessary in the context of characteristic clinical and serologic findings.

SYMPTOMATIC MANAGEMENT AND INDICATIONS FOR REFERRAL

As long as there are no signs of ocular disease, the primary physician may attempt symptomatic relief. The first steps are to eliminate any unnecessary medications that may be contributing and reduce any environmental dryness that exacerbates the aqueous deficiency of aging. Often this can be accomplished by use of a room humidifier. A 2-week trial of one of the many commercially available *artificial tear substitutes* may also be helpful. Of the commercially available preparations, methylcellulose (Visulose, 0.5% or 1%), polyvinyl alcohol (Liquifilm Tears, 1.4%, or Liquifilm Forte, 3%), and hydroxypropyl methylcellulose, 1% (Ultra Tears, Tears Naturale, and Adsorbotear) have been used successfully. These nonprescription drops are soothing and, through a variety of formulations, provide aqueous replacement and sometimes mucomimetic substances.

Drops may be instilled as often as desired. Topical application of one to two drops, four times a day, is a useful starting dosage. The patient may increase the frequency of application to as often as hourly to achieve comfort; a bland ointment can be used at night. Toxicity is uncommon, but topical sensitivity or corneal epithelial damage may occur. More severe cases may warrant *punctal plugs*, which have proven superior to methylcellulose inserts (Lacrisert); acceptance of these has been limited. Steroids and antibiotics should not be prescribed for uncomplicated disease.

The patient should be instructed to seek immediate ophthalmologic attention in the event of a red eye, visual disturbance, or eye pain. An eye specialist should be consulted when simple symptomatic treatment does not give rapid relief.

PATIENT EDUCATION

It is critical for the primary physician to be certain that the patient knows how to instill the drops into the eye. Instructions should include the careful instillation of the drop into the lower fornix without contact occurring between the dropper and the eye and the utilization of digital pressure in the punctal or inner region of the lower lid to reduce drainage and prolong contact. The patient should also be educated that the instillation of more than one drop at a time exceeds the physical capacity of the inferior fornix and is wasteful.

CHAPTER 203 EVALUATION OF COMMON VISUAL DISTURBANCES: FLASHING LIGHTS, FLOATERS, AND OTHER TRANSIENT PHENOMENA

CLAUDIA U. RICHTER

Flashes of light, floaters, specks, distortions, halos, and discolorations are among the transient visual phenomena reported by patients. Flashes of light (*photopsia*) and dark moving lines and specks (*floaters*) are particularly common occurrences that are usually benign but may signal a retinal tear or detachment. Visual distortion (*metamorphopsia*) can be the presenting symptom of age-related macular degeneration. Other short-lived disturbances accompany such diverse conditions as migraine, digitalis toxicity, and acute glaucoma. The primary physician needs to know the significance of these visual phenomena and when they presage a serious ophthalmologic or systemic event that requires prompt ophthalmologic attention.

PATHOPHYSIOLOGY AND CLINICAL PRESENTATION

Floaters are vitreous opacities that cast a shadow on the retina. They can be single or multiple, characteristically moving across the visual field and transiently blurring vision if they cross the macula. Their presence is most notable when gazing at a clear blue sky or blank white wall. New onset of floaters may occur as a consequence of *vitreous detachment, a retinal tear or detachment*, or an intraocular hemorrhage.

Vitreoretinal traction is the principal cause of retinal tears and detachments, which can lead to sudden onset of flashes and floaters. As the vitreous gel liquefies with age, its fibrous matrix contracts and pulls away from the retina. Because the vitreous is attached to the retina at several sites, any traction can cause tearing that leads to a retinal hole. Detachment may develop by flow of fluid from the vitreous through the hole and beneath the retina. If the tearing involves a superficial retinal vessel, hemorrhage into the vitreous may occur.

Acute or chronic intraocular inflammation and/or infection are sometimes the cause, as in the immunocompromised patient with *cytomegalovirus (CMV) retinitis*. The sudden appearance of one or more floaters suggests onset of serious underlying pathology. Floaters that are multiple and long-standing are associated with *myopia* and *aging* with or without a vitreous detachment.

Flashes (photopsia) are perceptions of bright small flickering lights or lightning-like flashes of light. They are most vividly seen in the dark and usually occur with mechanical stimulation of the retina. They account for "seeing stars" when one suffers head trauma or coughs very hard. New onset may be a consequence of vitreous traction on the retina, leading to *retinal tear* or *detachment*. Just rubbing the eyes can cause similar symptoms. *Migraine* pathophysiology accounts for recurrent episodes, which are more complex and longer lasting (*scintillating scotoma*).

Distortion (metamorphopsia) refers to the curvilinear distortion of straight lines or patterns. This visual disturbance is the consequence of an altered shape of the retinal surface, either from collection of fluid beneath the retina or scarring on the surface. Metamorphopsia is seen with age-related *macular degeneration*, epiretinal fibrosis, and a variety of ocular diseases that cause traction on the retinal surface and/or retinal scarring.

Zigzag Lines. *Migraine* can produce a complex set of prodromal visual phenomena that include *zigzag lines* (sometimes referred to as *fortification phenomena*) and flashes of light with transient blind spots (*scintillating scotoma*). These may present with or without a subsequent headache. Typically, the zigzag lines occur adjacent to a gray area of shaded darkness. Both the gray area and the zigzag lines slowly expand. The visual phenomena typically end in 20 to 30 minutes with or without the onset of the headache and leave no residual visual deficit (see Chapter 165).

Halos, Discolorations, and Visual Hallucinations. The first clinical manifestations of *digitalis toxicity* may be visual (see Chapter 32) and include lightning flashes, yellow discoloration, halos, and the appearance of frost over objects. *Acute glaucoma* (see Chapter 207) also produces colored halos around lights but not lightning flashes. Visual hallucinations caused by *seizure* activity in the occipital cortex and the adjacent association area produce static light and stars. Hallucinations from the parastriate area 18 cause luminous sensations or colored flashes and rings.

DIFFERENTIAL DIAGNOSIS

The sudden onset of a visual phenomenon may be the first sign of important underlying ophthalmic or systemic pathology. Causes can be listed according to clinical presentation (Table 203.1).

Floaters
  Myopia
  Aging
  Vitreous detachment
  Retinal tear
  Retinal detachment
  Intraocular inflammation (uveitis, retinitis)
  Vitreous hemorrhage
Flashing Lights
  Vitreoretinal traction
  Retinal detachment
  Mechanical stimulation (cough, rubbing the eyes, head trauma)
  Classic migraine
  Seizure activity in the visual cortex (static light, colored flashes)

Table 203.1. Causes of Floaters and Flashing Lights

WORKUP

History. A complete and detailed description of the visual disturbance uninfluenced by leading questions is the most important part of the history, followed by information regarding their onset, course, and presence of any associated symptoms (e.g., headache, decreased visual acuity). The sudden onset of flashing lights and/or floaters is highly suggestive of vitreoretinal traction, possibly in association with a vitreous detachment, retinal tear, or retinal detachment. New onset in an immunocompromised patient should suggest CMV retinitis. Flashes of light on waking and rubbing the eyes are usually harmless, as are floaters that have been present for an extended time without marked increase in number. The patient who complains of halos needs to be checked for glaucoma (see Chapter 198). A report of lightning flashes, yellow discoloration, or frost over objects in a patient taking a digitalis preparation requires consideration of digitalis toxicity. Visual distortion should lead to a search for subretinal fluid accumulation.

Physical Examination. Visual acuity testing, measurement of the intraocular pressure (see Chapter 198), and careful examination of the fundus should be included. One looks for hemorrhage in the vitreous, a ballooning white area suggestive of a retinal detachment, areas of retinal inflammation, and abnormalities in the appearance of the macula suggestive of macular degenerative disease. In the immunocompromised patient, funduscopic examination should include a look for the manifestations of CMV retinitis (e.g., focal, granular, perivascular yellow-white lesions with or without hemorrhage in a "brushfire" pattern). Detection of retinal tears and small retinal detachments requires indirect ophthalmoscopy or diagnostic contact lens examination performed by the ophthalmologist. Patients with migraine will

have a normal ophthalmologic examination.

Studies. The most important study in patients with new flashes and/or floaters is *indirect ophthalmoscopy* and scleral depression done by the ophthalmologist. Patients with metamorphopsia need *fluorescein angiography*. The patient with halos needs to be checked for glaucoma by measurement of *intraocular pressure* (see Chapter 198). The patient taking a digitalis preparation who reports visual disturbances should have a serum drug level measured (see Chapter 32).

PATIENT EDUCATION AND INDICATIONS FOR REFERRAL

New onset of unexplained flashes or floaters requires urgent referral to an ophthalmologist because of the possibility of a retinal tear, retinal detachment, or an inflammatory/infectious process (e.g., CMV retinitis). Vision is best preserved when treatment of such conditions is prompt. If the patient or examiner detects a field loss, referral is even more urgent. Metamorphopsia is also an indication for urgent referral, because age-related macular degeneration has a bet-ter visual prognosis when subretinal neovascularization is treated with early macular photocoagulation. A report of halos should lead to referral for evaluation of glaucoma. Visual hallucinations require workup for seizure activity and visual cortex pathology.

Patients with chronic flashes and floaters should have a complete ophthalmologic examination, including indirect ophthalmoscopy, but it is not urgent. All patients with flashes and floaters need to be warned that a sudden onset of new floaters or flashes or the appearance of a peripheral visual field defect may represent a retinal hole or detachment necessitating prompt ophthalmologic attention. The patient with chronic floaters in the absence of ocular disease can be reassured; prognosis is excellent, as it is for the person with visual phenomena associated with migraine. Flashes that occur with minor mechanical stimulation (cough, rubbing of the eyes) require only reassurance and explanation, as long as there is no evidence of more serious pathology.

CHAPTER 204 EVALUATION OF EXOPHTHALMOS

CLAUDIA U. RICHTER

Exophthalmos is defined as protrusion or proptosis of the eye. It may be a variation of normal physiognomy or a sign of systemic or orbital disease. The primary physician must be able to recognize it and evaluate the patient for a possible endocrinologic, neoplastic, or vascular cause and decide on the need for further study or referral.

PATHOPHYSIOLOGY AND CLINICAL PRESENTATION

Pathologic forms of exophthalmos may result from inflammation, infiltration, a mass lesion, or a vascular abnormality.

Graves' Disease. The ophthalmopathy of Graves' disease occurs as a consequence of an autoimmune inflammatory process leading to infiltration of the soft tissues of the orbit. Risk factors include cigarette smoking, radioiodine therapy, persistent hyperthyroidism, and recurrence of hyperthyroidism after withdrawal of antithyroid drug therapy. Administration of prednisone at the time of radioiodine therapy can prevent treatment-induced ophthalmopathy. Pathologically, there is an inflammatory infiltrate of lymphocytes, mucopolysaccharides, and edema, followed by proliferation of fibroblasts and increase in the volume of orbital connective tissue. The proliferation of orbital fibroblasts and their fibrotic restriction of extraocular muscle movement account for the clinical picture of Graves' ophthalmopathy.

In its mildest form, there is minor lid retraction, stare, lid lag, and mild protrusion of the eye (proptosis). A particularly severe form, "malignant" exophthalmos, causes edema of the lids and conjunctiva, marked proptosis, limitation of extraocular movements, exposure keratopathy, and optic nerve compression. Although it is usually a bilateral disease, it may pre-sent unilaterally or asymmetrically.

The relatively close clinical relationship between ophthalmopathy of Graves" disease, pretibial dermopathy, and hyperthyroidism suggests a common pathophysiologic mechanism. However, the ophthalmopathy can occur in the absence of thyroid dysfunction or pretibial dermopathy. The precise pathophysiology remains to be elucidated. It may be triggered by antibodies to circulating thyroid antigen, accounting for the exacerbation seen with some treatments for thyrotoxicosis. Its precise mechanism(s) continues to be elucidated (see Chapter 103).

Primary orbital neoplasms, such as *meningiomas*, produce exophthalmos by mass effect. Some vascular lesions, such as *hemangiomas*, produce only a mass effect, whereas a *carotid-cavernous sinus fistula* may present with a diffusely congested orbit with exophthalmos, prominent episcleral vessels, and elevated intraocular pressure. Mass lesions and vascular abnormalities are unilateral processes. They may lead to diplopia, ocular irritation, and photophobia (secondary to corneal exposure). Stretching or compression of the optic nerve can impair visual acuity.

Orbital cellulitis is an extremely serious, although rare, cause of proptosis. Because the orbit is bordered on three sides by paranasal sinuses, orbital infection can result from sinusitis extending directly through the lamina papyracea. Lid edema, ptosis, proptosis, chemosis, and diminished ocular movements make for a dramatic clinical presentation. Retrograde extension can lead to cavernous sinus thrombosis.

DIFFERENTIAL DIAGNOSIS

Bilateral exophthalmos is usually caused by Graves' disease, but occasionally it occurs with Cushing's syndrome, acromegaly, lithium ingestion, metastatic tumor, and orbital lymphoma.

Unilateral exophthalmos may be caused by tumor, inflammatory and infectious diseases, vascular abnormalities, and skeletal abnormalities. Common orbital tumors include hemangioma, meningioma, and optic nerve glioma. Tumors extending into the orbit include those originating in the eye, lids, and paranasal sinuses. Orbital pseudotumor is an inflammatory lesion that can mimic a mass lesion. Inflammatory etiologies include sarcoidosis, foreign body, orbital thrombophlebitis, and ruptured dermoid cyst. Hemangioma, aneurysm, varices, carotid-cavernous fistula, and cavernous sinus thrombosis constitute important vascular etiologies. Skeletal abnormalities such as Paget's disease may also produce exophthalmos. Asymmetry of the orbits, severe unilateral myopia, facial nerve paresis, eyelid retraction, and congenital glaucoma may give the appearance of exophthalmos. Ptosis or enophthalmos of the opposite eye can mimic exophthalmos.

WORKUP

The first task is to determine if the condition is unilateral or bilateral. Bilateral disease has a limited differential diagnosis, with Graves' disease accounting for most cases. Attention is directed toward its confirmation (see Chapter 103). The broader differential of unilateral disease necessitates a more extensive workup.

History should include inquiry into the time course of the exophthalmos. Old photographs are helpful in determining if the problem is of new onset or simply a long-standing anatomic variant. Associated symptoms are also important to note. Visual acuity changes, diplopia, pain, excessive lacrimation, photophobia, and foreign body sensation are indications of adverse effects from the exophthalmos. A prior history or current symptoms of trauma to the orbit, thyroid disease, cancer, severe sinus infection, or worsening headache should be noted.

Physical examination begins with documenting the degree of exophthalmos by exophthalmoscopy. The distance to be measured is from the lateral orbital rim to the apex of the cornea with the patient looking straight ahead. The upper limit of normal is 21 to 22 mm; a difference between both eyes of 2 mm is also considered significant. Visual acuity, intraocular pressure, and extraocular muscle function should also be tested. The conjunctiva and cornea are observed for signs of drying, aided by fluorescein or rose bengal dye if available. Color vision, pupillary reactivity, and visual fields are assessed to investigate possible optic nerve compression, which may produce a pale or swollen optic nerve head on ophthalmoscopic examination. The globe and orbit need to be auscultated for bruits and pulsation suggestive of vascular fistula. The sinuses must be checked for tenderness and discharge. In the setting of bilateral disease, the neck should be checked for goiter and bruit, the pretibial region for dermopathy, and the remainder of the examination for signs of thyroid hormone excess (see Chapter 103).

Laboratory Studies. *Thyroid indices* (e.g., thyroid-stimulating hormone, total T_3, free T_4 index) should be ordered in the patient with bilateral disease, but the absence of hyperthyroidism does not rule out Graves' disease. Even in patients without evidence of thyrotoxicosis, *antibodies to thyrotropin receptors* and *peroxidase* can be detected (see Chapter 103).

Patients with unilateral exophthalmos are candidates for orbital imaging. At present, axial and coronal *computed tomography* is the study of choice in the evaluation of orbital abnormalities. It provides good definition of both bony and soft orbital tissues. *Ultrasound* is sometimes used to screen for a mass lesion. Orbital *magnetic resonance imaging* may be helpful in the noninvasive evaluation of certain vascular and neoplastic disorders. Invasive study is the province of the ophthalmologist.

SYMPTOMATIC MANAGEMENT, PATIENT EDUCATION, AND INDICATIONS FOR REFERRAL

Symptomatic Management and Prevention. The primary physician must be cognizant of potential ocular complications of exophthalmos and give advice for relief of minor symptoms. Periorbital and lid edema may be reduced by *elevating the head of the bed* at night. Exposure keratopathy causes a foreign body sensation, which can be relieved by use of *artificial tear lubricants* and *taping* the *eyelids* closed at night. If such simple measures are inadequate, referral to the ophthalmologist for consideration of eyelid or orbital surgery may be necessary.

Graves' Disease. Preventive measures include complete *cessation of smoking* and effective treatment of the underlying hyperthyroidism. Treatment of the underlying

Graves' disease must be done carefully in the setting of eye involvement. As noted, ophthalmopathy can worsen with some forms of therapy, perhaps due to increased release of thyroid antigen. Some authorities suggest use of *antithyroid drugs* to minimize such release; others add high-dose corticosteroids to the program (e.g., *prednisone*, 0.5 mg/kg for 1 month, beginning a few days after radioiodine administration; see Chapter 103).

Specific treatment of Graves' ophthalmopathy is undertaken only when symptoms become severe or vision is threatened. Likelihood of progression is hard to determine, and available therapies have their own adverse effects. Nonetheless, inflammatory symptoms such as periorbital edema and ocular discomfort are treated with *corticosteroids* or *orbital radiation* in conjunction with total cessation of any smoking (smoking decreases their efficacy). Such therapy may inhibit the cytokines, which perpetuate the inflammatory reaction.

Referral and Admission. Ophthalmologic consultation should be obtained early in unilateral, severe, or unexplained exophthalmos. Exophthalmos due to neoplasm requires a team approach that includes the ophthalmologist, oncologist, and radiation therapist. A suspected vascular etiology is also grounds for referral. Endocrinologic consultation is indicated for managing the ophthalmopathy of Graves' disease. Emergency admission is needed if orbital cellulitis is encountered.

Patient Education. Patients with Graves' disease need to know that their eye symptoms may persist or progress despite appropriate systemic therapy for the underlying disease but also that there are approaches to limiting risk (e.g., smoking cessation, effective control of the hyperthyroidism, steroid therapy in conjunction with radioiodine). Patients with Graves' disease need to know the adverse consequences of smoking and undergo an aggressive smoking cessation program (see Chapter 54). Home measures to lessen eye discomfort and prevent eye injury, such as *elevating the head of the bed*, use of *artificial tear lubricants*, and *taping* the *eyelids* closed at night, are important to review with the exophthalmic patient, as are symptoms warranting prompt evaluation (e.g., change in vision, ocular pain, eye injection, diplopia).

CHAPTER 205 EVALUATION OF EXCESSIVE TEARING

ROGER F. STEINERT

The presence of watereyes reflects an increased production of tears or a decreased ability to drain them. Patients complain of watery eyes or may actually describe tears overflowing and running down their cheeks, a condition called *epiphora*. The primary physician must decide if structural pathology exists or if reassurance is the appropriate treatment.

PATHOPHYSIOLOGY AND CLINICAL PRESENTATION

Normal Tear Production and Drainage. Tears are produced by the main and accessory lacrimal glands. They flow out through upper and lower puncta, which open into canaliculi. These, in turn, drain into the lacrimal sac and then into the nasolacrimal duct, which opens under the inferior turbinate in the nose. Tears do not flow down the drainage system merely by gravity but rather are pumped by lid motion.

Hypersecretion of Tears. Epiphora most often results from hypersecretion. Common stimulants are *blepharitis and keratitis* of any etiology (e.g., infections, foreign body), *atopy*, and *sinusitis*. Excessive moisture may be the complaint in a patient who has one of these inflammatory processes. *Pseudoepiphora* is reflex tearing in the presence of dry eyes (see Chapter 202). Aberrant regeneration of the seventh nerve may result in *gustatory lacrimation* ("crocodile tears").

Impaired Lacrimal Drainage. Tear film movement may be obstructed by eyelid-margin lesions or conjunctival redundancy or folds. The pumping function of the lid may be impaired by *seventh nerve palsy* or conditions stiffening the lids, such as scars or scleroderma, or by laxity of the lids from aging. The puncta must be properly positioned. *Ectropion* prevents tears from gaining access to the canaliculus. *Senile ectropion* is the most common cause in the elderly and is characterized by a sagging lower lid. The punctum or the canaliculus may be occluded congenitally, by chemical or thermal injury, or by neoplasms. In addition, canalicular *infections* may cause occlusion. The most common of these are *Actinomyces israeli (Streptothrix)* and *Candida*. Finally, obstruction of the lacrimal sac and nasolacrimal duct may be idiopathic, congenital, or caused by neoplasms, ethmoiditis, and turbinate disease.

The more distal the obstruction, the more likely that the epiphora will be accompanied by purulent discharge or *dacryocystitis*, as the stagnant tears become infected. Digital pressure may express purulent material from the puncta.

DIFFERENTIAL DIAGNOSIS

The most common causes of watery eye are senile ectropion and increased physiologic tearing. The differential can be organized according to causes of increased production and impaired drainage (Table 205.1).

Excessive Tear Production
 Keratitis
 Blepharitis
 Conjunctivitis
 Atopy
 Sinusitis
 Facial palsies
 Reflex tearing of dry eyes
Impaired Tear Drainage
 Dacrocystitis
 Punctal obstruction (tumor, burn, senile atresia, infection)
 Ectropion
 Sagging of the lower lid
 Obstruction of the lacrimal sac and nasolacrimal duct (idiopathic,
  congenital, neoplasms, ethmoiditis, and turbinate disease)

Table 205.1. Causes of Watery Eyes

WORKUP

History. The physician should determine if tears actually run down the cheek and, if so, how frequently. Overflowing tears in the absence of environmental irritants suggests structural pathology. Watery eyes noted on exposure to cold, air conditioning, or a dry environment may be due to exaggerated physiologic tearing.

Inquiry into whether the problem is unilateral or bilateral can be helpful. Unilateral tearing is more often obstructive, but stenosis can be bilateral; environmental irritants should cause bilateral epiphora. Any sinus disease, facial fractures, infections, and surgery should be noted as possible etiologic factors, as should symptoms suggestive of Sjögren's syndrome (see Chapter 146).

Physical Examination. Lid structure and motion should be observed. Patency of the puncta is visualized under low magnification. Gentle pressure is applied over the lacrimal sac on the side of the nose and over the canaliculi to attempt to express purulent material for examination and culture. Examination for signs of dry eye (see Chapter 202) is needed to rule out paradoxical tearing, which requires an entirely different therapeutic approach.

Studies. The ophthalmologist may also evaluate the lacrimal drainage system in several ways. *Fluorescein dye* instilled in the conjunctival sac should make its way to the nose (Jones test). *Saline irrigation* and *probing* may prove patency or localize an obstruction. *Dacryocystography* (radiocontrast dye injection) may dramatically outline the obstruction and the proximal lacrimal system. Dacryoscintigraphy, in which aqueous radioactive tracer is introduced into the tear film and followed during blinking, may demonstrate functional impairment (pump failure).

SYMPTOMATIC MANAGEMENT AND INDICATIONS FOR REFERRAL

Irritants must be eliminated. Sicca is treated with appropriate *lubricants* (see Chapter 202). Dacryocystitis is treated with *hot compresses* at least four times a day and systemic *antibiotics* (usually erythromycin 250 mg four times a day or dicloxacillin 250 mg four times a day directed against staphylococcal species). Patients without infection can be reassured the condition is not harmful.

Unresponsive patients are properly referred to an ophthalmologist for further evaluation and treatment. In symptomatic cases, lid surgery to correct malposition or dacryocystorhinostomy to relieve nasolacrimal obstruction may be indicated.

CHAPTER 206 MANAGEMENT OF THE PATIENT WITH AGE-RELATED MACULAR DEGENERATION

Age-related macular degeneration is a major cause of vision loss in the elderly. The age-related form affects an estimated 30% of persons over the age of 75. Proper geriatric eye care includes early recognition of macular degeneration so that ophthalmologic referral can be timely and the risk of visual impairment minimized.

PATHOPHYSIOLOGY AND CLINICAL PRESENTATION

Mechanisms. The retinal pigmented epithelium is critical to the maintenance of healthy retinal photoreceptors. Any compromise to the former can lead to a decline in receptor cells and loss of vision. In macular degeneration, the retinal pigmented epithelium begins to degenerate or at least change its biochemical relation with photoreceptor cells. The mechanism(s) remains poorly understood. There is a *genetic* propensity, but as of yet no specific genes have been identified. Suspected risk factors include *cardiovascular disease, atherosclerotic* risk factors, *dietary* factors (e.g., *lack of antioxidants, zinc*), and *sun* exposure. Most data supporting these hypotheses are too limited to draw conclusions, but data from two major prospective epidemiologic studies (The Nurses' Health Study and The Physicians' Health Study) revealed *cigarette smoking* to be a potent independent risk factor, with a dose-response relationship, particularly in women.

Pathologic Changes. Deposits of debris called *drusen* accumulate between the epithelial cell and the underlying basement membrane (Bruch's membrane). Although not the cause of visual loss, drusen serve as an important clinical marker of the processes that lead to it.

Hard or nodular drusen are pinhead-sized yellow-white lesions visible ophthalmoscopically in the macular region. They represent focal degenerative change. *Soft or granular drusen* are larger, have less distinct edges, and represent more widespread epithelial dysfunction. The development of *diffuse or confluent drusen* coincides with still more advanced degenerative disease and heralds detachment of the pigmented epithelium from Bruch's membrane.

Detachment of the retinal epithelium is a consequence of the degenerative process that both weakens and thickens Bruch's membrane. Detachment leads to visual loss as the overlying photoreceptor cells atrophy. In addition, new blood vessels may form (*neovascularization*) in response to the degenerative changes in Bruch's membrane. The fragile new vessels tend to leak and sometimes bleed, producing serous or hemorrhagic detachment of the pigmented epithelium from the neurosensory retina and detachment of the pigmented epithelium. If there is bleeding, fibrovascular scarring may ensue. Such complications of neovascularization exacerbate the extent and speed of visual loss. Fortunately, fewer than 20% of persons with age-related macular degeneration have neovascularization.

Clinical Presentation and Course. Because the degenerative process is concentrated in the macula, central visual acuity is most affected. Patients may complain of a loss of visual acuity that is not corrected by eyeglasses. In patients without neovascularization, the loss of visual acuity tends to be gradual and limited. Macular examination of such persons may reveal all forms of drusen, but there is no neovascularization or evidence of its consequences. The presentation without neovascularization is sometimes referred to as "*dry*" or *neovascularization* macular degeneration. It accounts for about 90% of all cases.

Those with *neovascularization* are labeled as having "*wet*" or *exudative* disease. Close to 90% of persons who lose central vision have the exudative type. With neovascularization present, vision loss may be acute and more extensive. *Distorted vision* (metamorphopsia) may herald the onset of serous retinal detachment. In addition to drusen, macular examination may show serous and hemorrhagic effusions and disk-shaped scarring.

DIAGNOSIS

Suggestive historical features include gradual or sudden loss of central visual acuity or distorted vision (metamorphopsia) in an elderly person. The latter suggests the degenerative process has progressed sufficiently to cause serous retinal detachment due to neovascularization. Characteristic ophthalmoscopic findings are concentrated in the macular region and include drusen, irregularities in macular pigmentation, hemorrhage, and discoid scarring.

Finding defects in central visual acuity further supports the diagnosis of macular degeneration. Such changes can be detected with the aid of an *Amsler grid*, a 10 × 10-cm card with a black background on which is printed a criss-crossed grid of vertical and horizontal white lines every 5 mm. In the center, there is a white dot. The patient is asked to focus on the dot and note if any of the lines appear wavy or distorted or if any of the boxes formed by the intersecting lines are missing. Each eye is tested separately with any prescribed corrective lenses worn and the grid held at a comfortable reading distance.

PRINCIPLES OF MANAGEMENT

Prevention. *Cessation of smoking* is essential. Smoking is the only known modifiable risk factor. Ongoing smoking is particularly harmful. Its identification as an independent risk factor with a dose-dependent effect makes smoking cessation a top priority (see Chapter 54). Despite occasional hints from uncontrolled studies that high doses of *zinc* or *antioxidant vitamins* (e.g., C, E, and beta-carotene) may be preventive, there are no data from ongoing prospective randomized trials that confirm these hypotheses. Although many patients with macular degeneration often take high doses of these substances on their own, there is no evidence to warrant encouraging the practice. Besides smoking cessation, there are no other known medical interventions for preventing degeneration of the pigmented retinal epithelium. However, the approach to preventing loss of visual acuity depends on whether the macular degeneration is accompanied by neovascularization.

Exudative Disease: Neovascularization Present. For the 10% of macular degeneration patients with neovascularization, the prognosis for preservation of central vision is poor but can be improved at least modestly with argon laser *photocoagulation* therapy. Candidates for laser photocoagulation therapy are those with neovascularization not unexceptably close to the fovea. Laser treatment of neovascularization close to the fovea risks destroying its intense concentration of photoreceptor cells. Other approaches, such as *surgical removal* of subretinal hemorrhage or choroidal neovascular membranes, have not been confirmed in prospective randomized trials.

To maximize benefit from laser therapy, early clinical detection of neovascularization is critical. Macular degeneration patients are instructed to watch for and promptly report any distortion of vision. Daily home use of an *Amsler grid* is an excellent and simple means of early detection. Any new defects or distortions in central vision require prompt reporting to the ophthalmologist and consideration of urgent laser treatment. Such treatment can reduce the frequency of vision loss from 60% to 25% in patients with exudative disease.

Nonexudative Disease: No Neovascularization. Although their prognosis is much better than for those with untreated exudative disease, patients without neovascularization have no definitive treatment options at the present time. For the 10% of macular degeneration patients who suffer central vision loss due to neovascularization disease, optical devices known as *low-vision aids* can be used.

PATIENT EDUCATION

No matter how severe the macular degeneration, patients can be reassured that they will not go blind because peripheral vision is largely unaffected. Such information is reassuring and greatly appreciated. The importance of early detection of neovascularization needs to be emphasized, as well as the clinical warning symptoms (e.g., distorted vision). Proper use of the *Amsler grid* should be taught so that daily self-monitoring can be performed at home. Most importantly, patient education regarding the role of *smoking* and approaches to cessation (see Chapter 54) should be a top priority for those with macular degeneration who continue to smoke.

INDICATIONS FOR REFERRAL

Any elderly patient suspected on the basis of history or physical examination to have macular degeneration should be referred to the ophthalmologist. Promptness is

critical if there is distorted vision, because it may herald early serous retinal detachment and neovascularization.

CHAPTER 207 MANAGEMENT OF GLAUCOMA

CLAUDIA U. RICHTER

Glaucoma is an optic neuropathy characterized by optic nerve cupping and visual field loss. It is the leading cause of permanent blindness. The types of glaucoma include *open-angle glaucoma* (both primary and secondary types), *angle-closure glaucoma*, and *congenital glaucoma*. Although the primary physician is not responsible for the definitive diagnosis or treatment of glaucoma, one needs to identify patients at risk (see Chapter 198), recognize early stages of optic nerve damage, and understand both the systemic effects of glaucoma medications and the effects of systemic medications on intraocular pressure.

PATHOPHYSIOLOGY AND CLINICAL PRESENTATION

The intraocular pressure is maintained by the dynamic equilibrium of aqueous production and outflow. The iris divides the anterior portion of the eye into anterior and posterior chambers that communicate through the pupil. Aqueous humor, produced by the ciliary body, fills the posterior chamber, flows through the pupil into the anterior chamber, and leaves the eye through the *trabecular meshwork*, a connective tissue filter at the angle between iris and cornea. The aqueous passes through the trabecular meshwork into Schlemm's canal and into the episcleral venous system.

Pathophysiology. Although *elevated intraocular pressure* is not part of the definition of glaucoma, intraocular pressure is the only modifiable risk factor. Increased intraocular pressure is caused by *obstruction to outflow.* In open-angle glaucoma, obstruction exists at a microscopic level in the trabecular meshwork. In angle-closure glaucoma, the iris obstructs the trabecular meshwork. An anatomic variation of the anterior segment of the eye results in pupillary block and obstruction of the trabecular meshwork by the iris.

Increased intraocular pressure increases vascular resistance, causing decreased vascular perfusion of the optic nerve and is-chemia. The increased pressure can interfere with axoplasmic flow in the ganglion cell axons, causing cell dysfunction and death, and it can compress the lamina cribrosa, the sievelike structure through which axons pass when leaving the eye. The altered supporting structure may then interfere with axonal function. These different mechanisms of axonal damage are of variable importance in different patients, but the final result is loss of ganglion cells and their axons, increased optic nerve cupping, and visual field loss.

Clinical Presentation. *Open-angle glaucoma*, which accounts for more than 90% of glaucoma cases, has multiple risk factors, including elevated ocular pressure, older age (more than 50 years), African-American race, and family history of glaucoma. Characteristic changes in the optic nerve and nerve fiber layer (see below) suggest early glaucomatous injury and facilitate diagnosis as does asymptomatic elevated intraocular pressure. Open-angle glaucoma is frequently called the "silent blinder" because extensive damage may occur before the patient is aware of visual field loss.

Acute angle-closure glaucoma presents with a *painful red eye.* The physical findings include decreased visual acuity, markedly elevated intraocular pressure, redness, fixed and nonreactive pupil in mid-dilation, and corneal haziness. Occasionally, the principal symptoms are nausea and vomiting, and the patient may be thought to have abdominal or coronary disease. Patients with acute angle-closure glaucoma require emergency treatment to lower intraocular pressure, and immediate referral to an ophthalmologist. *Subacute* attacks of angle-closure glaucoma may present with intermittent episodes of *halos* around lights or of *painful blurred vision.* Patients susceptible to angle-closure can be identified by shining a light parallel to the iris plane from the temporal side of the globe: eyes with narrow angles will have a shadow fall on the nasal iris.

DIAGNOSIS

Ophthalmoscopy. *Cupping* of the optic nerve is the pathognomonic finding of glaucoma. Changes in the contour of the optic cup in the center of the optic disc provide the first definitive evidence of glaucomatous damage. The usual cup has a round regular contour. The cup in early glaucoma becomes notched on the superotemporal or inferotemporal rim. Later changes include an increase in the depth and width of the physiologic cup, nasal displacement of the central retinal vessels, and progressive pallor of the optic nerve head. Other disc changes associated with glaucoma are asymmetric discs and disc hemorrhages. There is some disagreement about the value of ophthalmoscopy in detecting early glaucoma. Assessment of disc pathology is not as simple as measurement of intraocular pressure. It requires greater skill, but it improves sensitivity to as much as 85%, which is especially helpful in detection of early disease. Performing pupillary dilation greatly facilitates the evaluation. Such specificity is unattainable by other screening methods before the onset of manifest visual field defects.

Measurement of Intraocular Pressure. Because *ocular hypertension* precedes optic nerve injury and is easier to perform than ophthalmoscopy, the measurement of intraocular pressure is the screening test of choice (see Chapter 198). Presence of elevated intraocular pressure (more than 21 mm Hg) in the absence of cupping indicates ocular hypertension but not glaucoma.

Visual Field Testing. When cupping is noted, formal visual field testing is indicated to check for the characteristic peripheral field deficits.

PRINCIPLES OF THERAPY

Although there is no direct treatment for the optic nerveinjury of glaucoma, it is possible to prevent further optic nerve damage and visual field loss by lowering intraocular pressure. Intraocular pressure is the only modifiable risk factor in glaucoma, and several prospective long-term randomized placebo-controlled trials have demonstrated that lowering intraocular pressure protects the optic nerve.

Chronic Open-angle Glaucoma

Treatment to achieve and maintain the target pressure involves in escalating order: topical medications, laser trabeculoplasty, and glaucoma surgery. Most patients are first treated topically with a beta-blocker, a agonist, topical carbonic anhydrase inhibitor, and/or prostaglandin analogue singly or in combination to reach the target pressure. Intraocular pressure, optic nerve appearance, visual field, and nerve fiber layer are monitored to watch for disease progression.

Topical b-Adrenergic Antagonists decrease aqueous humor production. Ophthalmic preparations include *carteolol, levobunolol, metipranolol, timolol*, and *betaxolol* (b_1-selective). Beta-blockers need to be administered once or twice daily and are well tolerated topically. However, they can have significant systemic side effects including lethargy, depression, bronchospasm, bradycardia, hypotension, worsening of congestive heart failure, heart block, and syncope. Betaxolol, the b_1-selective blocker, is less likely to trigger bronchospasm but is also slightly less efficacious in controlling glaucoma.

a2-Selective Adrenergic Agonists represent new alternatives to beta-blockers and include *apraclonidine* and *brimonidine.* The a2-selective medications decrease intraocular pressure by reducing aqueous humor production. Topical side effects of these medications include topical hyperemia and allergic conjunctivitis. Systemic side effects of a2-selective agonists include lethargy, fatigue, drowsiness, dry mouth, and decreased blood pressure.

Nonselective Adrenergic Agonists, Epinephrine and its prodrug *dipivefrin*, initially reduce aqueous humor production and later increase aqueous humor outflow. Systemic side effects of epinephrine include headaches, hypertension, and tachycardia.

Carbonic Anhydrase Inhibitors decrease intraocular pressure by reducing aqueous humor production. Carbonic anhydrase inhibitors are now available topically (*brinzolamide, dorzolamide*) and orally (*acetazolamide, dichlorphenamide*, and *methazolamide*). The topical carbonic anhydrase inhibitors have largely displaced the oral medications and are better tolerated. The oral carbonic anhydrase inhibitors are associated with significant systemic side effects including anorexia and weight loss, fatigue, malaise, paresthesias of fingers and toes, depression, diarrhea, metallic taste, nephrolithiasis, agranulocytosis, and aplastic anemia. The blood

dyscrasias are not dose dependent and may also occur with the topical drugs. Some patients report the drops cause a bitter taste in their mouths.

Prostaglandin Analogues lower intraocular pressure by increasing uveoscleral outflow. They represent a new class of drugs for treatment of glaucoma and rival beta-blockers in efficacy. *Latanoprost* is the first available prostaglandin analogue for use in glaucoma. The drug is administered topically once daily. It appears well tolerated but may cause darkening of the iris. Systemic side effects (e.g., muscle and joint pains and allergic reactions of the skin) are uncommon.

Cholinergic Agonists reduce intraocular pressure by increasing aqueous outflow through the trabecular meshwork. Both *direct-acting* agonists (*carbachol* and *pilocarpine*) and *cholinesterase inhibitors* (*demecarium, echothiophate*, and *physostigmine*) are available. The ocular effects include small pupils with dimming of vision, induced myopia with blurring of vision, cataract, and retinal detachment. Systemic side effects include headache, tremor, salivation, bronchospasm, pulmonary edema, hypertension, hypotension, bradycardia, diarrhea, nausea and vomiting, and, with cholinesterase inhibitors, prolonged respiratory paralysis when given with succinylcholine.

Laser and Surgical Therapies. *Laser trabeculoplasty* effectively lowers intraocular pressure in many patients and is usually performed on patients whose glaucoma is uncontrolled by topical medication, although some ophthalmologists may perform it as initial therapy. Trabeculoplasty's effectiveness appears to be due to an alteration of the biology of the trabecular meshwork and improved aqueous outflow. Approximately 75% of laser-treated patients have a sufficient decrease in intraocular pressure to avoid glaucoma surgery, at least in the short term; pressure remains under control after 4 years in 50%.

Surgery is indicated when medical therapy and laser trabeculoplasty do not lower the intraocular pressure to a level protective of the optic nerve and visual field. The usual procedure is a *trabeculectomy*, which forms a drainage route from the anterior chamber to the subconjunctival space. If filtering surgery fails or cannot be performed, an aqueous tube shunt implant may be placed or laser cycloablation to the ciliary body performed.

Acute Angle-closure Glaucoma

Proper management requires prompt recognition, immediate treatment to lower intraocular pressure, and urgent referral to an ophthalmologist. Topical antiglaucomatous medications such as a beta-blocker, a agonist, and/or carbonic anhydrase inhibitor are administered. *Topical pilocarpine* 2% is administered to facilitate breaking the pupillary block. Acetazolamide may be administered orally or intravenously. Laser or surgical iridectomy is performed to prevent recurrent attacks and is indicated prophylactically in the other eye.

Prevention

Several drugs commonly used in internal medicine may increase the risk of developing glaucoma or precipitate an attack. Long-term high-dose use of nasal or inhaled *glucocorticosteroids* is associated with an increased risk of glaucoma, especially in the elderly. Such therapy should be administered only in conjunction with a plan for glaucoma screening. Drugs with *anticholinergic effects* (e.g., tricyclic antidepressants) may precipitate angle-closure glaucoma in patients with narrow angles and should be used with care. Persons with *systemic hypertension* and coincident ocular hypertension should have their systemic pressure reduced gradually. Reports exist of hypotensive optic neuropathy after precipitous lowering of systemic blood pressure. Treatment should be carried out in conjunction with the guidance of an ophthalmologist.

PATIENT EDUCATION

The first priority is to teach the patient the importance of careful follow-up examinations and compliance with the treatment regimen to preservation of vision. Reviewing techniquefor proper use of topical medications helps to maximize delivery of effective doses and minimize systemic absorption. Topical drug solutions are concentrated to facilitate absorption. If excess drug runs into the lacrimal duct and down into the nose, then systemic absorption through the nasal mucosa will occur. To avoid this, the patient should be taught to occlude the lacrimal duct either by direct pressure when applying drops or by closing the eyelids for 5 minutes after applying the drops. Patients should be advised about the ocular side effects of systemic drugs and the systemic effects of their glaucoma treatments.

RECOMMENDATIONS

- Have all persons over the age of 40 years screened for increased intraocular pressure (see Chapter 198).
- Take note of any cupping of the optic nerve during routine ophthalmoscopy.
- Refer promptly for treatment any persons with ocular hypertension or suspected optic nerve cupping.
- Refer urgently any person with suspected acute angle-closure glaucoma (e.g., painful red eye, decreased visual acuity, markedly elevated intraocular pressure, redness, fixed and nonreactive pupil in mid-dilation, and corneal haziness).
- Treatment begins with a topical beta-blocker, a agonist, topical carbonic anhydrase inhibitor, and/or prostaglandin analogue singly or in combination to reach the target pressure. If medical therapy proves inadequate or intolerable, laser trabeculoplasty or surgery may be indicated.
- Patients taking drops require instruction in occlusion of nasal lacrimal ducts to minimize risk of systemic absorption through the nasal mucosa.
- Have intraocular pressure, optic nerve appearance, visual field, and nerve fiber layer monitored by an ophthalmologist to watch for disease progression.
- Know the patient's ocular medications and their systemic side effects.
- Monitor intraocular pressure carefully in persons (especially the elderly) taking high-dose nasal or inhaled steroids.

CHAPTER 208 MANAGEMENT OF CATARACTS

ROGER F. STEINERT

INTRODUCTION

Cataracts are opacifications of the crystalline lens of the eye. They are unusual in young patients, but the incidence rises sharply in later years, such that virtually all elderly patients have some degree of cataract. Because of the implications of this diagnosis, the term *cataract* is best reserved for opacities resulting in functional impairment. The primary care physician should be able to detect cataract formation, monitor its progression, advise the patient on when to seek ophthalmologic consultation, help the ophthalmologist assess medical candidacy for surgery, and support the patient in the perioperative and rehabilitation phases.

PATHOPHYSIOLOGY AND CLINICAL PRESENTATION

Most cataracts occur in the elderly and reflect *senescent change*; occasionally, they ensue from systemic disease and are also frequently associated with intraocular inflammation and glaucoma. *Cigarette smoking* and *glucocorticosteroid use* have been linked epidemiologically to cataract formation. Presenile and senile cataract formation are painless and generally progress over months or years. Those found during the early years of life are either congenital or the consequence of *diabetes, Wilson's disease, Down syndrome*, and other metabolic diseases. *Trauma* is an important precipitant.

Senile Cataract. In the age-related *nuclear cataract*, the lens opacity results from protein denaturation and hydration. Sodium and calcium concentrations increase, potassium and ascorbate levels diminish, and glutathione disappears. The underlying metabolic changes leading to senile cataract are unknown. In diabetes mellitus, excess sugar is diverted to the sorbitol pathway. An insoluble alcohol accumulates, and this osmotic load causes the protein to hydrate.

As the human lens ages, the nucleus hardens (*nuclear sclerosis*). The first visual event may be a shift toward nearsightedness because of the increased refractive index and thickness of the sclerotic nucleus. As a result, the patient may temporarily experience enhanced reading vision without glasses (" *second sight*"), and a change in spectacles may be the only treatment needed. Eventually, the nucleus acquires a yellow-brown coloration ("brunescent cataract") and becomes progressively more opaque. Only a few patients are aware of the gradual spectral change, with a yellow cast to the visual world; they usually acknowledge it only after the cataract is removed. Visual impairment initially is more marked at distance than near, and a patient may fail a driver's license examination and still be able to read a newspaper. Loss of contrast sensitivity may cause a functional impairment out of proportion to the results of a standard high-contrast visual acuity test.

Presenile Cataract. Posterior *subcapsular cataracts* form at the back of the lens, usually centrally. This type of cataract is often responsible for the "presenile" cataract in the 40- to 50-year-old age group. It may be spontaneous but is often associated with prolonged use of topical, inhaled, or systemic *steroids* and with *diabetes mellitus*. The central location of the opacity causes the vision to worsen when the pupil becomes small, as in reading or on bright days. The refractile nature of the opacity commonly causes severe difficulty with glare, such as driving at night. Pupillary dilatation by mydriatic or cycloplegic drops or use of subdued light improves vision in such cases, as more light is allowed to enter the eye.

Traumatic Cataract. These most commonly result from intraocular foreign bodies that perforate the lens capsule, allowing the lens protein to hydrate and thereby denature and opacify. Occasionally, a lens will opacify after severe blunt nonpenetrating trauma. Electric shock and high-dose ionizing radiation may lead to lens opacification. Prolonged exposure to *ultraviolet E*, as occurs with unprotected *sun exposure*, is an important risk factor for cortical cataract formation; risk of nuclear cataract is not significantly increased.

WORKUP

Initial evaluation by the primary physician includes *visual acuity* determination both near and at distance. The lenticular opacity can be appreciated with the *direct ophthalmoscope* while attempting to visualize the fundus. If the angle is not shallow, dilation with one drop of 2.5% phenylephrine or 1% tropicamide is helpful. With the ophthalmoscope lens set at zero and standing about 12 inches from the patient, a bright red reflex is seen in the normal eye. Cataract formation is clearly seen by the *disruption of the red reflex*. Plus power (black numbers) in the ophthalmoscope of about 15 or 20 diopters will put the lens of the eye in focus as the physician approaches the eye. The fundus should be examined for retinal abnormalities, particularly macular degeneration (manifested by hemorrhage, scarring, and drusen), which can cause loss of vision symptomatically similar to that from cataract. In all cases of visual impairment, an ophthalmic consultation is indicated.

PRINCIPLES OF MANAGEMENT

Conservative Measures and Indications for Surgery. The only definitive treatment for cataract is surgery, and in some instances (e.g., traumatic cataracts and very advanced senile cataracts that cause inflammation and glaucoma), emergency surgery is mandatory. However, most cataract surgery is elective and reserved for unacceptable visual impairment not improved by conservative measures. In early nuclear sclerosis, an *eyeglasses prescription* may sufficiently improve vision to defer surgery. Sometimes chronic *pupillary dilation* will suffice for a patient with posterior subcapsular cataract. When such measures no longer suffice and the patient believes visual dysfunction is impairing the quality of life, then cataract surgery can be discussed as a treatment option. For many older persons, a major stimulus for cataract surgery is visual impairment compromising ability to drive a motor vehicle.

Patient Selection for Surgery. In addition to marked visual impairment, other considerations help in patient selection for surgery and approach to anesthesia. Cataract surgery is often performed under local anesthesia (block or topical) with mild sedation; however, because any patient movement during surgery may be disastrous, general anesthesia may be necessary. The primary physician can assist the ophthalmologist in assessing whether age, mental status, or medical condition make general anesthesia appropriate. When cataract surgery is being contemplated for improvement of driving, total medical condition, especially overall psychomotor capability, needs to be taken into account; just treating the cataract may not necessarily improve one's ability to safely operate a motor vehicle. Nonetheless, prospective cohort study correcting for confounding factors suggests that the rate of automobile accidents in seniors with cataracts can be reduced by nearly 50% with cataract surgery.

Updated: 9/03/02

Surgical Approaches. There are several options for cataract surgery. The most common is *phacoemulsification*, which uses ultrasonic energy to break up the hard nucleus and aspirate it through a small opening (about 3 mm). The small phacoemulsification wound can be constructed as a self-sealing valve, often not requiring sutures, which allows the patient rapid return to full physical activity. Although most cataract extractions in the United States use the standard phacoemulsification technique, specific circumstances may cause the surgeon to use *extracapsular extraction*, in which the lens capsule is opened and the nucleus is removed in one piece through a large wound (about 10 mm).

Postoperatively, the surgeon will prescribe topical medications. Final visual correction may be given as soon as 1 to 2 weeks postoperatively.

Visual Rehabilitation. Three methods of *visual rehabilitation* are available: eyeglasses, contact lenses, and lens implants.

Cataract spectacles used to be the only approach to correcting vision after surgery. They must be powerful to compensate for the absence of the crystalline lens. In addition to thickness and weight, these spectacles magnify vision by approximately 25%, which precludes use of a cataract lens for only one eye, because a double image would result. The spectacle thickness also severely limits side vision, producing a midperipheral blind spot. Such difficulties make adjustment to cataract glasses problematic at best, and some patients find ambulation nearly impossible with these spectacles. Cataract spectacles are now used only in highly unusual circumstances.

Contact lenses are optically superior to eyeglasses. Because the lens power is so much closer to the eye than with eyeglass lenses, magnification is only 5% to 7%, and most patients will not perceive diplopia with a contact lens, although stereoscopic acuity will be reduced. Peripheral vision will be normal. Many elderly patients have difficulty handling contact lenses, but extended wear lenses (usually soft) may facilitate use because they may be worn for weeks to months between removals for cleaning. Use of these lenses is not without difficulty, however. Lens deposits, damage, and loss may result in frequent visits to the ophthalmologist, with high cost and time lost. Devastating infectious corneal ulcers are much more common in elderly patients with extended-wear contact lenses.

Intraocular lens implantation is standard practice where not specifically contraindicated. At the time of cataract extraction (and occasionally as a secondary procedure in cases of spectacle and contact lens intolerance), the surgeon implants a delicate plastic device with optical power to replace the cataractous lens. The implant is permanent, requires no care, and restores normal optics without magnification. Although once controversial, with advances in manufacturing and surgical technique there is minimal extra risk to the implant. The implant is contraindicated in some conditions, such as chronic uveitis, which is assessed by the ophthalmologist preoperatively.

Intraocular lenses continue to improve. When the optical portion is made of a flexible material such as solid silicone elastomer, acrylic, or hydrogel, the lens can be folded during insertion so that only a small wound is needed. Multifocal lenses are now available; they may allow patients nearly total freedom from bifocals and reading glasses.

Prevention. Prevention of cataract formation is important and often overlooked. *Protective eyewear* are the best means of reducing risk of cortical cataract formation due to ultraviolet B radiation from the sun. Sunglasses need to be specially treated to fully prevent penetration of ultraviolet radiation, although wearing a hat with a brim and sunglasses with plastic untreated lenses does reduce exposure. However, the darkness of a lens's tint is not necessarily a measure of protective capacity. Dark unprotective sunglasses may actually exacerbate exposure by blocking visible light transmission, causing pupillary dilation, and thus increasing penetration of ultraviolet radiation. Outdoor workers are at particularly high risk and should wear close-fitting protective sunglasses.

Smoking cessation and *limitation of steroid use* to lowest dose and minimum strength necessary (particularly in the elderly) are other potentially important preventive measures. The use of nutritional supplements such as *antioxidants* has not yet been proven to slow the rate of cataract progression despite the theoretical potential benefit.

PATIENT EDUCATION AND INDICATIONS FOR REFERRAL

Preventive measures should be taught to all patients, with an emphasis on use of *protective eyewear* (especially for those with much sun exposure), *smoking cessation*, and *limitation* in dose and duration of *steroid use*.

For elderly patients with age-related nuclear cataracts, the primary physician should help explain the condition and outline treatment options. Patients appreciate knowing that cataract formation is not a "growth" and that it poses no harm to the eye. Patients also need to understand that although surgical correction is highly successful in up to 99% of patients, it is not risk free. Occasionally, complications do occur. When vision is good in one eye and there are no important functional limitations, a conservative approach may be preferable to surgery. The degree of interference with daily activities (e.g., driving, reading, watching television) should be reviewed to help in decision making.

Those with cataracts that significantly impair daily living (e.g., causing falls, prohibiting reading, or interfering with driving) should be referred for consideration of microsurgical cataract extraction with intraocular lens implantation, which has a high likelihood of dramatically improving quality of life.

CHAPTER 209 MANAGEMENT OF DIABETIC RETINOPATHY

CLAUDIA U. RICHTER

Diabetic retinopathy is a leading cause of blindness in the United States in people under age 65 years. Its incidence has increased with improved long-term survival of diabetics. The prevalence increases with duration of disease and is greatest in older age groups. Effective treatment is available not only to prevent many of the most serious complications of retinopathy, but also to reduce the risk of developing retinopathy. Therapy is most effective when rendered promptly. It is of great importance for the primary physician to know when to check for retinopathy and when to refer to the ophthalmologist for more detailed evaluation and consideration of treatment. Diabetes can also cause other eye problems, including refractive changes, cataracts, glaucoma, and reversible cranial nerve palsies (see Chapter 102, Chapter 200, Chapter 207, and Chapter 208).

PATHOPHYSIOLOGY, CLINICAL PRESENTATION, AND COURSE

Two types of diabetic retinopathy can be recognized ophthalmoscopically: nonproliferative and proliferative.

Nonproliferative retinopathy is generally the early form and consists of intraretinal vascular damage. Loss of capillary pericytes, thickening of basement membranes, swelling and proliferation of endothelial cells, and intravascular thrombosis occur. This results in both dilation of small vessels and vascular closure, leading to ischemia. In addition, there is abnormal endothelial permeability with breakdown of the normal blood–retina barrier. Retinal capillaries become permeable to water, lipids, and large molecules, which are not adequately removed by the usual cellular pump mechanism of the adjacent retinal pigment epithelium.

Clinically, this process results in *microaneurysms, intraretinal hemorrhages, cotton-wool infarctions*, and lipid and serous exudation with *retinal edema*. Microaneurysms are dilated capillaries that sometimes thrombose. They appear as red dots in the retina, similar to the small blot intraretinal hemorrhages, which result from bleeding in the deep layers of the retina. Flame-shaped hemorrhages occur in the striated superficial ganglion cell layer. White-centered hemorrhages represent hemorrhagic infarcts. Cotton-wool infarcts, also known by the misnomer soft exudates, are nerve fiber layer infarctions. The swollen axons become ophthalmoscopically visible as white, feathery, soft lesions. Hard exudates are true exudations of the intravascular lipid into the retina, leading to yellow, glistening, spherical aggregates of lipid, sometimes arranged in a circular pattern or circinate ring around leaking blood vessels. Retinal edema is more difficult to see. Accumulation of serous fluid in the intercellular spaces of the retina results in retinal thickening.

Patients with nonproliferative retinopathy are asymptomatic unless retinal edema or ischemia involves the central macula. Macular edema causes blurring or distortion followed by loss of central vision. Macular edema is the leading cause of visual loss in diabetics, especially older type II patients. Hypertension and fluid retention tend to adversely affect vascular exudation and macular edema.

Proliferative retinopathy consists of vascular pathology that extends from the retina into the vitreous cavity. This form of retinopathy generally occurs at a later stage than nonproliferative retinopathy and tends to have a worse visual prognosis without prompt treatment. Advancing capillary and arteriolar closure with more widespread retinal ischemia herald the onset and are manifested by an increase in the number of cotton-wool spots, larger intraretinal hemorrhages, venous beading, and small networks of weblike intraretinal vessels. There is a correlation between duration and degree of hyperglycemia and progression of retinopathy. Tight control (hemoglobin A1c less than 7.0%) slows the onset and severity of retinopathy and other microvascular complications of diabetes (see Chapter 102).

The retina responds to advancing ischemia with *neovascularization*, the hallmark of proliferative retinopathy, by forming networks of new vessels that extend from existing retinal vessels anteriorly into the vitreous cavity. These vessels first appear as a fine network of small vessels proliferating from the optic disc, the major retinal vessels, or from areas adjacent to retinal ischemia. As neovascularization progresses, dense, white, fibrotic tissue forms and adheres to the posterior vitreous. Such fibrosis can cause the vitreous to contract and pull anteriorly, rupturing the fragile network of vessels growing into the vitreous and producing a vitreous hemorrhage that fills the eye and compromises vision. *Retinal detachment* can also occur, either from tractional forces on the retina or in combination with retinal holes forming. The iris may also be involved with neovascularization, leading to *glaucoma* from obstruction of the trabecular meshwork.

Proliferative retinopathy can present with small floating specks or cobwebs in the visual field, representing a small vitreous hemorrhage. Sudden profound loss of vision, sometimes associated with flashing lights, may signify retinal detachment or severe vitreous hemorrhage.

Clinical Course. The *clinical course* of diabetic retinopathy does not appear until 3 to 5 years after the onset of type I diabetes. Onset in type II diabetes is probably similar but more difficult to pinpoint because of difficulty establishing onset of the underlying disease. Type I diabetics tend to progress more rapidly to proliferative retinopathy, with an incidence of 50% after 15 years. Older type II diabetics have a higher incidence of macular edema–induced vision loss.

Pregnancy poses an additional vision risk for diabetics because retinal pathology can progress with unanticipated speed and may require laser treatment sooner than expected. Close monitoring by an ophthalmologist is necessary.

WORKUP

Screening Ophthalmoscopy. Screening asymptomatic diabetic patients for retinopathy is an essential part of effective diabetic care. Available screening methods for detecting diabetic retinopathy include *nondilated ophthalmoscopy, dilated ophthalmoscopy* performed by the ophthalmologist, and *stereoscopic fundus photography*. Stereophotography is the most sensitive and nondilated ophthalmoscopy the least. Dilated ophthalmoscopy has a sensitivity of about 80% and a specificity of 99% for detection of proliferative retinopathy. Pending less costly stereophotographic methods, dilated ophthalmoscopy by an ophthalmologist is required. Dilation allows examination of the more peripheral retina and stereoscopic biomicroscopy to evaluate macular edema. Examination of the nondilated eye with a hand-held ophthalmoscope is inadequate for screening, especially when performed by the nonophthalmologic physician.

The natural history of diabetic retinopathy dictates the proper *screening schedule*. Current screening guidelines for diabetic retinopathy jointly adopted by the American College of Physicians, the American Diabetes Association, and the American Academy of Ophthalmology include the following:

- *For type I diabetes*, screen annually beginning 5 years after the onset of diabetes, generally not before the onset of puberty.
- *For type II diabetes*, screen initially at the time of diagnosis and then annually. If the initial examination uses stereo fundus photography and is found to be normal, then the next examination need not occur for 4 years. After that, annual screening is required, regardless of method used.
- *For pregnant* diabetic women, have dilated ophthalmoscopy performed during the first trimester and close follow-up throughout pregnancy. When planning pregnancy, the diabeticwoman should be counseled on the risk of developing or worsening retinopathy. No screening is needed for women with gestational diabetes.

Such screening does not obviate ophthalmoscopic examination by the primary physician, who might be able to detect an important lesion in the interval between screening examinations, but nondilated ophthalmoscopy by the primary physician is no substitute for a formal eye examination by the ophthalmologist.

PRINCIPLES OF MANAGEMENT

Prevention. Both primary and secondary prevention are achievable by tightly controlling serum glucose, as demonstrated in the two landmark multicenter, randomized, prospective controlled trials of diabetes management: the *Diabetes Control and Complications Trial* (DCCT) for type I disease and the *United Kingdom Prospective Diabetes Study* (UKPDS) for type II disease.

In the DCCT trial, type I patients treated with intensive insulin therapy to normalize the blood glucose experienced a reduction in the risk of developing retinopathy of 76%; in those with preexisting retinopathy, the risk of progression was reduced by 54%. Transient worsening of existing retinopathy occurs during the first year of intensive treatment in about one fourth of patients and consists of soft exudates and intraretinal microvascular changes. Such changes usually disappear by 18 months with continued intensive insulin therapy, and reduction in long-term risk of progression is the same as for patients without early progression. The DCCT study was confined to patients with type I diabetes who had either no retinopathy or mild retinopathy. Whether similar results can be achieved in patients with more severe retinopathy remains to be demonstrated. In *type II diabetes*, the UKPDS similarly revealed that tight control (hemoglobin A1c less than 7%) significantly reduced both the risk of developing retinopathy and its progression. Evolving strategies for normalization of hyperglycemia have made tight control safer and more achievable (see Chapter 102).

The risk of accelerated progression of retinopathy may be greater in patients with proliferative or severe nonproliferative retinal disease, making close ophthalmologic follow-up essential. Other measures that may be helpful in preventing progression of retinopathy include good *control of hypertension* and *cessation of smoking*. Neither the use of aspirin to reduce platelet aggregation nor the use of clofibrate to decrease lipid exudates has proven effective.

Treatment. Once retinopathy is detected, its treatment is the province of the retinal specialist. Laser photocoagulation reduces the rate of vision-threatening complications from both forms of retinopathy.

Nonproliferative Retinopathy. The treatment of choice for clinically significant macular edema is *focal laser* treatment of the macular region, which reduces the rate of severe vision loss by over 50%. Vision loss from macular ischemia is not treatable.

Proliferative Retinopathy. The primary therapeutic modality outside the macular area is *panretinal photocoagulation*. The stimulus to form new vessels is reduced, and risk of severe vision loss is reduced by 50% to 65%. Potential complications include mild reduction in vision, decreased night vision, loss of peripheral vision, inadvertent burns to the central macula, and hemorrhage and exudative detachment of the retina or choroid, leading to angle-closure glaucoma.

When a vitreous hemorrhage will not spontaneously clear or when dense fibrovascular proliferation affects the macula and causes severe vision loss, *surgery* is necessary. Vitrectomy may also allow more aggressive laser photocoagulation (either intraoperatively or postoperatively) of proliferative retinopathy.

Other Hyperglycemia-related Complications. A myopic shift in refractive error can occur due to hyperglycemia-induced osmotic swelling of the lens. Reestablishment of glycemic control can reverse this refractive shift. Diplopia due to localized demyelination of the third, fourth, or sixth cranial nerve usually recovers within 1 to 3 months. Cataracts may also form (see Chapter 208).

PATIENT EDUCATION AND INDICATIONS FOR REFERRAL

Patient education by the primary physician is essential to prevention, early detection, and prompt treatment of retinopathy. Reviewing the benefits of tight glycemic control can be a potent motivating force that improves patient behavior. The importance of smoking cessation, hypertension control, regular ophthalmologic examinations, and immediate reporting of eye symptoms needs to be stressed in conjunction with the good news that effective treatment to prevent vision loss is available.

Ophthalmologic referral is indicated for screening (see above) and is urgent when there is

- Change in vision, new appearance of floaters, or complaint of eye pain;
- Discovery of retinopathy (particularly if abnormal vessels are seen suggestive of neovascularization due to proliferative retinopathy, if there are symptoms or signs of macular edema, or signs of moderate to severe nonproliferative retinopathy);
- Loss of ability to visualize the fundus.

Treatment decisions regarding diabetic retinopathy should be made by the ophthalmologist skilled in management of retinal disease.

CHAPTER 210 CORRECTION OF VISION

Part 1: Contact Lenses

ELIZABETH S. GOULD

Over 24 million Americans wear contact lenses. With proper prescription and safe use, they provide excellent correction of vision and convenience. Primary physicians are sometimes asked about the relative merits of various types of contact lenses and may be the first physician consulted when a problem with their use develops. Knowing the basics about contact lens use and the complications that may ensue can facilitate optimal eye care.

Types of Contact Lenses, Advantages, and Disadvantages

Hard and Rigid Contact Lenses. *Hard contact lenses* were the first to be developed and were fabricated from polymethyl methacrylate. The very low oxygen permeability of such lenses limited their use to daytime wear and frequently caused corneal edema. *Rigid gas-permeable lenses*, allowing greater oxygen permeability, have replaced the original hard design and provide improved comfort and longer wearing times. Rigid lenses require longer initial adaptation and may dislodge more frequently than soft contact lenses. However, rigid gas-permeable lenses provide excellent vision, especially with astigmatic patients. They are relatively easy to clean and can last for several years if cared for properly. Long-term tolerance is good, and the risk of corneal ulcerations, corneal neovascularization, and infection is low. Rigid gas-permeable lenses require advance skill and knowledge by the practitioner in fitting and designing the lenses, much more so than soft lenses.

Soft lenses were developed in the early 1960s and represent most current contact lens fittings. The primary clinical advantage of soft contact lenses is the good initial comfort and tolerance. They can be worn for longer periods, do not dislodge easily, and allow the patient to switch easily between contacts and glasses, because there is less molding effect on the cornea. The disadvantages include less effective astigmatic correction of vision compared with rigid lenses, need for more frequent thorough cleaning and disinfection, and more frequent replacement. In addition, there is increased risk of ulcerative keratitis, neovascularization, and contact lens intolerance.

Disposable soft lenses represent an attempt to further enhance convenience and long-term comfort. Disposable lenses are available as single use, weekly, bimonthly, monthly, and quarterly. *Daily wear* soft contact lenses are removed for sleep and are cleaned and disinfected before insertion the following day. Daily contact lens wear does not significantly alter the mucosal defenses of the outer eye that function to prevent infection. *Extended wear* soft lenses were developed with the goal of allowing the patient to sleep with their lenses for one or more nights.

The first extended wear lenses were approved by the U.S. Food and Drug Administration (FDA) in 1979. In the mid-1980s, at the peak of popularity of extended wear lenses, it was estimated that 30% of new patient lens fittings were for extended wear. Although most patients did well, practitioners became concerned with changes in ocular tissues, including corneal microcysts, stromal edema, endothelial polymegathism, infiltrates, neovascularization, and increased risk for ulcerative keratitis.

Risk of Ulcerative Keratitis

Ulcerative keratitis (epithelial defect over a stromal infiltrate) is an infrequent but serious complication of contact lenswear. It can occur with soft or rigid gas-permeable lenses worn on a daily or extended-wear basis. The relative risk is 10 to 15 times greater with extended-wear use of lenses. *Pseudomonas aeruginosa*, a common sight-threatening pathogen, can quickly invade the injured cornea, resulting in permanent vision loss by destroying the corneal stroma. Prompt ophthalmologic referral is indicated. Response to antibiotics is usually good. The best treatment is prevention. The FDA has restricted approved use of extended-wear lenses to no more than 7 continuous days. Practitioners and patients need to be informed about the increased relative risk of overnight lens use. It is estimated that 49% to 74% of cases of contact lens–associated ulcerative keratitis could be prevented by eliminating overnight wear.

Part 2: Refractive Surgery

ROGER F. STEINERT AND ELIZABETH S. GOULD

Patients with refractive errors have traditionally relied on external devices—glasses and contact lenses—to obtain clear vision. Refractive surgery offers patients a method to reduce or eliminate their dependence on these prostheses. Laser *in situ* keratomileusis (LASIK) is currently the most advanced and predictable refractive procedure available. Intense interest in this field is stimulating rapid technologic advances. Patients often ask their primary physicians for advice regarding the advisability of proceeding with such surgery, necessitating some basic knowledge about the procedures, their efficacy, and safety and criteria for patient selection.

Radial Keratotomy. Until 1990, radial keratotomy for myopia (nearsightedness) was the most commonly performed refractive surgery. Deep radial incisions placed in the cornea from the periphery toward the pupil cause the central curvature to flatten, optically compensating for myopia. Problems inherent in the procedure include unstable correction, fluctuation during the day, a tendency in some patients for a long-term drift toward hyperopia (farsightedness), vulnerability to rupture from a severe blow to the eye, irregular astigmatism, and halos from the radial scars.

Laser Vision Correction: Photorefractive Keratectomy and Laser *In Situ* Keratomileusis. Laser vision correction uses ophthalmic lasers to correct myopia, hyperopia, and astigmatism by reshaping the cornea. The most common forms of laser vision correction are photorefractive keratectomy (PRK) and *LASIK*, both using the excimer laser. Pulses from the argon fluoride 193-nm excimer laser precisely remove collagen from the corneal stroma, allowing controlled reshaping of the corneal and correction of refractive errors.

Photorefractive Keratectomy. In PRK, the epithelial surface is first removed. The excimer laser then is applied to the surface. Each laser pulse removes a fraction of a micron of tissue. In the correction of myopia, a greater amount of tissue is removed from the center of the cornea and progressively less toward the periphery, achieving a flatter corneal contour. In hyperopic correction, the pattern is reversed, to steepen the cornea. In astigmatism correction, more tissue is removed on the steeper meridian. Postoperatively, the epithelium heals across the recontoured anterior corneal stromal surface.

Laser In Situ Keratomileusis. In LASIK, the excimer laser energy is used in essentially the same manner as in PRK. The difference is that the surgeon first creates a flap of anterior corneal tissue, typically about 30% deep, using a device known as the microkeratome. The reshaping laser pulses are applied to the exposed stromal surface, after which the flap is replaced. As a result, the corneal surface is disrupted much less than in PRK. Return of vision is faster, the patient experiences minimal pain, and the risk of anterior corneal scarring is eliminated. Patient acceptance of LASIK has been enthusiastic. Because of the minimal wound-healing response, LASIK can treat a broader range of refractive error than PRK, but LASIK requires higher surgical skills because of the necessity to create a flap with the microkeratome. Several brands of excimer lasers for PRK have been approved by the FDA for relatively mild to moderate cases of myopia and astigmatism.

Results. In the clinical trials, 66% of patients could see 20/20 or better with no glasses and 95% could see 20/40 or better. Retreatments can be performed within several months after LASIK and 6 or more months after PRK if the refractive error is not acceptably corrected. Depending on specific patient variables, LASIK can generally treat myopia up to – 14 diopters, hyperopia up to +4 diopters, and up to 5 diopters of astigmatism. Presbyopic patients need to be educated that the surgery will not eliminate their need for reading glasses.

Complications. Flap complications decrease with surgeon experience and rarely lead to a decrease in visual acuity. After LASIK, patients may experience glare, halos, monoculardiplopia, and dry eyes. These are generally transient and typically decrease over the first several months.

Patient Selection. Candidates for PRK and LASIK are usually at least 21 years of age and have a relatively stable refractive error. Presbyopic patients will still need reading glasses. Some patients elect surgically induced monovision, leaving one eye with low myopia for near vision. Relative contraindications include patients with an ocular history of herpes simplex keratitis, irregular astigmatism, keratoconus, corneal scars, and exposure keratitis. General health contraindications include patients with autoimmune disease disorders that could alter wound healing. Absolute contraindications for PRK, but not necessarily LASIK, include rheumatoid arthritis, lupus, immunocompromised patients, and systemic illness that affects wound healing such as keloid formers.

Intrastromal Corneal Ring Segments. Intrastromal corneal ring segments are small transparent ring segments that are implanted into the nonseeing periphery of the cornea. The procedure currently is able to correct only myopia up to -3 diopters and no astigmatism. The two main advantages of the intrastromal corneal ring segments are that they preserve the central corneal visual zone and are removable, allowing the cornea to return to its original state. Deposits around the implants have been reported in 57% to 100% of eyes treated. Corneal instability has been reported, resulting in a diurnal variation with a myopic shift at the end of the day.

Intraocular Lenses. The surgical correction of myopia with an intraocular lens implanted in the phakic eye is in early investigation. Compared with corneal refractive surgery, the refractive result with phakic intraocular lenses is more predictable, the range of correction is higher, and the quality of vision is improved by decreasing optical aberrations by moving the optical correction to the intraocular plane. Serious potential complications include endothelial cell loss leading to corneal edema, iritis, cataract development, and glaucoma. Long-term follow-up of patients in controlled studies is necessary to confirm the adequacy of the elective surgical procedure. Currently, this procedure is usually reserved for higher levels of myopia and hyperopia than can be treated by other corrective surgeries. Surgical removal of the clear lens is occasionally considered, because it uses current highly refined and reliable cataract surgical technology. Risks are similar to cataract surgery, however.

Thermokeratoplasty. The cornea can be reshaped by heat, which causes contraction of collagen. Past attempts at this concept failed due to instability of the induced corneal shape. More precision in the level of heating, with the goal of creating stable permanent cross-linking of the corneal collagen, has recently been demonstrated by the infrared holmium laser. Externally applied laser pulses may achieve the ability to correct for low to moderate hyperopia, offering technical simplicity and nearly immediate useful vision. Approval of these procedures by the FDA is pending.

PART 14 EAR, NOSE, AND THROAT PROBLEMS

CHAPTER 211 SCREENING FOR ORAL CANCER

JOHN P. KELLY

There are over 30,000 new cases of oral cancer each year in the United States, representing 4% of cancer cases in men and 2% in women. Over 9,000 deaths result from oral cancer yearly. Despite the ready accessibility of the oral cavity to inspection by physicians, dentists, and patients themselves, 50% of oral cancers already have metastasized at the time of diagnosis. Perhaps that is because pain, a manifestation of advanced disease, is the symptom that most commonly leads patients to seek medical attention. When detected early, oral cancer has a very good prognosis. The primary physician has an important role in early detection. Prevention is another responsibility, given the relation of oral cancer to use of tobacco and alcohol.

EPIDEMIOLOGY AND RISK FACTORS

The peak incidence of oral carcinoma is in the sixth decade for women and is equally frequent in each decade after the age of 50 for men. However, the appearance of the disease in the third and fourth decades is not rare and must not be overlooked.

Use of *tobacco* in all its forms is highly correlated with the risk of oral cancer. The frequency of oral cancer of the cheek and gum rises 50-fold among long-term users of *smokeless tobacco.* Use has reached epidemic proportions among teenage boys, causing the Surgeon General's Report to warn against it. Such tobacco products contain multiple carcinogens in addition to tobacco, including nitrosamines, aromatic hydrocarbons, and polonium. Pipe smokers are at increased risk for cancer of the lip. Squamous cell or epidermoid carcinoma of the lower lip also has a particularly high incidence among fair-skinned people whose occupation or residence subjects them to prolonged sun exposure.

Risk of oral cancer is high among those with heavy *alcohol* consumption. Whether this is due to a direct effect of alcohol on the oral mucosa or to associated smoking or vitamin deficiency remains to be fully elucidated.

Cancer of the tongue is highly correlated with the atrophic glossitis seen with tertiary syphilis. Cancer of the tongue is more common among nonsmokers. Mucosal atrophy from other causes is also associated with an increased incidence of oral cancers. Most notably, *chronic iron deficiency* leading to Plummer-Vinson syndrome is known to alter mucosal tissues, and this change may be related to the increased incidence of oral carcinoma. *Epstein-Barr virus* and *papilloma virus* have been found in cells of the tongue manifesting oral hairy leukoplakia, a hyperplastic change found in patients with AIDS.

Chronic irritation of the oral mucosa by ill-fitting dentures, poorly restored teeth, or particularly spicy diets has often been mentioned as contributing to the development of oral carcinoma. However, no epidemiologic data support this view.

The precise etiology of oral cancer is unknown. The etiologic factors mentioned above probably act as cocarcinogens, effecting malignant change in concert with some primary agent not yet elucidated. Increased chromosomal fragility has been found in nonsmokers who develop oral cancers.

NATURAL HISTORY

In considering the natural history of oral cancer, it is important to address premalignant and malignant disease.

Premalignant Disease

Leukoplakia, a "white patch" on the oral mucosa, is of interest because in about 10% of instances it represents premalignant change with dysplastic features on biopsy. Clinically, it ranges from slightly raised white translucent areas to dense white opaque plaques, with or without adjacent ulceration. It is difficult to differentiate completely benign from premalignant leukoplakia, except by *biopsy*. However, patients demonstrating a speckled pattern interspersed with areas of ulceration or erosion are more likely to have dysplastic disease. Lesions may occur anywhere on the oral mucosa, but those on the tongue have the greatest risk of malignant transformation. Such transformation may take anywhere from 1 to 20 years. In addition to premalignant dysplasias and squamous cell carcinoma, the differential diagnosis of oral leukoplakiaincludes traumatic irritation (from malposed teeth or ill-fitting dentures), chemical "burns" (typically from aspirin dissolved in the oral cavity), viral infection (so-called hairy leukoplakia seen in HIV infection), lichen planus, oral candidiasis, discoid lupus, and pemphigus vulgaris.

Erythroplasia, a red hyperplastic area of mucosa, is highly suggestive of an early carcinoma. Although most cancer screening protocols have emphasized a search for white lesions, the predominant color in premalignant or early lesions is red, not white. In fact, whereas some white lesions may only be "premalignant," the red lesions must be considered to be true malignancies unless proven otherwise by biopsy.

Malignant Disease

The average 5-year survival rate for localized oral cancer exceeds 65% but barely reaches 30% for patients with metastatic disease. When untreated, oral carcinoma metastasizes to the regional lymph nodes of the neck, ultimately leading to respiratory embarrassment or involvement of the great vessels. Ipsilateral node involvement is most common, but metastasis to the contralateral side—especially from primary lesions of the tongue or floor of the mouth—occurs with such frequency that treatment for control of metastatic disease is difficult. Hence, early diagnosis and control of the primary lesion are important. The lungs are the most frequently involved extranodal metastatic site.

Local recurrence is common. Many instances may actually represent new primary disease, suggesting a susceptibility of the entire oral mucosa to malignant change in affected patients. As many as one patient in five may be expected to develop a second primary oropharyngeal cancer, with smokers who do not quit incurring the greatest risk.

Other Oral Lesions

Other oral lesions appear black, blue, or brown. Benign conditions such as *vascular malformations, heavy metal ingestion, amalgam tattooing*, pigmented *nevi*, and the pigmentations associated with such systemic conditions as neurofibromatosis, intestinal polyposis, and Addison's disease must be differentiated from the blue-black lesion of *malignant melanoma* (see Chapter 177). Biopsy is essential if this diagnosis is suggested by the appearance of the lesion.

SCREENING AND DIAGNOSTIC PROCEDURES

The challenge to primary care physicians is to recognize premalignant and early malignant lesions of the oral cavity. The greatest hope for improved outcome is detection before the appearance of grossly invasive disease. The ready accessibility of the oral cavity to *inspection* and the appearance of premalignant mucosal changes facilitate early detection. *Biopsy* of suspicious lesions should follow. Leukoplakia and erythroplasia are the most potentially important mucosal changes.

Initial evaluation of a suspicious lesion begins with eliciting appropriate historical data to eliminate such relatively harmless lesions as the acute aspirin burn. Irritative

lesions can be identified by removing or repairing jagged teeth and poorly fitting or protruding dental prostheses and following the clinical healing of the mucosal wound over a short period of time. Mucosal ulceration that fails to heal within a week or two after elimination of a presumed mechanical irritation must be biopsied. In any patient with a suspicious lesion, use of a noxious agent such as tobacco must be eliminated at the outset.

Any red or white lesion that persists for 2 weeks after initial recognition and elimination of irritating agents requires referral for biopsy. High-risk patients, specifically those with histories of smoking and drinking, should be referred for biopsy promptly, as should any patient with a deeply ulcerative or fungating lesion. Exfoliative cytology and **in vivo** staining with toluidine blue, although sometimes suggested as noninvasive diagnostic methods, do not provide sufficient sensitivity or specificity to take the place of incisional biopsy.

Any swelling beneath a normal-appearing oral mucosa must be evaluated as well. Such lesions are commonly benign and are the result of infection, bony exostosis, or mucus retention phenomena, but they may represent neoplasms of the minor salivary glands or other submucosal structures.

RECOMMENDATIONS

- A thorough visual and manual examination of the lips and oral cavity should be a part of every patient's evaluation; mucosal patches that are either red or white are sought.
- A high index of suspicion must be maintained for patients with a history of smoking, drinking, and heavy exposure to sunlight.
- Atrophic or hyperplastic areas of the oral mucosa must be viewed with suspicion, particularly if they are red or white (erythroplasia or leukoplakia) and last more than 2 weeks after cessation of smoking, drinking, and exposure to irritants.
- Referral for definitive biopsy is indicated for persistent lesions.

CHAPTER 212 EVALUATION OF HEARING LOSS

A. JULIANNA GULYA

It is estimated that more than 10% of the population of the United States has a hearing problem. The problem is particularly common among the elderly and can impair quality of life. People with seriously impaired hearing often become withdrawn or appear confused. Subtle hearing loss may go unrecognized. Patients with hearing loss often can be greatly helped, particularly if the loss is due to a conductive problem. The primary physician has the responsibility to detect hearing loss, to search for an etiology, and to decide when referral to an otolaryngologist is indicated.

PATHOPHYSIOLOGY AND CLINICAL PRESENTATION

Pathophysiology

Basic Mechanisms of Hearing and Their Impairment. Impaired hearing may result from an interference with the conduction of sound, its conversion to electrical impulses, or its transmission through the nervous system. Hearing involves an acoustic stage during which sound waves cause the tympanic membrane to vibrate. Ossicles amplify the sound, and the oscillation of the footplate of the stapes in the oval window transmits the sound waves to the perilymph of the inner ear. The endolymph of the scala media (or cochlear duct) is wedged between the perilymph of the scala vestibuli and scala tympani. Displacement of the basilar membrane stimulates the hair cells, converting sound waves to neural impulses, which are conveyed to the temporal lobes.

Molecularly, during the reception of sound, potassium ions flow through the upper surface of the cochlear hair cells; the ions then recycle by flowing down to the base and supporting cells and into the endolymph. *Connexin*, the "gap protein" that allows small molecules to pass from one cell to the next, facilitates this potassium flow. It is synthesized by the cells surrounding the sensory hair cells of the cochlea and by the fibrocytes of the cochlear duct.

Interference with mechanical reception or amplification of sound, as occurs with disease of the auditory canal, tympanic membrane, or ossicles, creates *conductive hearing loss*. Degeneration or destruction of hair cells or the acoustic nerve produces *sensorineural hearing loss*, as do defects in the synthesis of connexin. Genetic studies have facilitated uncovering a molecular basis for hearing loss. Mutations in the gene that codes for connexin are associated with nonsyndromic hearing loss, both early in life and with aging (see below). Congenital malformations of the inner ear, not necessarily hereditary, may also compromise hearing.

Conductive Hearing Loss

Conductive loss presents with diminished perception of sound, particularly for low-frequency tones and vowels. There is often a history of previous ear disease. In the Weber test, the tuning fork is perceived more loudly in the ear with a conductive hearing loss. The Rinne test shows that bone conduction is better than air conduction. Obstruction of the auditory canal by severely impacted cerumen, a foreign body, exostoses, external otitis, otitis media with effusion, or scarring or perforation of the drum due to chronic otitis may be present.

Otosclerosis, a surgically remediable cause of conductive hearing loss, is a disorder of the bony labyrinth that fixes the footplate of the stapes in the oval window. Clinical otosclerosis has an estimated prevalence of about 1% among whites and 0.1% among blacks. Two thirds of the cases are seen in women. There appears to be an association between pregnancy and otosclerotic hearing loss. The condition is thought to be inherited in an autosomal dominant fashion, with varying clinical expressivity. It generally presents in the second or third decade of life.

Exostoses are bony excrescences of the external auditory canal. They are characteristically located in the anterior, posterior, and superior quadrants of the canal. Nearly always bilaterally symmetric, their occurrence seems to be related to repetitive exposure to cold water (e.g., as in ocean swimming). They can cause symptoms by blockage of the external auditory canal, resulting in conductive hearing loss, or by sequestration of debris with subsequent infection.

Glomus Tumors or paragangliomas are benign highly vascular tumors derived from normally occurring glomus formations of the middle ear and jugular bulb. Presenting symptoms include conductive hearing loss (from middle ear mass effect); spontaneous hemorrhage from the canal; and paralysis of the ninth, tenth and eleventh cranial nerves (the jugular foramen syndrome). With progression, they may involve the intracranial space or cause bony destruction of the base of the skull.

Sensorineural Hearing Loss

Sensorineural loss arises from dysfunction of the cochlear sensorineural elements and/or of the cochlear nerve. Patients may complain that they can hear people speaking but have difficulty deciphering words because speech discrimination is poor. Shouting may only exacerbate the problem. The patient with high-frequency loss may have difficulty hearing doorbells, telephones, or a ticking watch and may note more difficulty in hearing the higher pitched female or child's voice. Recruitment, an abnormally rapid increase in perceived loudness with increased sound intensity, may be present and indicates cochlear dysfunction. With Rinne testing, air conduction is reported better than bone conduction. Tinnitus is often a concomitant complaint.

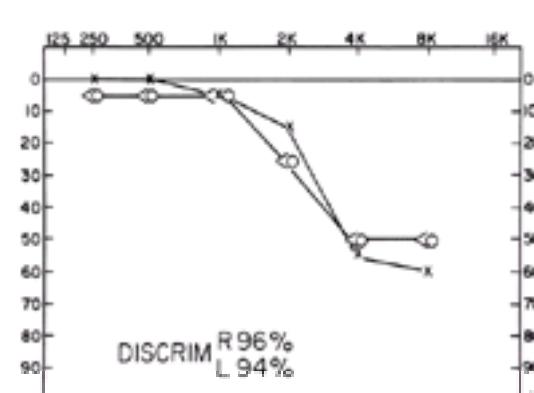
Presbycusis is hearing loss associated with aging and is the most common cause of diminished hearing in the elderly. There are four types of presbycusis, distinguished according to the correlated pathologic changes in the cochlea. Hair cell loss and cochlear neuron degeneration are the most widely recognized changes. The hearing loss is bilaterally symmetric and gradual inonset. Most cases begin with a loss of the high frequencies with slow progression. Eventually, middle and low-frequency sounds also become difficult to perceive (Fig. 212.1 and Fig. 212.2).


FIG. 212.1. Presbycusis due to hair cell loss. Note good hearing thresholds at the speech frequencies of 250 to 2,000 c/s. X = L ear, air; O = R ear, air; < = R ear bone.
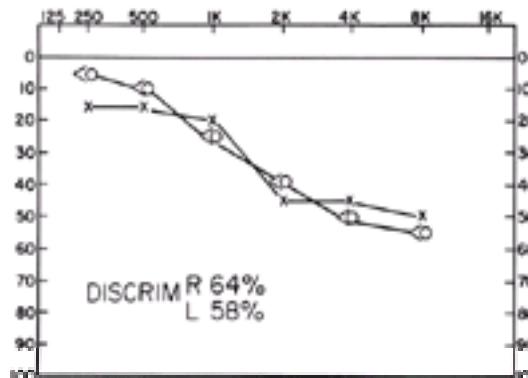

FIG. 212.2. Late presbycusis due to loss of cochlear neurons. Note poor discrimination. X = L ear, air; O = R ear, air; < = L ear bone.

Noise-induced hearing loss is of major epidemiologic and economic significance. Chronic exposure to sound levels in excess of 85 to 90 dB causes hearing loss, particularly in the frequency range around 4,000 Hz. The patient may be unaware of the problem because the speech frequencies (500 to 4,000 Hz) are initially unaffected. At first, there may be a temporary threshold shift in which there is a reversible elevation in the threshold for sound perception. The ear may feel full, or the patient may complain of a sense of pressure. If loud noise exposure ceases at this point, hearing returns to its previous level. If exposure persists, however, a permanent threshold shift ensues. The term *acoustic trauma* more specifically relates to a particular single noise event (e.g., a shotgun blast) that induces an immediate irreversible hearing loss.

Drug-Induced Hearing Loss. The aminoglycoside antibiotics, such as gentamicin, are representative of ototoxic drugs. An early sign of gentamicin ototoxicity is disequilibrium. Monitoring antibiotic blood levels is the best, but not perfect, way to avoid such problems, adjusting dose according to peak serum levels. Restricting dosing to once daily and duration of therapy to less than 1 week also help reduce risk. Other potentially ototoxic drugs, including those causing symmetric sensorineural hearing loss, include furosemide, ethacrynic acid, cisplatin, quinidine, and aspirin. Aspirin doses averaging 6 to 8 g/d predictably cause tinnitus and completely reversible hearing impairment.

Ménière's disease manifests with a unilateral, fluctuating, low-frequency, sensorineural hearing loss, usually associated with tinnitus, a sensation of fullness in the ear, and intermittent episodes of vertigo. Vertigo may be the presenting symptom of Ménière's disease, with later onset of fluctuating hearing loss. Progression of hearing loss may occur, eventually encompassing the higher frequencies as well.

Acoustic neuromas, benign tumors of the eighth cranial nerve, are rare but important considerations in the evaluation of asymmetric sensorineural hearing loss, often in conjunction with disequilibrium (see Chapter 166). Speech discrimination is much worse than predicted by the pure-tone hearing loss. Symptoms progress in relentless progressive fashion.

Sudden sensorineural hearing loss can be due to head trauma or can appear without obvious cause or warning. In *idiopathic* sudden sensorineural hearing loss, recovery appears to be predicted by the pattern of hearing loss sustained, age (greater or less than 40), presence or absence of vertigo, and electronystagmogram pattern. The etiology of the idiopathic variant is still a matter of debate, but viral infection seems to be the most likely cause. Uncommonly, an acoustic neuroma may present with sudden hearing loss. Sudden hearing loss demands expeditious referral to an otolaryngologist for further evaluation and possible therapy with corticosteroids and antiviral agents.

Hereditary sensorineural hearing loss is generally bilaterally symmetric. Many syndromes have been identified in which hereditary hearing loss is associated with anomalies in other organ systems, but nonsyndromic hereditary hearing loss is also recognized. Among persons with isolated ("nonsyndromic") hearing loss, there is a high frequency of mutations in the gene *GJB2*, which codes for synthesis of *connexin*. Mutations in this gene are found not only among congenitally nonsyndromic deaf children, who are usually homozygous for the mutation, but also in the carrier state among adults with late-onset isolated hearing loss. The frequency can be as high as 3% across many different populations. It is suspected that the carrier state may predispose to hearing loss later in life and account for some if not many cases of age-related hearing loss that are commonly encountered. More work is needed to confirm these intriguing and potentially important findings. Although screening for mutations of this gene is not difficult, the degree of hearing loss and its time of onset cannot yet be predicted.

Injury to the inner ear or cochlear nerve may produce an asymmetric sensorineural hearing loss. Skull fracture, meningitis, and mumps are major etiologic factors. Trauma may also cause conductive hearing loss, for example, hemotympanum, tympanic membrane perforation, or ossicular dislocation.

Other Etiologies. *Congenital syphilis* may produce adult-onset sensorineural hearing loss. One or both ears may be affected; the course can be variable, with remissions and exacerbations. Vertigo is sometimes present as well, producing a symptom complex mimicking Ménière's disease.

Multiple Sclerosis should be considered when a young woman shows discrimination scores reduced out of proportion to the pure tone thresholds (similar to the pattern seen with acoustic neuromas). The site of the lesion is retrocochlear (often in the brainstem), and there may be an associated history of optic neuritis and/or vertigo.

Perilymph Leaks or Fistulas may cause hearing loss, with or without vertigo, in individuals who have had inner ear surgery (e.g., stapedectomy), have sustained head trauma, or have congenital inner ear anomalies. The round and/or oval windows may be involved, and it is theorized that there is intracochlear membrane rupture as well. Surgical repair may be required.

DIFFERENTIAL DIAGNOSIS

The causes of hearing loss can be grouped according to whether the problem is conductive or sensorineural (Table 212.1). The categorization is of practical use because the conductive defects lend themselves to correction in many instances.

CONDUCTIVE	SENSORINEURAL
Impacted cerumen	Presbycusis
Foreign body	Noise-induced deafness
Occlusive edema of auditory canal	Drugs (aminoglycosides, loop diuretics, quinidine, aspirin)
Perforation of tympanic membrane	Ménière's disease
Chronic otitis media	Acoustic neuroma
Serous otitis media	Hypothyroidism (mild loss)
External otitis	Idiopathic sudden deafness
Otosclerosis	Congenital syphilis
Exostoses	Diabetes
Developmental defects	Perilymph leak
Glomus tumors	Multiple sclerosis

Table 212.1. Common and Important Causes of Impaired Hearing

WORKUP

History. Evaluation of the patient with hearing loss should focus on detection of the site of lesion. This search is aided by identifying whether the impairment is

conductive or sensorineural. History is of substantial importance. It is worth trying to find out the sounds or situations in which the patient has most trouble hearing. Difficulty understanding spoken words suggests sensorineural hearing loss. Inquiry into drug use is essential, focusing on aminoglycosides, quinine derivatives, salicylates, chemotherapeutics, and the loop diuretics furosemide and ethacrynic acid. A history of otitis, noise exposure (both recreational and work related), or head trauma should be noted.

Inquiry into acoustic trauma is important, especially the details of occupational exposure. Family history is no less important, particularly in the consideration of gene mutations, otosclerosis, and acoustic neuromas (associated with von Recklinghausen's disease).

Physical Examination. The external auditory canal should be inspected for obstruction by impacted cerumen, a foreign body, external otitis, or exostoses. The tympanic membranes are examined for inflammation, perforation, and scarring. One notes any fluid in middle ear. A reddish mass visible through the intact tympanic membrane may indicate a high-riding jugular bulb, an aberrant internal carotid artery, or a glomus tumor. Pneumatic otoscopy assesses tympanic membrane mobility.

Nasopharyngeal examination is indicated in patients with persisting serous otitis media, particularly if it is unilateral. If there is vertigo or suspicion of a glomus or acoustic tumor, cranial nerve examination is performed to assess central nervous system involvement (see Chapter 166).

Testing Hearing. The *watch tick* was an easy, although crude, method of detecting high-frequency impairment when ticking watches were common. *Whispering*, gradually increasing the intensity of the whisper, is readily performed. One asks the patient to repeat a number of words whispered into the tested ear while masking the contralateral ear (e.g., with a Barany noise box). The best words are familiar bisyllabic ones in which both syllables are equally accented (e.g., pancake, hot dog). With practice, one can roughly estimate the patient's hearing thresholds.

Tuning forks can be used both to detect hearing loss and to differentiate conductive from sensorineural hearing losses (*Weber* and *Rinne* testing). A tuning fork that vibrates at a frequency of 512 Hz is acceptable; the 128-Hz tuning fork used for testing vibratory sensation is not. Testing is done to establish the threshold of perception by striking it against the heel of the hand and withdrawing it at 1 foot per second starting 1 inch from the ear until it becomes imperceptible. The distance is noted.

Differentiating Conductive from Sensorineural Hearing Loss. The *Weber* test is helpful. The normal response to a fork vibrating from a tap of the knee and placed midline on the skull is equal loudness in both ears. If there is a conductive loss, the sound will be heard more clearly in the ear with the loss. If there is a sensorineural loss in one ear, sound will be perceived as being heard in the better ear.

The *Rinne test* complements Weber testing. When the vibrating fork is placed on the mastoid process, it is heard for a period of time and then dies away. It is heard again if the same fork is promptly moved without any reactivation to the external auditory canal. Normally, sound conducted by air is heard about twice as long as a sound conducted by bone, because of the greater sound transmission efficiency of the middle ear apparatus.

Alternatively, with firm application of the tuning fork against the mastoid process for a few seconds and immediate transfer to the external auditory canal, the sound should be perceived as "louder" in front of the canal when compared with the mastoid position. With a substantial (generally 25 dB or greater) conductive loss, the ratio reverses. With lesser degrees of impairment, the ratio approaches 1:1. The normal ratio is preserved in sensorineural losses.

The *Schwabach test* compares the examiner's hearing by bone conduction with that of the patient's. The vibrating tuning fork is alternately placed on the mastoid process of examiner and patient. If the examiner's hearing is normal, he or she will perceive the sound for a longer time than the patient with a sensorineural deficit and for a shorter time than the patient with a conductive problem.

Laboratory Studies. An *audiogram* is an essential component of the evaluation of the patient with hearing loss. The pattern of threshold loss has considerable diagnostic and therapeutic importance, helping to establish the type of hearing loss and to localize the site of lesion. Interpretation usually requires the joint efforts of an otolaryngologist and an audiologist, but a few common patterns are useful for the primary physician to recognize (see the Appendix-audiometery).

Expensive imaging technology should be used sparingly but can be helpful in carefully selected patients. *Computed tomography* is used in the evaluation of certain middle ear and mastoid disorders, such as chronic infection and glomus tumors. *Magnetic resonance imaging*, particularly with gadolinium enhancement, has assumed a preeminent role in the evaluation of the patient with suspected retrocochlear disease (e.g., acoustic neuroma or multiple sclerosis).

Auditory brainstem response testing has also been found useful in the site-of-lesion testing, as has *electronystagmography* (see Chapter 166). Both tests require expert performance and interpretation and should be ordered only in consultation with consultants experienced in their use and interpretation.

Otoacoustic emissions, particularly those evoked by sound stimuli, are used to test the integrity of the outer hair cells of the cochlea, from which they are believed to emanate. Oto-acoustic emissions show promise as a screening test for assessing auditory function in infants and other difficult-to-test patients.

Screening for Hearing Loss. An important aspect of geriatric care is assessment for hearing loss. In support of screening for hearing loss are the major impact hearing loss can have on quality of life, the availability of effective means to detect and correct hearing loss, and the ability to screen adequately in the primary care setting. The U.S. Preventive Services Task Force recommends periodic hearing assessment of all elderly persons.

The best screening methods and the optimal interval are the subjects of ongoing study. The American Academy of Otolaryngology–Head and Neck Surgery has developed a simple one-page "test" that the individual patient can self-administer to see if a hearing evaluation by an otolaryngologist is warranted.

Screening for Hearing Loss Gene Mutations. Screening for hearing loss gene mutations is technically feasible because of the frequency of mutations in *GJB2* and the ease with which these can be detected (gene size is small). However, the meaning of the findings remains unclear, making proper use of the information problematic. Further study is needed, and the reader should watch the literature closely because this is a rapidly evolving aspect of hearing loss research.

SYMPTOMATIC MANAGEMENT, PATIENT EDUCATION, AND INDICATIONS FOR REFERRAL

The primary physician's role in the treatment of hearing loss is relatively limited, but simple advice and support are much appreciated. Elders report that cupping the hand behind the ear can be of help both in actual hearing and alerting others to speak more clearly or louder. Speech reading (interpreting what is being said by extrapolating from the words heard and the facial expressions) may also help and is facilitated by good lighting. Clear enunciation, not merely elevated volume of speech, along with directly facing the presbycusic patient while engaged in conversation optimizes verbal communication. Removal of impacted cerumen or other obstruction, cessation of ototoxic drugs, and treatment of otitis media (see Chapter 218) should not be overlooked. Advising patients exposed to occupational or recreational noise to use ear protection when in a noisy environment and to avoid further exposure is important.

Cerumen removal may be accomplished by gentle body temperature water irrigation using a syringe or an irrigation jet. Removal of wax, as well as some foreign bodies, may be performed using a cerumen spoon or forceps under direct visualization provided by headlight and speculum. Insects are better exterminated first by instillation of mineral oil into the canal before removal is attempted.

Referral to an otolaryngologist for further evaluation and treatment is indicated when a conductive etiology or acoustic neuroma is suspected or when simple symptomatic measures do not suffice. The otolaryngologist needs to determine whether the patient is a candidate for medical or surgical therapy and whether a hearing aid is appropriate. A true sudden hearing loss demands immediate otolaryngologic referral.

A great variety of hearing aids is available on the market. Patients with sensorineural hearing losses—especially those with a flat threshold and good discrimination—benefit from amplification and deserve as much consideration as those patients with conductive hearing losses. Even those patients with steeply sloping high-frequency sensorineural hearing loss with poor discrimination may find amplification useful. Only an adequate trial, after careful otolaryngologic evaluation and competent hearing aid fitting, can allow one to make a decision regarding the helpfulness of amplification.

Appendix: Audiometer

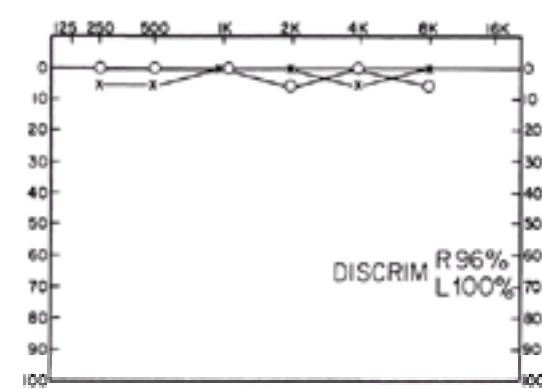
Audiometry helps to classify a hearing loss as conductive or sensorineural and subclassify according to the pattern detected. The basic audiogram consists of pure-tone air and bone conduction testing with evaluation of speech reception threshold and speech discrimination. The minimal intensity (decibel) at which the patient perceives each tone is charted as the threshold for that frequency. The responses are recorded as indicated in Fig. 212.3. The pure-tone air threshold curve measures both conductive and sensorineural hearing. To appreciate a conductive component to a hearing loss, bone conduction thresholds are obtained. The bone conduction audiogram bypasses the conduction system and measures cochlear/cochlear nerve capacity. In bone conduction testing, the mastoid process of each ear is directly stimulated with an oscillator or vibrator over a similar frequency spectrum and results are graphically recorded. A discrepancy between air conduction thresholds and those for bone-conducted sounds, the so-called air–bone gap, is indicative of a conductive hearing loss (Fig. 212.4)


FIG. 212.3. Normal pure tone air audiogram. O = R ear, air; X = left ear, air.
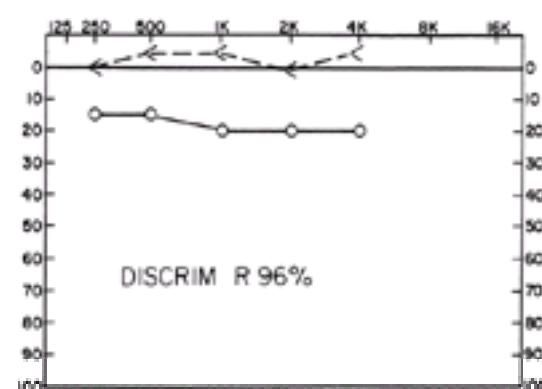

FIG. 212.4. Air–bone gap. O = R ear, air; < = R ear, bone.

Additional testing includes *speech reception threshold* (SRT) and *speech discrimination testing*. The SRT is defined as the lowest intensity at which the patient can correctly identify 50% of presented words. The SRT should match, within a few decibels, the average of the pure-tone thresholds. Discrimination testing evaluates speech understanding using standardized word lists. Speech discrimination that is diminished out of proportion to the measured hearing loss is suggestive of cochlear nerve pathology. Ordinarily, patients with good pure-tone thresholds should also understand speech well.

CHAPTER 213 APPROACH TO EPISTAXIS

WILLIAM R. WILSON

Most spontaneous nosebleeds are self-limited. Patients present for medical care when the bleeding becomes unusually brisk, will not stop, or episodes become frequent. Severe or recurrent bleeding necessitates evaluation for nasal pathology and, less commonly, an underlying generalized disorder. The immediate therapeutic objective is control of bleeding.

PATHOPHYSIOLOGY AND CLINICAL PRESENTATION

Etiologies. The primary mechanism of epistaxis is disruption of the nasal mucosa, primarily caused by *trauma*. In patients with deviated septum or septal spurs in the anterior portion of the nose, trauma occurs easily, either from the drying effects of poorly humidified air or secondary to probing in or bumps on the nose. Picking, rubbing, or forceful blowing may also trigger bleeding when the nasal mucosa is inflamed from a viral, bacterial, or allergic cause.

Ulcerations, which tend to form over septal deviations and spurs, bleed easily. Repeated mucosal exposure to cocaine leads to anoxic tissue necrosis from drug-induced intense vasospasm; perforation may result from cocaine use and cause chronic crusting and bleeding. Collagen diseases such as lupus are occasionally responsible for ulceration.

Bleeding diatheses sometimes present as epistaxis (see Chapter 81). Nosebleeds are the most common initial presentation of *hereditary hemorrhagic telangiectasia* (Osler-Weber-Rendu syndrome) and its most frequent bleeding complication. Characteristic features include telangiectasias on the nasal mucosa, lips, and tongue; a positive family history; and onset of repeated bleeding episodes by the third or fourth decade. Adolescent boys with a nasopharyngeal angiofibroma experience brisk posterior epistaxis. Sinus x-rays demonstrate a nasopharyngeal mass.

Wegener's granulomatosis, midline granuloma, and *nasal malignancy* share a presentation of epistaxis, unremitting sinus infection, and opacified sinuses on x-ray. Posterior epi-staxis, bleeding from the sphenopalatine plexus deep in the nose, is commonly attributed to hypertension, but epidemiologic studies show that few hypertensives experience nosebleeds.

Site of Bleeding. Regardless of etiology, the site of bleeding has distinguishing clinical characteristics. Active *anterior epistaxis* usually presents as unilateral, continuous, moderate bleeding from the septum. Recurrent episodes of bleeding, lasting a few minutes to half an hour over the preceding few days and controlled by pinching the anterior nose, are characteristic. Most adult cases and almost all spontaneous nasal hemorrhage in children occur on the anterior aspect of the nasal septum. Most are venous, but an arterial source becomes more common with advancing age because of mucosal and vascular atrophy.

Posterior epistaxis is associated with intermittent very brisk arterial bleeding, with blood flowing into the pharynx unless the patient is leaning forward. When the patient is leaning forward, the blood may run from one or both sides of the nose. Spontaneous posterior hemorrhage is more common in the older age groups and after severe facial trauma. The vessel rupture is usually just superior or inferior to the posterior tip of the inferior turbinate on the lateral nasal wall.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of nosebleeds can be divided into local and systemic disorders (Table 213.1). The local causes are most commonly inflammatory or traumatic. More than 90% of bleeds are related to local irritation; most occur in the absence of a specific underlying anatomic lesion.

LOCAL DISEASE	SYSTEMIC DISEASE
Dry indoor environment	Granulomatous disease (Wegener's, sarcoidosis)
Upper respiratory infection	
Chronic sinusitis	Hereditary hemorrhagic telangiectasia
Trauma (nose picking, forceful blowing)	
Occupational exposure to irritants	Infection (chickenpox, influenza)
Cocaine abuse	
Angiomas	Bleeding diathesis
Allergies	Malignant hypertension
Lack of humidification	
Malignancy	

Table 213.1. Major Causes of Epistaxis

WORKUP

History should begin with inquiry into the amount of bleeding, duration, and frequency. After the bleeding is under control, the patient can be questioned about easy bruising, hematuria, melena, heavy menstrual periods, family history of bleeding disorders, the use of oral anticoagulants or drugs with antiplatelet effects (aspirin and so forth), occupational exposure to irritating chemicals or dust, dry home, chronic cocaine use, and repeated nose-blowing or picking.

Physical examination should be performed with the patient sitting and leaning forward so that the blood flows from the nose. This allows the physician to assess the rate and site of bleeding and to prevent the swallowing of blood, which will quickly lead to emesis. The pulse and blood pressure should be taken, and the skin, mucous membranes, and conjunctiva should be checked for rash, pallor, purpura, petechiae, and telangiectasias. Lymph nodes should be examined for enlargement, suggesting sarcoidosis, tuberculosis, or malignancy. The sinuses are percussed for evidence of sinusitis, which would make Wegener's, midline granuloma, and nasal tumor considerations.

Laboratory studies are best ordered on the basis of findings from the history and physical examination. Patients suspected of a bleeding diathesis should have a prothrombin time test, partial thromboplastin time test, bleeding time, blood smear, and platelet count obtained (see Chapter 81). Sinus films are appropriate to evaluate the patient with recurrent bouts of sinus pain, tenderness, and bleeding.

PRINCIPLES OF MANAGEMENT

The first objective is to stop the bleeding. The approach depends on whether the source is anterior or posterior.

Anterior Septal Bleeding A few simple first-aid measures suffice for most cases. The patient should *sit up* (this reduces venous pressure) and *lean forward* (which prevents the swallowing of blood if the bleeding is anterior). A small piece of cotton or cotton balls soaked in 1:1,000 epinephrine or a vasoconstricting nosedrop such as *phenylephrine* (Neo-Synephrine) or *oxymetazoline* (Afrin) is placed in the vestibule of the nose and pressed against the bleeding site for 10 to 15 minutes. It is then

removed to observe for rebleeding. This will stop almost all venous types of anterior nosebleeds. Humidification and a lubricant such as petrolatum ointment promote healing.

If these remedies fail, the mucous membrane can be anesthetized by applying cotton soaked with 4% cocaine or 4% lidocaine for 5 minutes. A *silver nitrate stick* can then be applied to the bleeding site and to any prominent vessels.

Occasionally, a small artery in the septal mucous membrane will either fail to stop bleeding or rebleed a short time later. These episodes can usually be controlled by anesthetizing and recauterizing the area. This is followed by placing a small amount of *oxidized regenerated cellulose* (Surgicel) against the bleeding artery or a small *packing of petroleumgauze* strip or Merocel sponge soaked with oxymetazoline and/or thrombin solution that is left in the nasal vestibule for 24 hours.

Patients with bleeding disorders require especially careful treatment to prevent abrading the mucous membrane. Therapy involves use of humidity, copious lubricants, and soft cotton tamponades wetted with long-acting vasoconstricting drops (oxymetazoline 0.05% Afrin nasal solution). Packing should be avoided at all costs but, if unavoidable, can be accomplished with a piece of oxidized cellulose, which does not require removal. Further treatment is best directed at the underlying bleeding disorder.

Posterior epistaxis constitutes an inherently more serious problem, because of the relative rapidity of blood loss and the relatively inaccessible and poorly visualized bleeding site in the posterior nose. Initial efforts should be made to bring the bleeding under control while awaiting an otolaryngologic consult. Hematocrit, blood pressure, and pulse should be immediately obtained, and, if necessary, a sample should be sent for type and crossmatch. The patient should be instructed to *sit up* and *lean forward*, and if there has been a temporary interruption in the bleeding, no treatment other than spraying the nose with a topical anesthetic and vasoconstricting substance, such as *4% cocaine* or oxymetazoline 0.05%, should be attempted. The nose should be suctioned or blown clear only when the medical personnel present are prepared to deal with brisk epistaxis. If the patient's blood pressure permits, a parenteral analgesic such as Demerol 50 or 100 mg intramuscularly should be given before the surgeon's *electrocautery* of the posterior nose or the placement of *compressing* balloons, packs, or tampons.

PATIENT EDUCATION

Prevention of Recurrences. Once septal bleeding is controlled in the office or emergency ward, several measures to prevent recurrences should be instituted:

- Instruct the patient on the need to avoid traumatizing the mucosa. Specifically, warn against habitual nose picking, constant rubbing with a handkerchief, and excessively forceful blowing. The fingernails of children should be trimmed short.
- Have the patient keep the septum well coated with petrolatum-based ointment such as zinc oxide, A and D ointment, or an antibiotic ointment until healed, usually in 3 to 5 days.
- Teach control of minor recurrent bleeding by the patient's use of cotton pledgets soaked in a vasoconstricting solution (e.g., 1:1,000 epinephrine) or a vasoconstricting nosedrop (e.g., *phenylephrine* [Neo-Synephrine] or *oxymetazoline* [Afrin]) and pressed against the bleeding site.
- Explain the importance of humidifying the home environment; have the patient keep a few windows partially open, place containers of water near radiators or stoves, or install a humidifier.
- Consider patient application of a water-based lubricant applied to the rims of the nostrils to maintain mucosal moisture.

First Aid. Few patients understand the proper treatment for care of minor nosebleeds at home; simple telephone instruction may obviate the need for an office or emergency room visit.

- Instruct the patient to *sit up* and remain calm, *lean forward* and *pinch the side* of the nostral against the septum on the side that is bleeding to tamponade the flow.
- Then have the patient spray the nose with any of the over-the-counter nasal sprays that contain *phenylephrine* (e.g., Neo-Synephrine) or oxymetazoline (e.g., Afrin).
- Follow with use of a small *pledget of cotton* lightly soaked with the spray and pressed against the bleeding portion of the septum. After 10 minutes, most nosebleeds will have stopped.
- Have the patient apply a *petrolatum-based ointment*, such as zinc oxide or Bacitracin, to the septum to prevent further drying and abrasion of the septum. It should is left in for a few days.
- Instruct the patient to limit heavy lifting, other forms of straining, bending over, intake of spicy or hot foods, hot showers, and medications that might impair hemostasis (see Chapter 81).

Reassure the patient when the nosebleed is purely a local phenomenon; many people attribute nosebleeds to hypertension and fear cerebral hemorrhage.

INDICATIONS FOR REFERRAL AND ADMISSION

Patients with *active posterior bleeding* should be admitted to the hospital immediately for emergency treatment to control the bleeding. All patients who undergo extensive posterior nasal packing need to be closely observed for signs of hypoxia and hypercarbia, because posterior packing can cause airway obstruction, particularly in elderly patients, due to downward displacement of the soft palate and subsequent palatal edema and swelling or slipped packing. Unfortunately, packs must be left in place for a minimum of 5 days to be effective. Posterior packing is associated with a great deal of discomfort. Patients generally require intravenous hydration because of poor oral intake due to painful swallowing. Additional needs include antibiotics to prevent sinusitis, pain medications, and careful observation by the nursing staff for impending airway obstruction. Packing can often be avoided, or removed earlier, if the patient undergoes an endoscopic nasal examination, and the site is visualized and electrocauterized directly, usually in the operation room. Failing this, where available, arterial embolization of the involved internal maxillary-sphenopalatine artery system can be used in life-threatening situations.

CHAPTER 214 EVALUATION OF FACIAL PAIN AND SWELLING

JOHN P. KELLY

The primary care physician often encounters patients whose presenting complaint of facial pain or swelling is related to the masticatory apparatus (teeth, gums, jaws, muscles) or salivary glands. Dental decay is the most prevalent disease in the United States and a major cause of conditions leading to facial pain and swelling. Because symptoms may be referred to nondental structures and because an odontogenic infection may involve areas of the head and neck seemingly unrelated to the teeth, the patient may first seek the advice of a physician rather than of a dentist. Prompt recognition and effective initial treatment may well prevent development of a serious complication such as abscess formation.

PATHOPHYSIOLOGY AND CLINICAL PRESENTATION

Odontogenic Infection. Dental decay is a multifactorial disease that encompasses dietary factors (most notably, refined carbohydrates), environmental factors (such as inavailability of fluoride ion during the production of the enamel of the teeth), and various host factors (not the least of which is the patient's oral hygiene habits). Oral bacteria use dietary carbohydrates to form plaque on the enamel of the teeth. Susceptible enamel is then decalcified, resulting in a "cavity" or carious lesion.

Tooth Decay and Inflammation of the Pulp. In its initial stages, tooth decay is asymptomatic. However, when the dentin beneath the enamel is exposed, the patient may complain of aching pain when the affected tooth comes into contact with hot, cold, or sweet substances. The frequent finding of referred pain may make localization of the offending tooth difficult and is one reason why a patient may first consult the physician rather than the dentist.

Progressive decay of the tooth will result in inflammation of the pulp (*pulpitis*). The symptoms will be unchanged until the dental pulp becomes necrotic and, eventually, suppurative. The cardinal symptom becomes deep throbbing pain on exposure to hot foods or drinks. The pain is abruptly relieved by ice or cold water. This symptom complex is distinct from the paroxysmal lancinating pain of trigeminal neuralgia, which has no relationship to extremes of temperature but may be related to eating because of the presence of trigger zones in the oral cavity (see Chapter 176).

Tooth Abscess. Simple dental decay, pulpitis, and pulpal necrosis are not associated with fever, swelling, or leukocytosis. However, when the infection of the pulp spreads beyond the confines of the tooth to involve the periodontal ligament and the adjacent alveolar bone, an acute *alveolar abscess* may ensue. In this condition, the affected tooth is tender to percussion or to masticatory forces and is mobile. The adjacent soft tissues begin to show edema, erythema, heat, and tenderness. The location of the involved tooth will determine the location of the swelling. Abscessed maxillary teeth will produce labial or infraorbital edema; an infected mandibular tooth will produce submandibular edema. Lymphadenopathy of the cervical chain can be seen in either maxillary or mandibular infection.

Complications. A facial cellulitis may result, causing fever and leukocytosis. Typically, the history reveals a preceding toothache with pain suggestive of pulpitis, followed by spontaneous regression and an asymptomatic period, corresponding to pulpal necrosis. Swelling and pain develop when the necrotic pulp becomes infected and the process spreads to adjacent anatomic structures. Further spread of infection along fascial planes or by hematogenous routes can result in life-threatening complications, such as *cavernous sinus thrombosis, meningitis, Ludwig's angina*, or *mediastinitis*. Although uncommon, such devastating complications are still seen today, even with the availability of antibiotics.

Periodontal Infection. Acute bacterial infection of the periodontal tissues is most often localized to the gingiva or mucosa adjacent to the involved tooth. The typical patient will complain of a "gum boil," and examination will reveal a discrete fluctuant swelling, which may drain easily on manual palpation.

In the late adolescent years, infection of the soft tissue surrounding erupting third molars or wisdom teeth (periocoronitis) is common. Low-grade chronic infection may be accompanied by symptoms described as "teething"; acute infection will result in pain, swelling, and difficulty in opening the mouth (trismus) as the adjacent masticator space becomes involved.

Salivary Gland Swelling. Acute infection of the major salivary glands (parotid, submandibular, and sublingual) may be either viral or bacterial.   *Viral parotitis* (mumps) occurs most frequently in school-aged children and appears either unilaterally or bilaterally. The efficacy of immunization programs has made this disease a relative rarity. Viral lymphadenopathy in the preauricular area, such as that seen in infectious mononucleosis and in cat-scratch disease, may masquerade as parotid swelling and must be considered.

Sialadenitis, bacterial infection of the salivary glands, commonly affects a single gland. The infection is generally an ascending infection in which bacteria gain access to a gland made susceptible to infection by stasis of saliva. Obstruction of the salivary duct by a stone or mucinous plug is the usual inciting event, but any low-flow state can lead to sialadenitis. The condition is frequently seen in elderly, debilitated, or postoperative patients in whom dehydration may lead to decreased salivary flow and consequent infection. The parotid gland is the usual target; involvement is more often unilateral than bilateral. Purulent drainage can be obtained from the duct orifice. Previous episodes of parotitis or congenital abnormality of the acinar structure of the parotid gland may produce sialoangiectasis, which facilitates pooling and stasis of saliva within the gland and increases the patient's susceptibility to episodes of acute infection.

Systemic Conditions. Noninfectious salivary swelling may occur with diabetes mellitus, uremia, Laennec's cirrhosis,chronic alcoholism, and malnutrition. A toxic reaction to a variety of drugs, such as iodine, mercury, and guanethidine, causes a painless bilateral parotid gland swelling. A specific triad of keratoconjunctivitis sicca, salivary gland swelling, and rheumatoid arthritis is known as *Sjögren's syndrome*. The syndrome has also been related to other chronic autoimmune connective tissue disorders, such as rheumatoid arthritis, systemic lupus erythematosus, and polyarteritis nodosa. Sjögren's syndrome may initially present without apparent systemic disease. Lymphoma may develop in a patient with long-standing Sjögren's syndrome.

Lymphoproliferative Disease. Both major and minor salivary glands may become infiltrated by a lymphoproliferative process and enlarge. Lymphoma, tuberculosis, and sarcoidosis (uveoparotid fever) have all been first diagnosed from salivary gland enlargement.

DIFFERENTIAL DIAGNOSIS

The causes of facial pain or swelling can be divided into odontogenic, nonodontogenic, and salivary gland etiologies (Table 214.1).

Odontogenic Pain
  Caries
  Pulpitis
  Periapical abscess
  Alveolar abscess

Nonodontogenic Pain
  Trigeminal neuralgia
  Temporomandibular joint dysfunction
  Myocardial ischemia (referred jaw pain)
  Giant cell arteritis (masseter claudication)

Salivary Pain and Swelling
  Viral infection (mumps)
  Bacterial infection
  Ductal obstruction
  Sjögren's syndrome
  Lymphoproliferative disease
  Tumor
  Chemical irritant

Table 214.1. Important Causes of Facial Pain or Swelling

WORKUP

History. Evaluation of facial pain and swelling requires thorough consideration of the pain's onset, severity, quality, location, radiation, aggravating or ameliorating factors, and duration. The various stages of dental infection can be characterized by specific pain histories. For example, pain brought on by contact with hot, cold, or sweet substances is indicative of dental caries, whereas aggravation by heat and relief by cold suggest a periapical abscess. If fever and swelling ensue, an alveolar abscess must be considered. Lancinating pain precipitated by contact with a trigger zone is typical of trigeminal neuralgia; it can be distinguished by history from abscess formation because symptoms are unrelated to the temperature of the contacting substance and swelling is absent.

In the patient who complains of salivary gland enlargement, it is important to inquire about site(s) of involvement, presence of fever or tenderness, history of chronic illness, malignancy, toxin or drug exposure, and symptoms of rheumatologic disease or sicca syndrome (dry eyes, dry mouth). Unilateral painful swelling of acute onset suggests sialadenitis, especially when seen in an elderly, debilitated, or postoperative patient. A unilaterally enlarged painless parotid may be due to tumor, particularly if there is a history of progressive increase in size and extension beyond the gland. Bilateral involvement requires consideration of lymphoma and sarcoidosis and Sjögren's syndrome (which is bilateral in about half of cases).

It is important to keep in mind that episodic jaw pain may be a manifestation of coronary ischemia (see Chapter 20).

Physical Examination. A semisitting position will usually allow both patient comfort and examiner access. Although a flashlight can be used, a lighting fixture that can illuminate the oral cavity and leave the examiner with both hands free is preferable.

Inspection of the mouth for fractured, decayed, or heavily restored teeth and for heavy deposits of debris and calculus ("tartar") on the teeth and gingiva requires little experience and will direct the examiner's attention to odontogenic disease as a likely source of the pain or swelling. A dental mirror or a short-handled laryngoscopy mirror serves as a better retractor than does a wooden tongue blade. Palpation of the teeth to determine tenderness or mobility will help to identify an abscessed tooth. The soft tissues should be palpated to detect the presence of indurated or fluctuant swelling adjacent to a suspicious tooth. Tenderness to percussion of a tooth, using a short sharp tap with the dental mirror handle, is diagnostic of an abscessed tooth. The salivary glands are palpated bimanually intraorally and extraorally; the salivary duct orifices should be observed for salivary flow or purulent drainage during palpation of the individual glands. Cervical lymph nodes should be checked for enlargement and tenderness.

Laboratory Studies. Suspicion of dental caries can be confirmed by x-ray, as can abscess formation. Most other conditions produce few radiologic changes. White blood count in the potentially toxic patient or blood sugar in the diabetic patient may aid in subsequent management. Suspicion of Sjögren's syndrome can be confirmed by *lip biopsy* and followed by serum *antinuclear antibody* testing to screen for underlying rheumatologic disease. Any purulent drainage should be sent for Gram's stain, culture, and sensitivity testing.

SYMPTOMATIC MANAGEMENT AND PATIENT EDUCATION

Tooth or Periodontal Abscess. While awaiting dental evaluation, the very uncomfortable patient may require strong analgesia (e.g., ibuprofen, 600 mg, or codeine sulfate, 30 mg every 4 to 6 hours) or local anesthetic block with 2% lidocaine. Antibiotics are indicated when swelling and signs of infection are present in addition to pain. *Penicillin* remains the primary antibiotic of choice in treatment of odontogenic infection. Initiation of an oral penicillin-VK regimen of 250 to 500 mg every 6 hours is appropriate at the first recognition of swelling associated with an infected tooth or periodontal tissue.

Before certain dental work, *endocarditis prophylaxis* should be considered in patients with valvular heart disease (see Chapter 16). A single 2.0-g oral dose of *amoxicillin* 1 hour beforedental procedures associated with bacteremia is the current recommendation of the American Heart Association. No postprocedure antibiotic treatment is deemed necessary. *Erythromycin* is no longer recommended for patients allergic to penicillin. The currently preferred alternatives to penicillin are *clindamycin* (600 mg), *cephalexin* (2.0 g), or *azithromycin* (500 mg) taken orally 1 hour before the procedure.

Referral of the patient to an oral surgeon for definitive drainage of the infection at the earliest opportunity is indicated and should be made simultaneously with the prescribing of antibiotics.

Sialadenitis. Acute swelling of a salivary gland, accompanied by purulent or inspissated saliva from the involved duct, requires antibiotic treatment. Stimulation of salivary flow with sour candies and warm compresses is a helpful local measure. The submandibular gland tends to be infected with the same flora as is found in odontogenic infections. Hence, *penicillin* is the drug of choice for *submandibular sialadenitis*. Acute *bacterial parotitis*, on the other hand, is associated with staphylococcal species, and one of the penicillinase-resistant antibiotics, such as *dicloxacillin*, is preferred. Antibiotic treatment for other infections that may have preceded the onset of the salivary infection can alter the oral flora and produce infection of the salivary system by unusual organisms, such as *Escherichia coli*. Thus, culturing of the purulent saliva is suggested.

Prevention. The U.S. Preventive Services Task Force has underscored the important role of the primary physician in promoting prevention of dental caries and gum disease. During the health maintenance examination, one should inquire into the time of last dental examination, examine the teeth and gums for plaque and gingival disease, urge regular brushing with a fluoride-containing dentifrice and flossing, and recommend yearly dental examination and plaque removal. Knowledge of the fluoridation status of the local public water supply is essential before the prescription of fluoride-containing vitamin preparations by the primary caregivers of the pediatric population.

INDICATIONS FOR REFERRAL

Early recognition of *dental decay* and *gingival inflammation* with consequent referral to a general dentist for complete evaluation and treatment is the most effective means of preventing infection. Referral to the dentist is especially important for patients who may have their mouth *hygiene compromised* by bulimia, Sjögren's syndrome, HIV infection, or upcoming treatment for cancer (e.g., head and neck irradiation, chemotherapy). In the patient with *valvular heart disease*, full dental evaluation on a periodic basis is mandatory and is particularly indicated before consideration of a valvular prosthesis so that potential sources of dental sepsis may be eliminated. Adequate antibiotic prophylaxis for subacute bacterial endocarditis must be provided for such patients at the time dental procedures are performed (see below and Chapter 16).

When physical examination indicates no other source of *facial pain*, referral for dental evaluation is indicated. Abscess formation necessitates prompt referral for definitive drainage. When the patient's clinical appearance demonstrates involvement of deep fascial spaces, as evidenced by fever, trismus, elevation of the tongue, or ophthalmoplegia, referral to an oral surgeon and admission to the hospital for parenteral antibiotics are urgent.

The patient with *acute salivary swelling* should be seen by an oral surgeon for radiographic examination to detect any obstructing sialoliths. Gentle dilatation of the duct may help to relieve the obstruction; in some cases, surgery is necessary to remove the stone. Sialography, or examination of the salivary system with radiographic contrast injections, is contraindicated in the acute period of infection, but noninvasive imaging with computed tomography or magnetic resonance imaging has largely taken the place of sialography in nearly all cases of salivary swelling, both acute and chronic.

When salivary swelling is chronic in nature, no antibiotics are indicated. If the differential diagnosis includes Sjögren's syndrome, sarcoidosis, or lymphoma, a biopsy of one of the minor salivary glands of the lower lip will usually confirm the diagnosis, without necessitating a more complex parotid biopsy.

CHAPTER 215 EVALUATION OF SMELL AND TASTE DISTURBANCES

Impairment of taste and smell, in addition to being intrinsically unpleasant, is annoying because it interferes with the ability to derive pleasure from food. Moreover, a diminished ability to detect noxious agents in the environment leaves the patient vulnerable to them. Patients may complain of total loss, attenuation, or perversion of these senses. Problems of smell are often reported as alterations of taste because much of the awareness of taste is olfactory. The primary physician should be capable of recognizing taste and smell disturbances that are manifestations of serious illness requiring detailedevaluation and simple forms in which symptomatic relief will suffice.

PATHOPHYSIOLOGY AND CLINICAL PRESENTATION

Smell. The olfactory area is located high in the nasal vault above the superior turbinate. The neurons of the first cranial nerve penetrate the cribriform plate and travel to the cortex at the base of the frontal lobe on top of the cribriform plate. The most common mechanism of anosmia or hyposmia is *nasal obstruction* that prevents air from reaching olfactory areas high in the nose. Food is tasteless while the problem persists. In most instances, such as those related to the common cold or allergic rhinitis, the process is fully reversible, but sometimes more lasting damage is done. *Chronic infection* may lead to partial replacement of olfactory mucosa with respiratory epithelium. *Influenza* is known for its ability to cause permanent destruction of the nasal receptors; the onset is often acute. Another mechanism of acute anosmia is *head trauma*, in which the nerve filaments coming through the cribriform plate are damaged.

More gradual onset of reduced smell is typical of an expanding *mass lesion* at the base of the frontal lobe. Meningiomas and aneurysms of the anterior cerebral circulation are the most important sources of this problem. Upward extension of mass lesion into the frontal lobe is manifested by lack of initiative, personality change, and forgetfulness; posterior extension may involve the optic chiasm.

Perversion of smell (parosmia) can result from local nasal pathology such as *empyema* of the nasal sinuses, or ozena, a chronic rhinitis of unknown etiology causing thick greenish discharge and crusting (see Chapter 219). *Klebsiella* and *Pseudomonas* are often cultured from the discharge. Olfactory hallucinations are central in origin and may present as the aura of a seizure. The responsible lesion is typically found in the area of the uncus. *Olfactory delusions* are reported by schizophrenic patients while their sense of smell remains intact.

Many disorders of smell are of unknown cause. The mechanisms of reduced smell associated with *hypothyroidism, hypogonadism, and hepatitis* are not understood. Speculation has centered on the influence of various trace metals, particularly copper and zinc, but replacement therapy has been disappointing.

Taste. The tongue, seventh and ninth cranial nerves, and the hippocampal region of the cerebral cortex make up the taste apparatus. The front of the tongue detects sweet and salty tastes, the sides sense sour tastes, and the large papillae in the back detect bitter tastes. The pharynx also has the ability to sense taste. The taste buds are concentrated in the anterior two thirds of the tongue, which is innervated by the chorda tympani branch of the seventh cranial nerve. The posterior third of the tongue and palate are supplied by the glossopharyngeal nerve.

The most frequent source of diminished fine taste is *impairment of smell*. In addition, the taste buds may be directly injured by *alcohol and smoking*. The common observation that food tastes better after these habits are terminated is due to improvement in both the olfactory receptors and the taste buds. *Aging* results in small but measurable changes in acuity for salty and bitter tastes but not for sweet or sour ones. Elderly men differ from elderly women in that men selectively lose sensitivity to low concentrations of salt, whereas women have a more progressive loss of salt sensitivity.

Diseases and drugs that dry the mouth, for example, *Sjögren's syndrome* and *tricyclic antidepressants*, reduce the threshold for taste. Chorda tympani and seventh nerve lesions are rarely bilateral and therefore do not produce a complete loss of taste. Cerebral mass lesions usually do not involve the hippocampal gyrus. Depression, endocrinopathies, and a host of drugs are associated with complaints of altered taste. The mechanisms are unknown, but in many instances the primary disturbance seems to be, in part, an alteration of smell.

DIFFERENTIAL DIAGNOSIS

Most of the conditions that disrupt taste are annoying but not life threatening (Table 215.1). However, a disturbance in the sense of smell may be a sign of more serious illness (Table 215.2).

Table 215.1. Some Important Causes of Impaired Taste

Table 215.2. Causes of Disturbances in Smell

WORKUP

Smell

History. A primary objective is to distinguish local nasal pathology from a central or cranial nerve lesion. History of head trauma, worsening headaches, olfactory hallucinations, change in personality, unexplained forgetfulness, visual disturbances, gradual onset, or steady progression of symptoms suggestsdisease beyond the nasal cavity. History of head congestion, nasal discharge, allergies, sinus problems, influenza, chemical exposure, or a recent cold suggests the nose as the source of difficulty. Inquiry into symptoms of hepatocellular failure (see Chapter 71) and hypothyroidism (see Chapter 104) may uncover a metabolic–endocrine etiology. A careful psychiatric history is needed when there is description of abnormal smells in the absence of any other pathology.

Physical Examination. One can document the disorder by challenging each nostril with a representative sample of each primary odor: pungent, floral, mint, and putrid. Smell is most accurately assessed by the use of chemicals, such as pyridine, garlic-like odor, nitrobenzene, bitter almond, thiophene, and burnt rubber odor. Kits are available that contain these substances. Ammonia, which will produce a response by irritation even in the absence of olfactory powers, should be avoided.

On physical examination, the head is assessed for trauma and the nares are inspected for polyps, deviated septum, mucosal inflammation, and discharge. The sinuses are transilluminated to look for evidence of sinusitis. Fundi are checked for blurring of the disc margins, and the visual fields are tested by confrontation for evidence of optic chiasm compression. The skin, thyroid, and ankle jerks are examined for signs of hypothyroidism (see Chapter 104), and the hair, voice, muscles, and testes are examined for hypogonadism. Any jaundice, hepatomegaly, ascites, or asterixis should be noted.

Laboratory Studies. *Sinus films* should be reserved for patients with clinical evidence of sinusitis (see Chapter 219). *Neuroimaging studies* (computed tomography or magnetic resonance imaging) should be considered only if there is a history of recent head trauma or symptoms and signs suggestive of a mass lesion (see Chapter 100, Chapter 101, and Chapter 165). The same principle pertains to the ordering of liver, thyroid, and gonadotropin studies (see Chapter 71, Chapter 104, and Chapter 120).

Taste

History. The initial objective of the evaluation is to localize the problem. Intracranial disease is distinctly rare, so assessment can be concentrated on disease in the mouth, in the area of chorda tympani, and seventh nerve. Alcohol abuse, smoking, dental disease, and severe mouth dryness suggest a buccal cavity source. Facial palsy, herpes zoster rash about the ear, recent ear surgery, hearing problems, vertigo, and tinnitus are clues to diseases that may injure the seventh nerve. Drug use and concurrent metabolic or endocrinologic problems (see Table 215.1 and above) deserve exploration. Isolated reduction in taste requires inquiry into smell impairment and concurrent depression. Dry eyes in conjunction with dry mouth suggest Sjögren's syndrome, especially if rheumatoid arthritis is present.

Physical Examination. Careful examination of the nose, ears, oral cavity, tongue, and teeth is essential. The condition of the gums and teeth is worth noting. Taste should be assessed by challenging the withdrawn tongue with sweet, salty, bitter, and sour stimuli on each side and asking the patient to indicate what he or she tastes. Lateralizing the defect suggests a lesion of the seventh nerve. Examination of the cranial nerves needs to concentrate on testing of olfaction, hearing, and facial motor functions.

Laboratory Studies. If history or physical examination suggests hypothyroidism, a thyroid-stimulating hormone level should be obtained; likewise a blood urea nitrogen and creatinine should be obtained if renal disease is suspected. Sjögren's syndrome can be confirmed by lip biopsy. Suspicion of a cerebellopontine angle tumor is an indication for computed tomography.

SYMPTOMATIC MANAGEMENT

Smell. Local nasal pathology is often self-limited, but when chronic sinusitis or allergic rhinitis persists, definitive therapy is indicated (see Chapter 219 and Chapter 222). Avoidance of toxic fumes (e.g., formaldehyde) and removal of nasal polyps should also help. When influenza has caused sudden, complete, and permanent loss of smell, little can be done. Ozena sometimes requires local or even systemic antibiotic therapy; saline irrigations to remove obstructing crusts are helpful (see Chapter 222). Correction of hypothyroidism improves smell. A literature has developed suggesting that zinc salts will restore normal olfaction and taste, although double-blind controlled study finds zinc to be no better than placebo.

Taste. Regardless of the cause of reduced taste, the patient should be encouraged to stop smoking and reduce alcohol consumption; often the development of a disability such as altered taste is sufficient motivation to get the patient to stop (see Chapter 54). If possible, medications that may impair taste should be stopped or reduced to determine what contribution, if any, they make to the taste disturbance. Any dental disease of consequence should be corrected. The same pertains to hypothyroidism (see Chapter 104). Concurrent depression may respond to a tricyclic antidepressant, but the drug may impair taste by causing a dry mouth (see Chapter 227); forewarning the patient can prevent side effects from becoming an unpleasant surprise. Disease related to the brainstem, chorda tympani, and inner ear requires referral for treatment.

INDICATIONS FOR REFERRAL

Olfactory hallucinations, change in personality, visual field defects, and impairment of memory in conjunction with disorders of smell and multiple cranial nerve defects, vertigo, and tinnitus in conjunction with altered taste are indications for neurologic consultation. Psychiatric consultation is worth considering when olfactory hallucinations are accompanied by other evidence of a thought disorder. Patients with ozena, nasal polyps, deviated nasal septum, refractory sinusitis, or a chorda tympani lesion may benefit from evaluation by the otolaryngologist.

Appendix: Halitosis

Halitosis is defined as a foul breath odor arising from a person's oral cavity or nasal passages. It differs from disorders of taste and smell in that the condition is typically not noticeable to the patient. The condition may be physiologic or a manifestation of oral–nasal or systemic pathology.

Pathophysiology. The most common physiologic cause is so-called morning breath. The universal condition derives from the cessation of regular salivary flow with sleep. Its marked reduction and resulting buccal cavity stasis allow mouth flora an opportunity to feed on remaining food particles, sloughed epithelial cells, and stagnant saliva. The byproducts of bacterial metabolism cause the foul odor. Pathologic halitosis may derive from impairment of normal salivary flow (e.g., parotid disease, Sjögren's syndrome), increased presentation of bacterial substrate (periodontitis, sinusitis), or a metabolic derangement (renal or hepatic failure; Table 215.3). In rare instances, the patient is the only one to note the condition, strongly suggesting a hallucination of psychiatric or epileptic origin.

Oral cavity: poorly fitting dental work, periodontal disease, sialadenitis, abscess
Posterior pharynx: tonsillitis, diverticulum, tumor
Sinus: sinusitis, tumor, necrotic disease
Esophagus: reflux, diverticulum, motor dysfunction
Lungs: abscess
Metabolic: renal or hepatic failure; ketoacidosis
Psychiatric: psychosis (self-perception only)

Table 215.3. Some Important Pathologic Causes of Halitosis

Workup. Similar to that described above for disorders of taste and smell, more attention should be paid to possible oral cavity pathology. It helps to begin the assessment by directly confirming the reported odor. Differentiating an oral source from a nasal one can be done by pinching the nares closed while exhaling and exhaling through the nose with the mouth closed. Esophageal and gastric etiologies may require eructation for detection. If the mouth is believed to harbor the suspected source, then the oral cavity should be examined carefully for poorly fitting dental work, periodontal disease, glossitis, tooth abscess, and tonsillar disease. The salivary glands should be checked for free flow of clear saliva in adequate volumes. Pulmonary disease and metabolic dysfunction are important to consider when the oral cavity and sinus tracts appear normal. Patients who have no objective findings but are convinced of halitosis derived from an internal source have a high probability of a hypochondriacal psychosis and need psychiatric referral.

Treatment. Treatment should be etiologic. Trying to mask the odor is far less effective than addressing its etiology. Mouthwashes are a poor substitute for good oral hygiene. Despite advertisements to the contrary, mouthwashes do little to suppress oral flora. Oral hygiene is particularly important in the elderly. Patients should be encouraged to floss and brush regularly, which help remove trapped food particles and promote healthy gums. Regular dental checkups are essential to recommend, although often overlooked.

CHAPTER 216 APPROACH TO THE PATIENT WITH HOARSENESS

WILLIAM R. WILSON

Hoarseness is a symptom of laryngeal disease. Most acute episodes are self-limited and due to viral upper respiratory tract infection or voice abuse. However, the patient bothered by persistent hoarseness requires careful assessment, because carcinoma of the larynx, tumor-associated damage to the recurrent laryngeal nerve, and other serious conditions may be responsible. Prompt evaluation maximizes the chances of detecting an early lesion and achieving a cure.

PATHOPHYSIOLOGY AND CLINICAL PRESENTATION

Pathophysiology of Hoarseness

Vocal quality is determined by complex factors, including the distance between vocal cords, tenseness of the cords, and the rapidity of vibration. Hoarseness results from interference with normal apposition of the cords. Inflammatory, traumatic, and neoplastic lesions cause hoarseness by altering cord structure and function. Often the quality of the voice disturbance reflects the underlying pathophysiology.

A "*breathy*" voice occurs when the vocal cords do not approximate completely, allowing air to escape during vocalization. The cords may be kept apart by tumor, polyps, or nodules. A similar presentation occurs when the cords fail to approximate due to unilateral or bilateral cord paralysis. Patients with hysterical aphonia purposefully hold the cords apart while speaking.

A "*raspy*" or harsh voice ensues from cord thickening due to edema or inflammation. This is the voice quality characteristic of many heavy smokers. The voice is of lowered pitch and poor clarity. Associated inspiratory or expiratory cervical stridor results from laryngeal obstruction.

A high "*shaky*" voice or a low, soft, vibrating vocalization (vocal fry) often are consequences of decreased respiratory force (phonasthenia). These voices characterize elderly or debilitated patients who may complain of additional voice difficulties, such as change in voice pitch or poor vocal projection.

A "*muffled*" voice is characteristic of epiglottitis, causing airway obstruction. Although not truly "hoarseness," this cause of altered voice originates as a sore throat usually due to *Hemophilus influenzae* and may be accompanied by painful dysphagia and dyspnea.

Clinical Presentation

Acute hoarseness is associated with etiologies of acute vocal cord edema and erythema, such as *viral infection, voice abuse*, sudden excessive *smoking*, inhalation of *irritant gases, aspiration*, and occasionally *allergy* (hay fever). Vocal cord nodules may develop when edematous cords are used excessively. Fibrous tissue begins to collect at the junction of the anterior one third and the posterior two thirds of the cord. This results in a lowered breathy voice, which can harm a singing or speaking career.

Acute laryngeal edema may present as part of a generalized edematous allergic response involving the lips, tongue, and other hypopharyngeal tissues. Foods are important precipitants, especially seafoods and nuts; medications (especially angiotensin-converting enzyme inhibitors) can have a similar effect. Rarely, edema can develop from hereditary deficiency of C1 esterase inhibitor as occurs in hereditary angioneurotic edema.

Mechanical Trauma. Swelling forms in response to mechanical trauma, such as dental surgery or intubation for general anesthesia.

Croup and Epiglottitis. In the pediatric population, *subglottic* edema from viral laryngotracheal bronchitis (*croup*) can obstruct the airway. In adults, acute *epiglottitis* has been noted with increasing frequency. As noted above, it is associated with risk of airway obstruction, especially in the setting of *H. influenzae* infection. Symptoms include severe sore throat, dysphagia, dyspnea, and muffled voice.

Chronic Hoarseness. *Chronic laryngitis* causes a low raspy voice, a nonproductive cough, and a "dry throat" sensation. There is little or no pain. The voice waxes and wanes, worsening as the day progresses. *Gastroesophageal reflux disease* has been recognized as a common contributing factor. Another typical patient is a *heavy smoker* who continually talks, subjecting oneself to a combination of chemical irritation and vocal abuse. In rare instances, an infectious or chronic inflammatory condition (e.g., tuberculosis or sarcoidosis) may produce a similar picture.

Chronic Laryngeal Edema with development of dependent polyps represents another form of chronic laryngitis; it may arise in the setting of hypothyroidism, radiation therapy to the neck, or chronic sinusitis with persistent drainage and cough. Patients with this condition speak in a lowered gravelly voice with short phonation time.

Leukoplakia, another form of chronic laryngitis, is the term for the white scalelike appearance of hyperkeratotic changes involving the vocal cords. It occurs secondary to chemical irritation, especially from tobacco smoke and alcohol. Symptoms include hoarseness but no pain. Leukoplakia, which may be a premalignant state, cannot be distinguished visually from squamous cell carcinoma in situ or early invasive cancer.

Contact Ulcers of the larynx occur on the posterior third of the vocal cords where the arytenoid cartilage is covered only by a thin layer of mucosa. Once this mucosa is abraded, an ulcer often forms. Symptoms are painful phonation and a weakened breathy voice. Chronic ulcerations may in time develop into granulations that hold the cords apart, and at times these may become large enough to cause some respiratory obstruction. The ulcerations and subsequent granulations result most commonly from acute or chronic laryngeal intubation but classically are the result of vocal abuse by orators who misuse their larynx attempting to lower the pitch of their voices when speaking forcefully.

Vocal Cord Paralysis occurs with nerve injury. Usually just one cord is paralyzed (except in patients with severe central nervous system disease), causing a weak breathy voice. The position of the cord is affected by the amount of time that has elapsed since injury, because paralyzed cords tend to move toward the midline. The degree of paralysis and the clinical presentation depend on where the neural injury is located. Injury to a vagus nerve results in the loss of all ipsilateral laryngeal muscle function and sensation, leading to aspiration and a weak breathy voice. A more peripheral injury of the recurrent laryngeal nerve leads to little if any aspiration and a voice that is hoarse and somewhat weak, but less breathy. Viral neuritis is the most common cause; function usually returns in 6 to 9 months.

Laryngeal Carcinoma usually occurs in patients with a history of smoking and drinking. If the vocal cords are involved, progressive hoarseness is an early sign, but if the tumor arises on the epiglottis, hypopharynx, or false cords, hoarseness may be a late development. Pain secondary to ulceration is also a late symptom and is often perceived as referred otologic pain, especially when swallowing. These patients may have a mildly fetid breath. Patients with a hypopharyngeal or laryngeal cancer can present with an unexplained lymph node in the neck.

DIFFERENTIAL DIAGNOSIS

The causes of hoarseness are best considered in terms of acute and chronic etiologies (Table 216.1).

ACUTE HOARSENESS	CHRONIC HOARSENESS
Acute Laryngitis Viral infection Vocal abuse Toxic fumes Allergy (seasonal)	Chronic laryngitis Chronic or recurrent vocal abuse Smoking Allergy Persistent irritant exposure
Acute Laryngeal Edema Angioneurotic edema Infection Direct injury Nephritis	Carcinoma of larynx Intrinsic to vocal cords Extrinsic to vocal cords
Acute Epiglottitis	Vocal cord lesions Polyps Leukoplakia Contact ulcer and granulomas Vocal nodule (see vocal abuse) Benign tumors
	Vocal cord paralysis Laryngeal nerve injury (tumor, neck surgery, aortic aneurysm) Brainstem lesion
	Vocal cord trauma Chronic intubation
	Systemic disorders Hypothyroidism Rheumatoid arthritis Virilization
	Psychogenic

Table 216.1. Important Causes of Hoarseness

WORKUP

History. The evaluation of hoarseness depends on the chronicity of the condition. One needs to determine whether the onset was sudden or gradual and the course self-limited or progressive. Difficulty in breathing or stridor suggests obstruction and is an indication for emergency hospital admission. It is helpful to find out if hoarseness is exacerbated by talking, whether the voice completely disappeared, and, if so, for how long. Any recent upper respiratory tract infection, sore throat, fever, chills, sputum, or myalgias should be noted, as well as excessive voice use. Exposure to dust, fire, smoke, or irritant fumes should be documented, as should tobacco and alcohol intake. A history of neck mass, neck surgery, intubation, or lung tumor may provide important clues to etiology. Symptoms of hypothyroidism (see Chapter 104) are worth checking for when the etiology is not readily evident.

Physical Examination. There are two rules of thumb regarding patients with hoarseness. First, hoarseness of more than 2 to 3 weeks duration requires an examination of the larynx. Second, this examination will provide, in most cases, an immediate diagnosis.

Indirect Laryngoscopy. A good view of the hypopharynx and larynx is somewhat difficult to obtain, but the primary physician is encouraged to try and with practice can master the technique. Indirect laryngoscopy with a head light and warmed laryngeal mirror is a time-honored method and still provides the best and most rapidly obtained view of the area. For the gagging patient, premedication with 10 mg of diazepam orally and an analgesic throat spray (Cetacaine or Xylocaine spray) are of benefit. For patients with uncontrollable gag reflexes, referral for examination with a fiberoptic laryngoscope will be necessary. This instrument is introduced through the nose, requiring pretreatment of the nasal passages with 4% cocaine or combination xylocaine–oxymetazoline solution for vasoconstriction and anesthesia. It is rare when a good laryngeal view cannot be obtained in this manner.

Even if laryngoscopy cannot be carried out, some clues as to etiology can be gleaned by a careful physical examination and noting voice quality. One needs to examine the oropharynx and carefully palpate the thyroid and cervical lymph nodes. The hoarse patient with an unexplained neck mass or lymph node requires a thorough check of the nose, paranasal sinuses, and nasopharynx. A breathy voice suggests poor cord apposition, which may be due to tumor, polyp, or nodule. A raspy voice is indicative of cord thickening due to edema or inflammation, as with chemical irritation, vocal abuse, and infection. The patient with a high shaky voice or a very soft one is having trouble mounting adequate respiratory force. Dyspnea is an indication for laryngoscopy.

Laboratory Studies. In most instances, the selection of studies depends on the findings at laryngoscopy and should be done in conjunction with the otolaryngologist. The patient with unilateral paresis of the left vocal cord may have a recurrent laryngeal nerve syndrome secondary to a tumor involving the nerve in the chest most commonly or at the skull base or neck necessitating radiologic evaluation of the chest and, if negative, skull base and neck. Pancoast tumors and carcinoma of the thyroid are unusual causes of vocal cord paralysis. If the cords appear chronically edematous and there is clinical suspicion of hypothyroidism, a check of a serum thyroid-stimulating hormone is indicated. Patients with a suspected carcinoma involving the larynx or with an unexplained neck node and hoarseness need a thorough evaluation of the aerodigestive tract before biopsy. Small-needle biopsies have circumvented the need for some open biopsies, which should be done only under select circumstances. The patient with recurrent edematous episodes and a positive family history might have angioneurotic edema; a check of the C1 esterase inhibitor level is indicated. Soft tissue films may be of use in the dyspneic patient.

PRINCIPLES OF MANAGEMENT AND THERAPEUTIC RECOMMENDATIONS

Regardless of causes, all patients with hoarseness should be strongly advised to *quit smoking* immediately (see Chapter 54). It is often in the setting of an associated medical problem that a smoker will finally decide to quit. Other measures are a function of the underlying etiology.

Acute Laryngitis. The best treatment is voice rest. When it is necessary to speak, the patient should use a moderate voice and not whisper. Warm sialogogues, such as *hot tea with sugar and lemon*, may be helpful. Antibiotics are not indicated unless there is documented bacterial infection. Cough suppressants, particularly with mucolytic agents, may be helpful. Also, *humidity* is of benefit. Inhalation of *steam* in a hot shower or breathing through a moist hot towel will provide immediate partial relief. When hay fever is the cause, a *topical steroid spray* such as dexamethasone or flunisolide helps providesymptomatic relief, but steroids should not be used unless there is an allergic etiology.

Professional singers or speakers should be advised to rest their voice when they become hoarse (especially during upper respiratory infections) to prevent permanent injury to the vocal cords. A vasoconstricting spray and analgesics are used by professionals when use of their voice is absolutely necessary. Occasionally, professional singers may be given a short course of topical or oral steroids to get through a singing commitment, but further cord injury may ensue.

Acute laryngeal edema represents a medical emergency; hospitalization is urgent. Treatment is based on the degree of swelling and subsequent airway compromise. An emergency airway is established if necessary; 0.3 mL of adrenaline 1 to 1,000 is administered subcutaneously, and steroids such as dexamethasone (Decadron 12 mg) may be given intravenously.

Vocal cord nodules should be treated early because often they respond to voice rest and vocal therapy. Nodules that do not respond to conservative therapy can be removed; use of an atraumatic technique (microlaryngeal surgery, carbon dioxide laser) is mandatory.

Angioneurotic edema does not respond to epinephrine or glucocorticosteroids. In an acute situation, intubation or tracheotomy may be required to maintain an airway. If available, infusion of *C1 esterase inhibitor* can be given. Otherwise, treatment is prophylactic, using anabolic steroids with attenuated androgenic effect (e.g., *danazol* and *stanozolol*) to stimulate synthesis of C1 esterase inhibitor. Such prophylaxis may be given for several days before planned surgery.

Temporary unilateral vocal cord paralysis can be treated symptomatically by the otolaryngologist through injection of collagen paste into the musculature of the paralyzed cord, moving it to the midline for 3 to 6 months. This permits the functioning cord to better approximate, thereby improving vocal quality. For permanent vocal cord paralysis, thyroplasty and arytenoid adduction procedures move the paralyzed vocal cord to the midline permanently and provide excellent results. As yet, no satisfactory procedure has been developed for bilateral vocal cord paralysis.

Carcinoma of the larynx can be cured, if detected in its early stages (T1N0). *Surgery, laser*, and *radiation* are all capable of achieving a 90% cure rate. Selection of modality depends on the type of expertise available locally and the location of the lesion. A better voice is usually obtained with irradiation. Metastases and a poor prognosis usually do not occur until the vocal cord cancer becomes larger (T3 to T4) and extends beyond the true cords. Early supraglottic carcinomas arising above the true cords can be cured in about 75% of patients with radiation therapy, partial laryngectomy, or a combination of the two. Larger lesions require combined induction chemotherapy and radiation with surgery for salvage, thereby sparing many larynges that otherwise might be resected. Prevention remains the best treatment; all smokers must be told to quit.

Leukoplakia is treated by vocal cord stripping under microscopic control. Regular follow-up examinations of the larynx are necessary. Repeated vocal cord stripping may be needed once or twice a year, particularly if the patient fails to limit use of irritants.

Dependent polyps are removed by microsurgery.

INDICATIONS FOR REFERRAL AND ADMISSION

Referral. If the primary care physician does not feel competent to visualize the vocal cords, a decision must be made about whether to refer the patient to an otolaryngologist. Hoarseness of greater than *3 weeks duration*, particularly when there has not been a history of an acute infectious process, requires referral. In those who have a resolving process and are at low risk for malignancy (young, nonsmoker, nondrinker), a complete otolaryngologic examination may be deferred pending full resolution.

Among patients who do undergo indirect laryngoscopy by the primary care physician, any patient with a *cord nodule, thickening*, or *paralysis* by indirect laryngoscopy requires referral, as does the patient with persistent unexplained hoarseness of more than 2 to 3 weeks duration and inability to tolerate indirect laryngoscopy.

Referral for *voice therapy* can help foster healthful vocal habits and is indicated for patients who experience repeated vocal trauma or who have organic disease and are in need of voice rehabilitation.

Admission. Any patient with concurrent *dyspnea* should be immediately hospitalized.

CHAPTER 217 EVALUATION OF TINNITUS

A. JULIANNA GULYA

Tinnitus is an important but nonspecific symptom of otologic disease. "Ringing," "buzzing," or "roaring" are terms used to describe the sensation, which can be extremely annoying and a source of concern. The occurrence of tinnitus requires assessment for serious and treatable otologic problems. In the absence of a specifically treatable etiology, it is still important to provide the patient with some symptomatic relief, especially at night when tinnitus tends to be most bothersome.

PATHOPHYSIOLOGY AND CLINICAL PRESENTATION

Tinnitus remains very poorly understood. It appears to be a nonspecific manifestation of disease in the ear, cochlear nerve, or central auditory apparatus and is often accompanied by hearing loss.

External and Middle Ear Conditions. Tinnitus may result from *impacted cerumen, perforation* of the tympanic membrane, or fluid in the middle ear. The sensation is commonly described as low-pitched, intermittent, and accompanied by muffled hearing and a change in the sound of one's own voice. In *otosclerosis*, tinnitus is constant but may disappear as the disease progresses. *Acute otitis media* sometimes produces a pulsating type of tinnitus that resolves as inflammation subsides. Pulsatile tinnitus is also associated with *glomus tumors* and posttraumatic *arteriovenous fistulas*.

Inner Ear and Cochlear Nerve Disease. *Presbycusis, noise-induced hearing loss*, and *acoustic trauma* can give rise to a high-pitched tinnitus that is near the frequency of greatest hearing loss. Transient tinnitus that follows acute noise exposure is a forerunner of hearing loss and a warning sign to avoid repeated exposure. *Ototoxic drugs*, such as the aminoglycoside antibiotics, may produce high-pitched tinnitus and hearing loss that often persist after cessation of drug use. Salicylates are frequently responsible for reversible dose-related tinnitus. *Ménière's disease* results in transient low-pitched tinnitus that varies with the intensity of the condition's other symptoms, often worsening when vertigo and hearing loss are imminent. An *acoustic neuroma* produces a similar set of symptoms, but usually the clinical course is progressive, with unilateral or asymmetric tinnitus frequently preceding other symptoms, such as vertigo (see Chapter 166).

Other Sources. When ambient noise is reduced, all people will notice some head sounds. These may stem from a variety of events, ranging from the rushing of blood (most severe is aortic insufficiency) to contraction of auditory muscles. Loss of hearing due to conductive defects may accentuate the perception of tinnitus. *Tinnitus cerebri* is described as a roaring in the head and is believed to be vascular or neurologic in origin. A *cerebral aneurysm* with an audible bruit, a jugular megabulb anomaly, *palatal myoclonus* with audible muscle contraction, and an unusually patent *eustachian tube* that transmits respiratory sounds are examples of "objective" tinnitus in which the sounds can be heard by the examiner. Tinnitus may also be associated with temporomandibular joint dysfunction (Costen's syndrome).

Depressed and neurotic individuals may have less tolerance for normal head sounds and complain of them when in quiet settings. The ability to withstand tinnitus is also subject to much individual variation. Tolerance is lessened by fatigue and emotional stress.

DIFFERENTIAL DIAGNOSIS

Most tinnitus results from the same conditions that cause hearing loss, whether conductive or sensorineural, peripheral or central (see Chapter 212). Subjective complaints of ear or head noise in the absence of otologic pathology may be a concomitant of psychogenic disease. Objective tinnitus suggests cerebrovascular pathology, palatal myoclonus, or a patulous eustachian tube.

There are few data on the frequency of the various conditions responsible for tinnitus. Of interest is the fact that reports from otologic practice list as many as 50% of cases being of unknown etiology.

WORKUP

The diagnostic assessment of tinnitus follows the same pattern as that for hearing loss (see Chapter 212). A few additional points follow.

History. The pitch of the tinnitus is, unfortunately, of limited use in diagnosis, although some conditions are more likely than others to be associated with tinnitus of a certain pitch. Distinguishing pulsatile, nonpulsatile, subjective, and objective tinnitus may be more helpful. Any association of the sound with respiration, drug use, vertigo, noise trauma, or ear infection should be checked. A history of head trauma should be sought, because it may be associated with an arteriovenous fistula or an aneurysm of the intrapetrous portion of the internal carotid artery. When the problem is present only at night, it suggests increased awareness of normal head sounds. Most patients with tinnitus of otologic origin have an associated hearing defect or soon develop one, whereas those without other signs of ear disease may have vascular lesion or an accentuated awareness of normal head noises.

Physical Examination. One inspects the external ear and tympanic membrane for cerumen impaction, foreign bodies, perforation, signs of otitis media (see Chapter 218), and abnormal middle ear masses. Weber and Rinne testing should be performed to determine sensorineural or conductive hearing loss (see Chapter 212). The cranial nerves are examined for evidence of neuropathy or for signs of an acoustic neuroma or a glomus tumor. Testing for nystagmus (see Chapter 166) is worthwhile if vertigo is reported. The skull should be auscultated for a bruit if the origin of the problem remains obscure. Compression of the ipsilateral jugular vein will abolish the objective tinnitus of a jugular megabulb anomaly.

Laboratory Studies. An audiogram can help to identify and localize the site of lesion underlying the hearing loss. Neuroimaging studies (e.g., computed tomographic or magnetic resonance imaging) may be indicated but should not be done without first consulting an otolaryngologist to ensure proper test selection, performance, and interpretation. Gadolinium-enhanced magnetic resonance imaging may be recommended, especially in evaluation of unilateral or asymmetric tinnitus with or without hearing loss.

INDICATIONS FOR REFERRAL

Referral is essential when a conductive hearing loss is discovered because many of these lesions are correctable. Suspicion of an acoustic neuroma, glomus tumor, or cerebrovascular abnormality is also an indication for consultation, especially before embarking on an expensive workup. Referral to the otolaryngologist may be necessary to satisfy the anxious patient that everything has been explored and that there is no serious or correctable underlying condition.

SYMPTOMATIC MANAGEMENT AND PATIENT EDUCATION

For many patients, the priority is relief from the constant ringing, which can be very disturbing, especially at night. Drugs of all types have been tried, including nicotinic acid, vasodilators, tranquilizers, antidepressants, and seizure medications. None has proven superior to placebo. Nighttime use of a clock radio that shuts off after a half hour of playing background music often allows the patient to fall asleep. Keeping a radio on during the day when the patient has to work in a quiet room is also helpful. Many devices are promoted that one wears like a hearing aid (tinnitus maskers) to help mask tinnitus; they are of questionable value. Biofeedback may help in certain cases in which the tinnitus is related to stress.

CHAPTER 218 APPROACH TO THE PATIENT WITH OTITIS

A. JULIANNA GULYA

Ear discomfort from otitis media accompanying an upper respiratory tract infection is one of the more common complaints encountered in primary care practice, particularly in pediatric settings. Adults are less susceptible but no less uncomfortable when otitis sets in. Symptoms range from vague fullness to frank pain and may be accompanied by diminution in hearing. Patients may present out of concern about the safety of upcoming air travel or underwater activities, especially if over-the-counter remedies have not brought improvement. The primary care physician should be able to effectively manage most cases. Knowing the roles of antibiotics and decongestants in the treatment of otitis media is essential. Discomfort referable to the ear may also be a consequence of otitis externa. Inspection often reveals signs of otitis media or external otitis. The primary care provider should know how to recognize and treat these common conditions.

PATHOPHYSIOLOGY AND CLINICAL PRESENTATION

Acute otitis media may be the consequence of abnormal *eustachian tube reflux* or *obstruction* that permits nasopharyngeal bacteria to infect the middle ear, which is normally free of or-ganisms. Obstruction can result from mucosal edema and/or ex-cessive mucus due to allergic or infectious etiologies. Viral na-sopharyngitis is the most common cause, especially in the winter. It may produce little more than a *serous otitis*, which is generally "*sterile*". If there is bacterial invasion, a *purulent otitis media* may ensue. Of the bacterial species that can be isolated, the most common are *Streptococcus pneumoniae, Haemophilus influenzae*, and *Moraxella catarrhalis*. Viruses, *Staphylococcus aureus, Streptococcus pyogenes*, and other less-virulent organisms are less frequently etiologic.

The principal clinical findings are ear pain, *hearing loss*, and mild to moderate *fever*. The tympanic membrane appears bulging, and an *opaque effusion* may be noted behind the drum if a purulent exudate develops in the middle ear. If pressure builds excessively, the tympanic membrane may perforate with consequent otorrhea. A translucent *effusion* is characteristic of *serous otitis*; one may also observe apparent foreshortening of the manubrium, enhanced whiteness of the stria mallearis, and retraction of the tympanic membrane in the attic region. Most patients make a full recovery. In some patients, recurrent purulent otitis, sustained hearing loss, chronic serous otitis, or chronic otitis media may ensue.

External otitis develops in the setting of skin breakdown in the external auditory canal, leading to inflammation of the surrounding tissues. Skin breakdown is a common denominator, be it from trauma (e.g., from finger nail or cotton swab), excessive moisture (e.g., swimmer's ear), infection of a hair follicle, or chronic eczema. Itching, crusting, pain, redness, and/or discharge may be reported. Movement of the pinna is characteristically painful. Gram-positives, gram-negatives, and fungi can be variably isolated as infectious agents.

Malignant (necrotizing) external otitis is seen in immunocompromised patients and older diabetics. It develops deep in the external canal and usually represents as a pseudomonas cellulitis of the canal and adjacent tissues. Characteristics include purulent discharge, severe ear pain, and temporomandibular joint pain. Signs of facial nerve involvement may follow.

Chronic otitis media is a consequence of untreated or recurrent acute otitis media. Bony destruction or sclerosis of mastoid air cells may result, and the tympanic membrane is often perforated, draining purulent fluid. (Marginal and attic perforations may be associated with invasive cholesteatoma.) Both aerobes and anaerobes can be cultured from the drainage, including *Staphylococcus, Streptococcus, Pseudomonas*, enteric gram-negative organisms, and *Bacteroides.* Patients report little pain or fever, except during exacerbation, but hearing loss and chronic foul otorrhea are common. Radiologic evaluation may reveal the extent of disease.

DIAGNOSIS

Acute Otitis Media. The cornerstone of the clinical diagnosis of acute purulent otitis media is the finding of a *bulging tympanic membrane* with impaired mobility and loss of the bony landmarks. With serous otitis media, fever and pain are absent, and although fluid is present in the middle ear, it is translucent; the tympanic membrane is retracted and the bony landmarks are present. Cultures obtained from the nasopharynx are generally not helpful in defining the infectious agent of an acute otitis media. Needle aspiration of the middle ear is occasionally used to confirm the diagnosis and to identify the causative organism; usually such *diagnostic tympanocentesis* is reserved for those cases unresponsive to appropriate antibiotic therapy or in cases involving immunocompromised individuals.

Chronic Otitis Media and Otitis Externa. Diagnosis of chronic otitis media is suggested by presence of a *perforated drum and discharge. Pain on movement of the pinna*, erythema, and discharge in the external auditory canal are diagnostic of otitis externa. On occasion, a seemingly recurrent external otitis may reflect an unrecognized tympanic membrane perforation and chronic otitis media. Accordingly, careful otoscopic examination after resolution of the acute infection is important.

PRINCIPLES OF MANAGEMENT AND THERAPEUTIC RECOMMENDATIONS

Acute Purulent Otitis Media. Treatment includes use of analgesics, decongestants, and antibiotics. *Amoxicillir* is often the drug of choice. Because resistant strains of *Hemophilus influenzae* have been isolated in a substantial proportion of cases and because *M. catarrhalis* may be responsible for other cases, the combination preparation *amoxicillin–clavulanate* (Augmentin) is a reasonable alternative, particularly when an initial course of amoxicillin does not suffice. For penicillin-allergic persons, *trimethoprim-sulfa* or *erythromycin* may be substituted. A *sympathomimetic decongestant* (e.g., *pseudoephedrine*) may help when the otitis occurs in the setting of an upper respiratory tract infection and eustachian tube obstruction. *Myringotomy*, although not considered therapeutic, is indicated for patients with intractable pain, progressive hearing loss, or acute mastoiditis and in those who have had a poor response to medical therapy. Antihistamines are usually contraindicated, because their drying effect may lead to inspissated secretions.

Acute Serous Otitis Media. Cases secondary to eustachian tube obstruction from allergy or upper respiratory infection may improve with use of sympathomimetic *decongestants* (see Chapter 222). When allergy is suspected, some physicians add an *antihistamine*, but definitive evidence for efficacy is lacking, and, as just noted above, antihistamines may thicken secretions, impeding their clearance.

Chronic Otitis Media. The mainstay of therapy of chronic otitis media is careful aural toilet, with 1.5% *acetic acid irrigation* and *topical antibiotics* (ophthalmic drops tend to be less irritating). The acetic acid irrigation gently debrides accumulated debris and restores the normal acid pH of the external auditory canal. Despite maximal medical therapy, surgery is often required. Patients should be watched for complications such as intracranial suppuration, facial paralysis, sensorineural hearing loss, and vertigo. Persistent fever and headache are ominous in the setting of otitis media (either acute or chronic) and mandate expeditious referral to an otolaryngologist.

Otitis externa is treated with *topical antibiotics*, for example eardrops containing *polymyxin, hydrocortisone, neomycin*, and analgesics. Four drops are applied four times daily for a week, in combination with preventing water contamination (a cotton ball coated with petrolatum ointment usually suffices). Neomycin-containing eardrops, such as Cortisporin, can cause allergic skin reactions. A simple patch test will identify a sensitized patient. More severe cases of external otitis in which the canal is obstructed by edema or purulent material require referral to an otolaryngologist for suction aspiration of debris and insertion of a wick to promote antibiotic penetration.

Cellulitis/malignant external otitis requires systemic antibiotic treatment that includes coverage against *Pseudomonas aeruginosa*. The infection can be a life threatening in diabetics and immunocompromised hosts, necessitating prompt hospitalization, initiation of parenteral antibiotics, and referral to an otolaryngologist for consideration of need for debridement.

INDICATIONS FOR REFERRAL

An otolaryngologist should be consulted if acute otitis media fails to respond to medical therapy or if a complication such as tympanic membrane perforation, recurrent acute otitis, chronic serous otitis, or chronic otitis media develops. The onset of persistent fever, headache, facial nerve paralysis (or other cranial neuropathy), vertigo, or sensorineural hearing loss in the setting of otologic infection mandates emergency otolaryngologic referral. As noted above, hospitalization for parenteral antibiotic therapy is indicated if cellulitis of the external ear develops.

PATIENT EDUCATION

The pain of acute otitis media almost always leads the patient to seek prompt medical attention. Patients who have active external otitis or chronic otitis media with perforation of the eardrum should be instructed to avoid swimming and water entering the ear. As already noted, a cotton ball coated with petrolatum ointment provides a simple yet effective barrier to water entry.

Airplane Travel. Patients with serous otitis or eustachian tube dysfunction who must travel by air without delay should use oral and intranasal *decongestants* (see Chapter 222), especially in anticipation of descent for landing when the risk of barotrauma is greatest. *Self-inflation* of the eustachian tubes can provide symptomatic relief. The patient is instructed to pinch the nose shut, inhale deeply, close the mouth, and try to blow the nose while keeping it pinched shut.

CHAPTER 219 APPROACH TO THE PATIENT WITH SINUSITIS

WILLIAM A. KORMOS

Sinusitis is an inflammation of one or more of the five paired paranasal sinuses surrounding the eyes. It is an extremely common, but likely overdiagnosed, condition, with over 30 million Americans treated for acute sinusitis annually. Many patients with nasal and sinus symptoms have self-limited viral infections or allergic conditions; the physician must distinguish these patients from the patient with a bacterial infection who may require antibiotics. Although acute sinusitis is often self-limited, there is significant morbidity associated with sinusitis. Extension of infection into the central nervous system and bone may be life threatening, and patients who develop chronic sinusitis rate their quality of life similar to patients with congestive heart failure or chronic obstructive pulmonary disease.

PATHOPHYSIOLOGY AND CLINICAL PRESENTATION

The normal sinuses are sterile structures lined with ciliated epithelium. Mucous is cleared from the sinus in a directed manner toward the ostia, or openings, which drain into the nasal cavity at the superior meatus and middle meatus. The superior meatus drains the posterior ethmoid and sphenoid sinuses, and the middle meatus drains the frontal, maxillary, and anterior ethmoid sinuses. Occlusion of these ostiomeatal complexes can lead to dysfunction of the normal sinus epithelium and bacterial infection. Although any sinus can become occluded through viral infection, anatomic abnormalities (including septal deviation, tumors, and polyps) or allergies can predispose to infection.

Acute Sinusitis. The *common cold* is actually a rhinosinusitis that frequently involves the paranasal sinuses. Computed tomographic study of patients with the common cold reveals that over 85% have a self-limited paranasal sinusitis that resolves without treatment. The maxillary sinuses are the most common site (87%), followed by ethmoidal (65%), sphenoidal (39%), and frontal (32%) involvement. Rhinorrhea and nasal stuffiness are the typical symptoms. In about 0.5% to 2% of cases, bacterial infection of the sinuses occurs, resulting in acute purulent bacterial sinusitis. It is characterized by nasal congestion, purulent nasal discharge, facial pain (that typically increases when the patient stoops forward), fever, fatigue, and other constitutional symptoms.

Bacteriology. In most cases, a single organism accounts for the infection; in about 25%, two organisms are present in high density. In over three fourths of cases, the causative organism proves to be either *Streptococcus pneumoniae* or *Haemophilus influenzae*. Other potentially etiologic organisms include *Moraxella catarrhalis, Streptococcus pyogenes*, and *anaerobes (Fusobacterium, Bacteroides, Peptostreptococcus)*. Anaerobes account for about 6% of all cases of sinusitis and usually occur in the setting of dental infections or chronic sinusitis, especially after recurrent courses of antibiotics. *Staphylococcus aureus* can be found on nasal culture, but only very infrequently is it isolated from sinus aspirates in acute sinusitis. *Viruses*, especially rhinovirus and influenza virus, have been isolated alone or in combination with bacteria in 15% to 20% of patients. This may represent true causation of the sinusitis or a preceding viral infection, leading to the bacterial superinfection. *Mycoplasma pneumoniae* and *Chlamydia pneumoniae* are not believed to be important etiologies for most patients. Patients who are immunosuppressed or immunocompromised are at risk for fungal infection, most commonly from *Aspergillus*.

Clinical Presentation. Sinus *pain* or *pressure* and *purulent nasal discharge* are the defining clinical features of acute sinusitis; fever is present in about half the cases. The location of the discomfort depends on the sinuses involved. *Maxillary sinusitis* is the most common and produces pain and tenderness over the *cheeks*. The pain is referred to the teeth in some patients. *Frontal sinusitis* produces pain and tenderness over the lower *forehead*. *Ethmoid sinusitis* results in *retroorbital* pain and may have tenderness over the upper *lateral aspect of the nose*. Isolated *sphenoid sinusitis* is uncommon but can present as retroorbital, frontal, or facial pain. Purulent nasal discharge may be visualized in the middle meatus if the frontal, maxillary, or anterior ethmoid sinuses are involved.

Chronic Sinusitis. Symptoms of chronic sinusitis include *nasal congestion* and *purulent discharge*, but pain and headache are usually mild or absent, and fever is uncommon. By definition, symptoms should be present for at least *2 to 3 months*. The predominant organisms are *S. aureus* and anaerobic organisms, such as anaerobic *streptococci and Bacteroides* species. *H. influenzae* and pneumococcus are less important etiologies in chronic infection. The pathologic importance of anaerobes in chronic sinusitis is reflected by the predominance of anaerobes in brain abscesses of sinus origin. Rarely, fungi such as *mucor, Rhizopus*, and *Aspergillus* species can produce invasive sinusitis in poorly controlled diabetics or leukemics. *Gram-negative bacilli* may cause sinusitis in hospitalized patients who are nasotracheally intubated or immunocompromised.

Complications of sinusitis are uncommon in the setting of antibiotic use but can be life threatening. Frontal sinusitis can lead to *osteomyelitis of the frontal bones*, especially in children. Patients present with headache, fever, and a characteristic doughy edema over the involved bone, which is termed "Pott's puffy tumor." The organisms involved are the same as those responsible for the underlying sinusitis except that *S. aureus* may also be involved. *Osteomyelitis of the maxilla* is an infrequent complication of maxillary sinusitis. *Orbital cellulitis* is most frequently a complication of ethmoid sinusitis due to direct extension of infection through the lamina papyracea. It usually begins with edema of the eyelids and rapidly progresses to ptosis, proptosis, chemosis, and diminished extraocular movements. Patients are usually febrile and acutely ill. Pressure on the optic nerve can lead to visual loss, which can be permanent, and retrograde spread of infection can lead to intracranial infection.

Retrograde extension of infection along venous channels from the orbit, ethmoid or frontal sinuses, or nose can produce septic *cavernous sinus thrombophlebitis*. These patients are highly febrile and appear "toxic." Lid edema, proptosis, and chemosis are present, but unlike uncomplicated orbital cellulitis, third, fourth, and sixth cranial nerve palsies are prominent; the pupil may be fixed and dilated; and funduscopic examination may reveal venous engorgement and papilledema. Although the process is usually unilateral at first, spread across the anterior and posterior intercavernous sinuses results in bilateral involvement. Patients may exhibit alterations of consciousness.

Finally, sinusitis can lead to *intracranial suppuration* either by direct spread through bone or via venous channels. A great variety of syndromes can result, including epidural abscess, subdural empyema, meningitis, and brain abscess. Clinical findings vary greatly, ranging from subtle personality changes with frontal lobe abscesses to headache, symptoms of elevated intracranial pressure, alterations of consciousness, visual symptoms, focal neurologic deficits, seizures, and, ultimately, coma and death.

DIFFERENTIAL DIAGNOSIS

The *common cold* and *allergic* or *vasomotor rhinitis* are by far the most common causes of "sinus" symptoms, but *polyps, tumors, cysts, foreign bodies*, and *vasculitides* such as Wegener's granulomatosis occasionally produce symptoms resembling sinusitis (see Chapter 222).

WORKUP

Clinical findings can be very helpful in diagnosis of sinusitis, especially when findings are considered in combination. In a prospective study comparing historical and physical findings with sinus films, no single feature had a likelihood ratio of more than 2.5 in predicting a positive x-ray, but when five individually predictive findings (see below) were considered together, the likelihood ratio rose to 6.4 if all were present and fell to 0.1 if none was found.

History. The diagnosis of sinusitis is entertained in the patient with symptoms of nasal congestion and discharge that persist beyond the expected 7 to 10 days of the common cold. The classic symptom of frontal, maxillary, retroorbital, or vertex pain that worsens on bending forward has not been found to independently predict radiographic sinusitis in several studies. A history of *purulent rhinorrhea*, however, has been associated with sinusitis in several studies (positive likelihood ratios of 1.5 to 3.5). In addition, prospective study in the primary care setting comparing clinical findings and radiographs in adult males presenting with symptoms suggestive of sinusitis also revealed that maxillary toothache and poor response to decongestants were useful predictors of radiologically confirmed sinusitis (positive likelihood ratios, 2.5 and 2.1, respectively). In a study from ear, nose, and throat practice using maxillary aspiration of purulent material for diagnosis, unilateral sinus pain also

correlated with outcome. Finally, the symptom of "*double sickening*" (upper respiratory infection symptoms with initial improvement followed by increasing nasal symptoms) had a positive likelihood ratio of 2.8 in one primary care study.

Risk factors such as nasal polyps, deviated nasal septum, trauma, foreign bodies, and rapid changes in altitude should be inquired about. Special attention is paid to toxic symptoms of high fever and rigors in association with complaints suggestive of extension of infection, such as edema of the eyelids and diplopia.

Physical Examination. One should examine the nasal cavity for purulent discharge draining from one of the turbinates and transilluminate the maxillary sinuses for impaired light transmission. Transillumination must be performed in a completely darkened room with a strong light source. In a few patients, tapping the maxillary teeth may reveal a dental source of maxillary sinus infection. In the prospective study alluded to above, the best independent physical examination predictors of sinusitis were *impaired transillumination* (positive likelihood ratio, 1.6) and *mucopurulent nasal discharge* (likelihood ratio, 2.1). Other studies have found transillumination either more or less useful, which is partly explained by observer experience with transillumination. Palpation over the maxillary and frontal sinuses isoften performed to elicit *sinus tenderness*. Although physicians often use this as a criterion to diagnose sinusitis, it does not appear to reliably distinguish between patients with and without sinusitis.

Laboratory Studies. As noted, the diagnosis of sinusitis remains a clinical one, albeit imprecise. The gold standard of a positive culture on sinus aspiration is too difficult and too invasive to be performed routinely for this predominantly self-limited condition. Additional testing may be appropriate in confusing cases, patients who fail to improve, patients with a suspected complication, or in patients with frequent recurrences. Some studies have suggested that an elevated erythrocyte sedimentation rate is useful in diagnosing sinusitis (likelihood ratio, 2.0); however, it is not common practice to obtain this test.

Sinus Films. Confirmation of sinusitis can be achieved by finding mucosal thickening, sinus opacification, or air–fluid levels on conventional sinus x-rays. For those with air–fluid levels or complete opacification, the positive predictive value is 80% to 100%; however, such findings are present only in 60%, reducing their sensitivity. Mucosal thickening has a sensitivity of 90%, but specificity is poor. Normal sinus x-rays in a person presenting with suspected sinusitis rules out maxillary and frontal disease (negative predictive value, 90% to 100%); ethmoidal involvement is harder to exclude. For the maxillary sinuses, a single occipitomental (Waters') view is acceptable to examine the sinuses. Bone erosion can be present in chronic sinusitis.

Computed Tomography and Magnetic Resonance Imaging. Sensitivity of computed tomography (CT) is extremely high, so high that specificity is compromised (almost half of asymptomatic persons undergoing head CT for nonsinus reasons show mucosal abnormalities). CT is best reserved for complicated disease and search for occult ethmoidal disease in patients with refractory symptoms and negative conventional x-ray studies. It has also been most useful to delineate anatomy before endoscopic surgery. Magnetic resonance imaging has proven useful for differentiating mucosal inflammation from tumor. Neither study is appropriate for patients with routine sinus infection.

Ultrasound has been used in the diagnosis of sinusitis. Sensitivity is lower than for sinus x-rays, but specificity is higher. Expertise is not widely available.

Sinus and Nasal Cultures. Although used as the gold standard for research purposes, a culture of the aspirate from the maxillary sinus is negative in up to 40% of patients who undergo aspiration for suspected sinusitis. Cultures obtained from nasal swabs and even protected endoscopes are invariably contaminated with nasal flora and cannot be relied on. False-positive isolates of staphylococcal species are common.

PRINCIPLES OF MANAGEMENT AND THERAPEUTIC RECOMMENDATIONS

Acute Purulent Sinusitis. The optimal treatment remains controversial. The inaccuracy of the diagnosis of sinusitis and self-limited nature of the disease has led to a discordance between microbiologic and clinical outcomes. Although sinus-aspirate studies clearly document efficacy of antibiotics in eradication of bacteria from infected sinuses, randomized placebo-controlled trials find 70% rates of clearing among patients treated with nothing more than placebo. Furthermore, although many causative organisms demonstrate increasing degrees of antibiotic resistant, randomized controlled trials show no benefit for powerful broad-spectrum antibiotics over the traditional narrow-spectrum b-lactams and sulfas. Although clear evidence is lacking, perhaps elimination of underlying ostial obstruction through use of decongestants is just as important as effective antibiosis.

Decongestants are available in both topical and systemic preparations. The mixed adrenergic agonist *pseudoephedrine* is reasonably effective and can be administered by mouth. Popular sympathomimetic nasal sprays include *phenylephrine* (Neo-Synephrine) and *oxymetazoline* (Afrin), which is the longest acting of the topical decongestants. Patients should be instructed to spray each nostril once and then wait a minute to allow the anterior nasal mucosa to shrink. A repeat spray will then reach the upper and posterior mucosa, including the nasal turbinates and sinus ostia. This procedure can be repeated as needed every 4 hours with phenylephrine and every 12 hours with oxymetazoline for up to 3 days. Tachyphylaxis and irritation develops with prolonged topical use, but risk is minimal with short-term administration (1 to 3 days).

When there is an underlying allergic component to the nasal obstruction, one needs to consider *antihistamines, nasal steroids*, and *sympathomimetic decongestants* (see Chapter 222). Antihistamines are not for routine use, because in the absence of an allergic process, they may thicken secretions and worsen sinus outflow obstruction. Even in the setting of allergy-induced acute sinusitis, their use may prove problematic if too drying. Nasal steroids may be worth a trial if there is concurrent allergic rhinitis, but theoretically they could impede the response to infection, necessitating close monitoring of such therapy. Local application of heat may be soothing. Inhalation of *steam* or water and *nasal irrigation* with saline can help relieve symptoms of congestion.

Antibiotics. Patients with mild acute sinusitis may respond sufficiently well to decongestants so as to not require antibiotics, but in more severe cases of acute purulent sinusitis, antibiotics are commonly used. In the few randomized controlled studies that exist, antibiotics do demonstrate some benefit over decongestants alone, but cure rates without antibiotics remain high (approaching 70%). Nevertheless, many physicians administer antibiotics routinely to patients with sinusitis, often in response to patient demands. In a randomized trial of patients recruited from primary care practices with radiographic sinusitis, 80% of all patients, including those treated with placebo and those treated with amoxicillin, had no or few symptoms after 2 weeks. There were no significant differences between the groups in symptom improvement or in relapse rates over the following year.

Choice of Agent. Effective treatment does *not* require starting with a very expensive, broad-spectrum, penicillinase-resistant antibiotic. *Amoxicillin* (500 mg orally three times a day) and *trimethoprim-sulfamethoxazole* (TMS-DS, 160/800 mg twice daily) still remain the best options for initial treatment. *Doxycycline* has reasonable activity against known pathogens and may be used if the patient is allergic to penicillins and sulfa drugs.

Concern about rising prevalences of *multidrug-resistant S. pneumoniae* and b-*lactamase–producing* strains of *H. influenzae* (up to 40%) and *Moraxella* (100%) has stimulated use of such broad-spectrum penicillinase-resistant antibiotic agents as *amoxicillin-clavulanate, cefuroxime, loracarbef, azithromycin, clarithromycin, and levofloxacin* for initial treatment of acute sinusitis. However, randomized controlled trials and a recent meta-analysis have failed to demonstrate any advantage for such antibiotics over *amoxicillin* or *TMS*, suggesting that b-lactamase–producing strains and multidrug resistance may not be as clinically significant as feared. Furthermore, although intermediate penicillin resistance may be present in up to 25% of pneumococci in some communities, standard full doses of amoxicillin (e.g., 500 mg three to four times a day), but not TMS or the macrolides remain effective in achieving high rates of clinical cure. The popular second-generation macrolides such as clarithromycin and azithromycin may be less effective against the penicillin-resistant pneumococcus than previously thought, further eroding the rationale for their frequent use. The frequency of acute sinusitis and the common practice of unnecessary use of very expensive very broad-spectrum antibiotics have serious adverse implications not only for cost (10 to 20 times more costly), but also for promotion of antibiotic resistance in the community. Such agents should be relegated to a second-line role, reserved for patients who fail to respond to amoxicillin or TMS.

Knowledge of the prevalence of resistant strains in one's community can help guide initial antibiotic selection and identify when an exception to the rule to start simply is appropriate. The strong presence of a very highly clinically resistant organism in the community makes it reasonable to consider starting with a broader spectrum penicillinase-resistant agent. Alternatively, if the organism is *S. pneumoniae*, increasing the dose of a b-lactam antibiotic may suffice.

Duration of Therapy. Although the proper duration of therapy has not been identified, it is typical to treat with antibiotics and decongestants for 7 to 10 days, depending on severity and response. Partial responses and early relapses can be treated with another week of the same program. Patients who remain unchanged after 2 full weeks of therapy or deteriorate sooner should have sinus films obtained and a penicillinase-resistant drug should be prescribed. Further failure to respond is an indication for ear, nose, and throat referral.

Surgery. Surgical intervention should be avoided in acute sinusitis unless patients fail to respond to medical therapy and complications are present.

Recurrent and Chronic Sinusitis. Recurrent sinusitis is usually due to underlying allergic disease or an anatomic lesion and requires treatment of the underlying pathophysiology (see Chapter 222). Chronic sinusitis (persisting for more than 3 months) has a different bacteriology (see above) necessitating consideration of broader spectrum antibiotic coverage (e.g., *amoxicillin-clavulanate*). Treatment may need to be prolonged for several weeks. Attention also needs to be directed at underlying precipitants. Sinus irrigation or surgical drainage may be necessary.

INDICATIONS FOR ADMISSION AND REFERRAL

Admission. Any patient who appears *toxic* or has clinical evidence suggestive of *extension* to the orbit, bone, brain, or cavernous sinus requires urgent admission for emergency assessment and high-dose intravenous antibiotics. Warning symptoms include high fever, rigors, lid edema, diplopia, pupillary abnormalities, ptosis, and palsies of extraocular movements. The patient should be seen by both an otolaryngologist and infectious disease consultant. Antibiotic coverage is directed against both staphylococci and gram-negative rods. Surgical drainage may be urgently needed.

Referral to an otolaryngologist should be considered for patients who fail treatment with two courses of antibiotics, have anatomic abnormalitiesthat predispose to sinusitis, or have frequent recurrences (greater than three per year). Functional endoscopic sinus surgery has provided a less invasive technique aimed at restoring normal anatomic drainage in the sinuses while preserving mucosal integrity.

PATIENT EDUCATION

Patients should understand that nasal congestion and frontal headaches are much more commonly caused by viral upper respiratory infections and allergic or vasomotor rhinitis than by true sinusitis. Nevertheless, decongestants are indicated in all these conditions to promote sinus drainage and prevent purulent sinusitis. The patient with recurrent symptoms should learn to recognize them and begin decongestant therapy, but the decision to begin antibiotics should be reserved by the physician. When antibiotics are prescribed, patients must be instructed to complete the entire course of therapy, because partial treatment will encourage the development of resistant organisms.

TREATMENT RECOMMENDATIONS

Acute Sinusitis

- Attend to any underlying etiologies, such as *allergic rhinitis* (see Chapter 222).
- Begin antibiotic treatment with *amoxicillir* (500 mg orally three times a day) or *TMS* (TMS-DS, 160/800 mg twice daily) unless the patient is immunocompromised or there is a known highly clinically resistant organism in high prevalence in the community. If the patient is allergic to both penicillin and sulfa, consider doxycycline.
- Consider concurrent use of a sympathomimetic decongestant (e.g., sustained-release *pseudoephedrine* 120 mg twice daily). Avoid routine use of decongestants that contain antihistamines because of their drying effect, which thickens secretions and risks aggravating obstruction.
- Treat with antibiotics for 7 to 14 days, supplemented by decongestants and systemic and topical hydration (e.g., humidification, isotonic saline nasal spray). Continue program for an additional 5 to 7 days if response is not complete.
- Consider a broad-spectrum penicillinase-resistant antibiotic agent (e.g., *amoxicillin-clavulanate, 500/125 mg three times a day; cefuroxime, 250 to 500 mg twice daily; loracarbef, 200 to 400 mg twice daily; azithromycin 500 mg day 1 followed by 250 mg every day on days 2 through 5; clarithromycin 500 mg twice daily; levofloxacin 500 mg/a*) only if there is a known highly clinically resistant organism in high prevalence in the community or if the patient fails an initial 2-week course of first-line antibiotic therapy with amoxicillin or TMS.
- Consider referral to an otolaryngologist when the patient fails two courses of antibiotics, has a suspected anatomic abnormality that predisposes to sinusitis, or has frequent recurrences (more than three per year).
- Obtain dental referral when there is suspicion of an eroding tooth abscess and add anaerobic antibiotic coverage (e.g., clindamycin or metronidazole).

Chronic Sinusitis

- Refer to ear, nose, and throat specialist for identification and definitive correction of the causative pathology.
- In the meantime, treat with a broad-spectrum penicillinase-resistant antibiotic (e.g., amoxicillin/clavulanate 875/125 mg twice daily).

CHAPTER 220 APPROACH TO THE PATIENT WITH PHARYNGITIS

WILLIAM A. KORMOS

INTRODUCTION

A wide variety of organisms may be responsible for pharyngitis, ranging from viruses and streptococci to gonococci and candida. The most common concern is infection due to group A b-hemolytic strep, *Streptococcus pyogenes*, because of the associated yet totally preventable risk of rheumatic fever (see Chapter 17). Because there is no single clinical feature pathognomonic for b-hemolytic strep infection, diagnosis requires attention to a host of clinical parameters complemented by timely judicious testing. The objectives are to promptly identify and treat patients with *S. pyogenes* infection and to avoid delay of therapy, inconvenience, expense, and unnecessary antibiotic exposure. Effective management of sore throat also requires an awareness of the full spectrum of etiologies and possible complications.

PATHOPHYSIOLOGY AND CLINICAL PRESENTATION

Respiratory viruses, chlamydia, mycoplasma, and streptococci account for most sore throats in adults. A host of other bacteria, viruses, fungi, and spirochetes have also been identified as etiologic agents. Allergy, inhalation of irritant gases, gastroesophageal reflux, and sleep apnea are among the noninfectious causes.

Group A b-Hemolytic Strep Infection. *S. pyogenes* infection accounts for 5% to 38% of sore throats in adults who are subjected to throat culture. The onset of discomfort is typically acute, with difficulty swallowing often noted. Pharyngeal erythema, exudate, cervical adenopathy, and fever greater than 101°F (38.3°C) are common but by no means pathognomonic. Children with "strep throat" exhibit exudate and high fever with greater frequency than do adults with the same disease. Cough, rhinorrhea, and other symptoms of upper respiratory infection are reported in less than 25% and suggest the presence of another etiology. About one fourth of adult patients give a history of recent exposure to streptococcal infection. The pharyngitis is self-limited; symptoms usually resolve within 7 to 10 days. Antibiotic therapy decreases severity and duration of symptoms.

Complications. Suppurative complications of streptococcal pharyngitis are uncommon in the setting of antibiotic use, but they are important and require attention. In *peritonsillar cellulitis*, the tonsils become edematous and inflamed. One or both tonsils may be involved. A grayish white exudate forms in conjunction with high fever, rigors, and leukocytosis. *Peritonsillar abscess* may ensue, with a fluctuant mass palpable. Other suppurative complications include retropharyngeal and parapharyngeal space infections. *Scarlet fever* is a rare complication of strep infection in adults. It results from infection with a toxigenic strain of *S. pyogenes*.

Acute rheumatic fever is the most important nonsuppurative complication. Although its incidence has declined dramatically over the past 40 years, recent epidemics in the 1980s have raised concern about the reemergence of this disease. The complication appears most frequently among children aged 5 to 15, but about 15% of hospitalized patients with rheumatic fever are over the age of 18. The chances of developing rheumatic fever increase with length of time that the organism persists in the pharynx and with the intensity of the immunologic response.

Acute glomerulonephritis is another nonsuppurative complication. Unlike rheumatic fever, it does not seem to be preventable by means of antibiotic therapy.

Other Streptococci. Groups C and G streptococci can cause pharyngitis, in some populations with a frequency approaching that of group A strep. Suppurative complications are rare, and rheumatic fever and glomerulonephritis never follow.

Viruses. Respiratory viruses, including adenovirus, parainfluenza virus, and rhinovirus, are the most common causes of sore throat. Pharyngitis can be the only manifestation of illness or may be accompanied by conjunctivitis, cough, sputum production, rhinitis, and systemic symptoms. Pharyngeal erythema, exudates, tonsillar enlargement, and cervical adenopathy are often present but with less frequency than in streptococcal disease.

Epstein-Barr virus is the agent responsible for *infectious mononucleosis* and is the cause of sore throat in 5% to 10% of young adults. Prodromal symptoms include malaise, headache, and fatigue followed by fever, sore throat, and cervical lymphadenopathy. Sore throat is the most common feature. The pharynx shows lymphoid hyperplasia, erythema, and edema. About half of patients develop tonsillar exudates, and about a third of patients will have petechiae at the junction of the hard and soft palate. Both anterior and posterior cervical adenopathy may develop; generalized adenopathy often follows. Splenomegaly is noted in about half of cases, and hepatomegaly and tenderness are present in about 10%. Clinical hepatitis sometimes ensues. A faint maculopapular rash and transient supraorbital edema occasionally appear. IgM antibody is the first to appear, followed by IgG antibody. Despite a transient flurry of interest about the possibility of Epstein-Barr virus infection causing chronic fatigue syndrome, confirmatory evidence failed to materialize (see Chapter 8).

Herpes Simplex Virus and Coxsackie A Virus. Herpes simplex virus and Coxsackie A virus are other causes of pharyngitis. Herpes infection may mimic streptococcal infection with an exudative pharyngitis; shallow ulcers on the palate are characteristic. Coxsackie A infection (herpangina) is characterized by vesicles and ulcers on the tonsillar pillars and soft palate.

Other Organisms. In patients engaging in orogenital sexual activity, *gonococci* can lead to sore throat, pharyngeal exudate, and lymphadenopathy but more often results in asymptomatic colonization of the pharynx. In rare instances, bacteremia may result (see Chapter 137). *Haemophilus influenzae* is a rare cause of pharyngitis in adults, but the infection can be extremely painful and complicated by epiglottitis with life-threatening airway obstruction.

Chlamydia pneumoniae and Mycoplasma pneumoniae. Chlamydia pneumoniae and Mycoplasma pneumoniae may account for a surprising percentage of patients presenting with pharyngitis, based on serologic evidence of infection, although the clinical significance of this finding remains unclear. The diagnosis of *M. pneumoniae* is rarely made clinically in the absence of pneumonitis.

Corynebacterium hemolyticum. Corynebacterium hemolyticum can cause pharyngitis and scarletiniform rash, particularly in teenagers and young adults. Administration of penicillin or erythromycin produces rapid improvement.

Meningococci. Meningococci are found in the pharynx in 5% to 15% of healthy people. Although sore throat may be a prodromal symptom of meningococcemia, isolated pharyngitis due to meningococcal infection is rare. Most instances of positive pharyngeal cultures for meningococcus represent asymptomatic colonization.

Corynebacterium diphtheriae. Corynebacterium diphtheriae causes outbreaks of diphtheria in unimmunized populations. The infection is characterized by development of an adherent whitish blue pharyngeal exudate ("pseudomembrane") that covers the pharynx and causes bleeding if removal is attempted.

Pneumococci and Staphylococci. Pneumococci and Staphylococci commonly reside in the nasopharynx and can cause severe disease in other parts of the respiratory tract. However, they do not cause pharyngitis except under the most unusual circumstances. When these bacterial species are cultured from the pharynx in both symptomatic and asymptomatic individuals, colonization, not causation, by these organisms should be suspected. However, mixed infections with normal mouth flora do occur in debilitated patients.

Fusobacteria. Fusobacteria and *spirochetes* can cause gingivitis ("trenchmouth") or necrotic tonsillar ulcers ("Vincent's angina"). Patients present with foul breath, pain, pharyngeal exudate, and a dirty gray membranous inflammation, which bleeds easily. A similar combination of bacteria and spirochetes can produce an extremely serious invasive gangrene of the mouth known as cancrum oris. This process occurs only in malnourished infants or patients with advanced malignancy and immunosuppression and is, fortunately, rare. *Treponema pallidum* can cause pharyngitis as part of primary or secondary syphilis. The diagnosis requires a high

index of suspicion and serologic confirmation.

Yersinia enterocolitica. Yersinia enterocolitica infection typically presents as enterocolitis, but occasionally in adults it presents as pharyngitis in the absence of enteritis. Fatalities have been reported.

Candida albicans. Candida albicans, present in the normal mouth flora, can produce pharyngitis if antibiotics, immunosuppressive agents, or debilitating illness upsets microbial interactions or host defenses. Oropharyngeal moniliasis (thrush) can be painful and is characterized by a cheesy white exudate, which can be scraped off to demonstrate yeast forms by smear and culture. Oral moniliasis may be the first symptomatic manifestation of HIV infection (see Chapter 13).

WORKUP

The first task is to attempt a clinical estimate of the risk of *S. pyogenes* infection. Often, this is done in a preliminary way over the telephone, which places a premium on risk stratification by historical features.

History. No single symptom or historical feature is diagnostic of group A b-hemolytic strep infection. Consequently, investigators have sought to identify symptoms that are at least independent predictors of strep infection and to see how clusters of such symptoms perform for triaging.

One such triaging cluster uses presence of *fever* and *difficulty swallowing* in support of the diagnosis of strep infection and *cough* as a negating factor. A score is assigned to each factor based on severity (0 through 3). The final score is derived by subtracting the score for cough from those for fever and difficulty swallowing. Designating a score of 2 or more as "positive" for a diagnosis of *S. pyogenes* infection, the system has a sensitivity of 85% and a specificity of 41.5%. In a pharyngitis population with the usual prevalence of strep (10% of sore throats due to *S. pyogenes*), a score of 6 (the highest possible score) would produce a positive predictive value of 34% for strep infection; a score of 23 (the lowest possible score) would reduce the risk to 1%. In a pharyngitis population with a high strep prevalence (prevalence, 34%), a score of 6 would indicate a 70% chance of strep infection; a score of 23 would reduce the risk to 3%. Although far from perfect, such a scheme may help in deciding who should come in for further evaluation.

History can help determine prevalence and risk from strep infection by inquiring into *exposure* to family members with current documented strep pharyngitis and any history of prior *rheumatic fever*. Other factors found predictive of strep infection that might be elicited over the telephone include *positive throat culture* in the preceding year, tender anterior cervical *adenopathy, temperature* higher than 101°F, and absence of rhinorrhea and itchy eyes.

Regarding other sore throat etiologies and complications, one should ask about orogenital sexual contact, concurrent steroid or immunosuppressive therapy, and any dyspnea.

Physical Examination. Several physical findings when considered collectively can help assess probability of group A b-hemolytic streptococcal infection. The cluster of marked *tonsillar exudate*, anterior *cervical adenopathy*, and temperature greater than *101°F* provides a positive predictive value of about 30% in pharyngitis populations with 10% prevalence of strep infection. The absence of these three features in addition to the presence of cough reduces the probability to 3%.

Examination of the pharynx is useful for identifying a less common cause of pharyngitis such as thrush, characterized by its white cheesy exudate; gingivitis or necrotic tonsillar ulcers suggest fusobacteria and spirochetes. Associated physical findings, such as a viral exanthem, conjunctivitis, petechiae, generalized lymphadenopathy, splenomegaly, or hepatic tenderness, may provide important clues to etiology. A "sandpaper" erythematous rash with accentuation in the groin and axillae is associated with scarlet fever. Patients with severe dysphagia or dyspnea require urgent evaluation to exclude airway obstruction. If epiglottitis is suspected, the airway should not be instrumented.

Laboratory Study for Suspected Strep Pharyngitis. Prompt diagnosis and treatment of *S. pyogenes* infection has been greatly facilitated by the advent of rapid strep-antigen testing. Throat culture has been relegated to a secondary role.

Rapid Strep-Antigen Testing. Office identification of group A streptococcal pharyngitis can be achieved by taking a swab of the posterior pharynx and subjecting the specimen to rapid strep-antigen testing. For most commercially available preparations, sensitivity ranges from 85% to 90% and specificity from 95% to 99%. Small numbers of organisms are less likely to be detected. Technique for obtaining the sample is similar to that for a throat culture and includes swabbing both tonsils and posterior pharynx.

Decision-analysis study finds that rapid strep-antigen testing followed by treatment is the optimal approach to workup when the patient's pretest probability for strep infection is between 1% and 50% (which is the case for most patients). Pharyngitis patients at high risk for rheumatic fever (i.e., those with a history of rheumatic fever) and those with a very high probability of strep infection (e.g., persons in a closed population experiencing an epidemic of streptococcal pharyngitis) can forgo testing and be treated directly.

Throat Culture. Culturing a retropharyngeal swab remains the standard for identification of streptococcal pharyngitis and has a high sensitivity (90% to 95%) when performed correctly. A culture should be obtained when rapid antigen testing is negative yet clinical suspicion remains high. Patients with typical symptoms and signs of a viral upper respiratory infection and no historical or physical examination evidence suggestive of streptococcal infection do not need a throat culture. Some cost-effectiveness studies find throat culture to be the best approach to uniform management of all pharyngitis patients, but as noted earlier, better results can be achieved by using pretest probability to customize one's approach to the individual patient. **Updated: 08/12/03**

Repeat culture after antibiotic treatment is not indicated because most positive cultures after treatment represent streptococcal carriers and not true infection. However, repeat culture should be performed in the patient with a history of rheumatic fever and may be considered during outbreaks of strep throat, especially when reinfection by close contacts is suspected.

In addition to the time required to obtain a result, an important shortcoming of throat culture is difficulty differentiating infection from colonization. As many as 20% to 30% of patients may be carriers. Definitive identification of significant infection with risk of rheumatic fever necessitates *serologic testing* for an antibody response. Such testing is of little practical use because results do not become available in time to be of help.

Laboratory Study for Other Etiologies. Laboratory testing is indicated when the result will have an impact on management. For example, viral pharyngitis due to respiratory pathogens is essentially a clinical diagnosis and requires no laboratory investigation. On the other hand, the patient with sore throat and diffuse lymphadenopathy, splenomegaly, and pharyngeal petechiae deserves evaluation for infectious mononucleosis. A *heterophile antibody* is a useful confirmatory test, provided there is no prior history of infectious mononucleosis. It may take as long as 3 weeks for the heterophile to become positive, necessitating a repeat test in a few weeks if it is initially negative. Alternatively, one can check serology for antibodies to Epstein-Barr virus. IgM antibodies can be demonstrated during the second week of illness, replaced later by IgG antibodies. Heterophile-negative mononucleosis may be due to cytomegalovirus infection.

The patient with a history of orogenital contact who is suspected of having possible gonococcal infection should have a throat swab plated onto *Thayer-Martin media* (see Chapter 137). Suspected candidal infection can be confirmed by scraping off the exudate and examining a *KOH prep* for yeast forms.

PRINCIPLES OF MANAGEMENT AND THERAPEUTIC RECOMMENDATIONS

Suspected *S. pyogenes* Infection

Rationale for Treatment. The reasons for treating strep infection are to speed symptomatic relief and prevent rheumatic fever, peritonsillar or retropharyngeal abscess, and spread of streptococcal infection. Rheumatic fever can be prevented by prompt eradication of *S. pyogenes* from the throat. The attack rate for rheumatic fever is reduced by over 90% if antibiotic therapy is instituted within a week of the onset of sore throat. However, the efficacy of prophylactic therapy is substantially reduced if there is a marked delay in initiating treatment. Starting antibiotics 2 weeks after sore throat is first noted is associated with a reduction in attack rate of only 67%, and delaying treatment until 3 weeks into the illness provides no more than a 40% reduction in attack rate.

Treatment Strategies. There are several approaches to treatment of pharyngitis. The choice depends on the probability of strep infection, the likelihood of patient

compliance, the chance of an adverse reaction to antibiotics, and the benefits of treating immediately versus waiting for culture results.

Immediate Treatment without Prior Testing. Pharyngitis patients with a *history of rheumatic fever* and those who are symptomatic and have a *household member* with a documented group A b-streptococcal infection should receive immediate treatment without need for prior testing or even an office visit. High-risk patients who have a prior history of rheumatic fever might already be on prophylactic therapy (see Chapter 17). Patients with a strongly suggestive clinical presentation (e.g., exudative pharyngitis, temperature higher than 101°F, tender bilateral anterior cervical adenopathy, and no rhinorrhea or cough) might also be candidates for empiric antibiotic therapy.

Antigen Testing Followed by Treatment of Positives. In most pharyngitis patients with a low to intermediate probability of strep infection, the preferred approach, as noted above, is rapid strep-antigen testing followed by treatment of positives. Throat culturing followed by treatment of a positive result is reserved for the patient with a good clinical story (two or more predictive factors) but a negative rapid antigen test.

Antibiotic Program. To be effective, antibiotic therapy must completely eradicate the streptococcus from the pharynx. This can be achieved by a single intramuscular injection of 1.2 million units of *benzathine penicillin* or a 10-day course of oral *phenoxymethyl penicillin* (250 mg three or four times a day). The advantages of the intramuscular route are the certainty of full treatment and convenience. Its major disadvantage is a 5- to 10-fold increase in the incidence of serious allergic reactions to penicillin. In the patient allergic to penicillin, oral *erythromycin* (250 mg four times a day for 10 days) is an effective alternative. Some antibiotics frequently prescribed for strep pharyngitis (e.g., oral cephalosporins and azithromycin) are not recommended because they are more expensive and/or have a less focused spectrum of action than penicillin or erythromycin. **Updated: 10/19/01**

Recurrent Infection. The patient who returns with recurrent pharyngitis and a positive strep culture should be examined for alternative possibilities besides reinfection. The patient may have been *noncompliant* with oral antibiotics, and benzathine penicillin may be an appropriate option. Alternatively, the patient may be a carrier for group A streptococcus and have a concurrent *noninfectious etiology* for a sore throat, such as allergic rhinitis. Appropriate treatment depends on the underlying etiology. Tonsillectomy, once quite popular in children, remains unproven in adults to reduce recurrent infections or symptoms. Consultation with an ear, nose, and throat specialist may be considered for recalcitrant cases.

Other Types of Pharyngitis

The Meningococcal Carrier State. The meningococcal carrier state sometimes presents a therapeutic dilemma in terms of both selecting patients who actually need treatment and in choosing antibiotics. Carriers should be treated only when there is evidence of active meningococcal disease in household or dormitory contacts. Penicillin will not eradicate the meningococcal carrier state, and because many strains are now sulfonamide resistant, rifampin should be used.

In Gonococcal Pharyngitis. In Gonococcal pharyngitis, the usual treatment with ceftriaxone 250 mg intramuscularly is effective (see Chapter 137). Ciprofloxacin and azithromycin have also demonstrated high cure rates. In the case of *diphtheria, antitoxin* is necessary to prevent myocarditis and peripheral neuritis and is the mainstay of therapy. Both erythromycin and penicillin can eliminate the organism from the upper respiratory tract. In *epiglottitis*, hospitalization is needed. *Necrotizing pharyngitis* due to fusobacterial infection responds to *penicillin* and good nutrition. In other bacterial etiologies of pharyngitis (*Chlamydia, Mycoplasma*), antibiotics have not been shown to improve clinical outcome.

Pharyngeal Candidiasis. Pharyngeal candidiasis in the immunocompromised patient may benefit from gargling with oral *nystatin* suspension (100,000 U/mL), 15 mL swish-and-swallow six times per day, or from using a 10-mg *clotrimazole troche* held in the mouth for 15 to 30 minutes three times each day.

Viral Sore Throats. Viral sore throats are treated symptomatically. Voice rest, humidification, and lozenges or hard candy provide some relief; saline gargling and aspirin or acetaminophen also help.

PATIENT EDUCATION

Many pharyngitis patients telephone in requesting empiric antibiotic therapy for sore throat. They assume antibiotics are effective against most pathogens, desire prompt symptomatic relief, want to avoid the time and expense of testing, and have little fear of an adverse reaction to antibiotics. Much of the unnecessary antibiotic exposure associated with management of pharyngitis is probably due as much to patient insistence as to the physician's desire to do something. However, studies demonstrate that patient satisfaction is not associated with receiving antibiotics but instead correlates with addressing patient concerns and communicating a diagnosis. Unwarranted antibiotic prescriptions also run the risk of "medicalizing" the sore throat, resulting in increased patient visits for future episodes. When the probability of strep infection is deemed too low to warrant testing or treatment (see above), patients should be reassured that the risk is nil and that antibiotics are unlikely to provide any benefit. For the insistent person and the one with an intermediate risk by triage history, an invitation to come in for rapid antigen testing is the most reasonable advice.

The patient who proves to have *S. pyogenes* infection and elects oral antibiotic therapy should be carefully instructed on the risk of rheumatic fever and the importance of completing a full 10-day course of antibiotics. Otherwise, many patients will stop taking the medication when symptoms resolve.

Patients with recurrent strep infections and intact tonsils will ask about tonsillectomy. Reviewing the risks and benefits of tonsillectomy over medical therapy may help them to choose the treatment that best meets their needs.

CHAPTER 221 APPROACH TO THE PATIENT WITH HICCUPS

Hiccup is usually a transient innocuous symptom but when persistent it may become an exhausting and disabling problem. Intractable hiccup has been attributed to a host of metabolic, peridiaphragmatic, neurologic, and psychogenic conditions, but many cases are of unknown etiology. The primary physician should be able to offer the exasperated patient symptomatic relief while conducting a judicious evaluation to determine the source of difficulty.

PATHOPHYSIOLOGY AND CLINICAL PRESENTATIONS

No useful function has been found for the hiccup, which occurs as a result of synchronous clonic spasm of intercostal muscles and diaphragm that causes sudden inspiration followed by prompt closure of the glottis and inhibition of respiratory activity. It is believed to be a reflex. There is debate about whether it is centrally mediated. The afferent pathway is from T10 to T12, and the efferent limb is along the phrenic nerve. During the hiccup, the glottis is closed. Some investigators believe the hiccup is related more to gastrointestinal than to respiratory function. Current understanding of pathophysiology does not yet permit an explanation of how the presumptive etiologies operate to produce the hiccup, although the classic explanation is that it is due to stimulation of the phrenic nerve.

It is often unclear whether the reported causes of hiccup are etiologies or only associations. In a series of 220 cases seen at the Mayo Clinic, men outnumbered women by five to one, and most were in their sixties. Over 90% of the women had no concurrent illness other than an emotional problem, whereas only 7% of men were labeled as having a psychogenic disorder. About 20% of men who experienced hiccup did so after undergoing intraabdominal, intrathoracic, or neurologic surgery. About 25% had a diaphragmatic hernia, another 20% had cerebrovascular disease or another central nervous system (CNS) problem, 5% had a metabolic illness, and in 10% no associated disease or psychiatric problem was identified.

DIFFERENTIAL DIAGNOSIS

The causes of persistent hiccup typically listed are clinical associations and cannot be considered proven etiologies (Table 221.1).

A. Structural Pathology
  1. Pericarditis
  2. Tumor
  3. Subdiaphragmatic abscess
  4. Pneumonia
  5. Pleuritis
  6. Myocardial infarction
  7. Hiatus hernia
  8. Peritonitis
  9. Gastric dilatation
  10. Pancreatitis
  11. Biliary tract disease
  12. Tympanic membrane irritation
  13. Aortic aneurysm
B. Metabolic Disturbances
  1. Uremia
  2. Diabetes
  3. Alcoholism
C. Central Nervous System Disease
  1. Tumor
  2. Infection
  3. Surgery
D. Psychogenic Disease
  1. Hysteria
  2. Anorexia nervosa
  3. Anxiety
*These are not proven etiologies.

Table 221.1. Conditions Associated with Persistent Hiccup [a]

WORKUP

Persistent hiccup that proves refractory to simple measures is an indication for further investigation. Extensive workup is usually not productive, but a check for a previously unsuspected metabolic or subdiaphragmatic process is sometimes rewarding.

History. Questioning should include inquiry into recent abdominal, thoracic, or neurologic surgery, abdominal pain (especially that which radiates to the tip of the shoulder or is worsened by respiration), prior renal disease, excess consumption of alcohol, fever, cough, diabetes, and emotional problems. Also of help is reviewing the various methods that the patient has tried for relief of symptoms. Any neurologic complaints should be noted.

Physical Examination. A temperature determination, a check of the tympanic membranes, percussion of the lungs for evidence of reduced diaphragmatic excursion, and auscultation for signs of an infiltrate, effusion, or pleuritis should be included. The abdomen is examined for distention, organo-megaly, upper abdominal tenderness, and signs of peritonitis. A careful neurologic examination is needed if there is a history of neurologic difficulties.

Laboratory Studies. Patients with an acute bout of hiccups need no laboratory studies, but those with *refractory hiccups* that persist for days need to be evaluated for a pharyngeal, thoracic, diaphragmatic, intraabdominal, CNS, or metabolic/pharmacologic etiology. If a careful physical examination that includes a check of the tympanic membranes, pharynx, chest, heart, abdomen, and CNS is unrevealing, one should obtain a chest x-ray, serum sodium, creatinine, and blood urea nitrogen determinations, and consider a computed tomography of the abdomen, concentrating on the subdiaphragmatic region. If CNS disease is suspected by history or physical examination, a computed tomography or magnetic resonance image may help detect the lesion. Treatment of the underlying etiology is the best means of curing refractory hiccups.

SYMPTOMATIC THERAPY AND INDICATION FOR REFERRAL

For patients with *self-limited* causes of hiccuping, several home remedies are capable of interrupting the reflex arc; others simply suppress it temporarily. *Breathholding* and breathing into a *paper bag* will decrease the frequency of hiccups, but if the underlying stimulus has not disappeared, they usually return after these maneuvers are terminated. Swallowing a teaspoonful of *granulated sugar* works by irritating the pharynx sufficiently to inhibit further hiccuping. A more noxious maneuver is to have the patient put his or her finger into the back of the pharynx and *stimulate the gag reflex*. Drinking from the wrong side of the glass is another gag reflex stimulant. Rubbing the nasopharynx with a cotton swab is sometimes effective. Passage of a *nasogastric tube* causing hypopharyngeal stimulation will usually work if other methods have failed.

When symptoms are *persistent* and the cause remains undiagnosed or untreatable, symptomatic relief becomes an important goal. *Chlorpromazine* in doses of 25 to 50 mg intravenously will often terminate refractory hiccups and can be followed by oral maintenance therapy of 25 mg four times a day. *Metoclopramide* given intravenously, followed by oral therapy (10 mg three times a day), has also proven effective. Atropine and quinidine have been used but with less success. *Phenytoin* and *carbamazepine* are helpful in patients with a CNS etiology.

When all other measures have failed and the hiccups remain disabling, consideration of surgical *infiltration of the phrenic nerve* is appropriate. Fluoroscopy is needed to see if one leaf of the diaphragm is responsible and can be singled out for treatment. In addition, one needs to be sure one leaf is not already paralyzed, a circumstance that would rule out this therapeutic option. The phrenic nerve serving the offending diaphragm is infiltrated with a long-acting anesthetic; if it works but the hiccups return, reinfiltration with alcohol or *crushing* may be necessary. If both leaves of the diaphragm are involved, one phrenic nerve is treated.

In most instances, hiccups will resolve spontaneously or respond at least partially to one of these therapeutic maneuvers.

CHAPTER 222 APPROACH TO THE PATIENT WITH CHRONIC NASAL CONGESTION AND DISCHARGE

It is estimated that 15% to 20% of the population suffer from chronic or recurrent nasal congestion. Allergic rhinitis accounts for most such cases; vasomotor rhinitis, mechanical obstruction, drugs, and abuse of decongestants contribute to others. Much discomfort, absenteeism, and expense result. The primary physician needs to distinguish an allergic etiology from obstruction, inflammation, or vasomotor instability. Proper utilization of allergy testing and effective use of antihistamines, decongestants, and topical corticosteroids are required.

PATHOPHYSIOLOGY AND CLINICAL PRESENTATION

Allergic Rhinitis. In atopic patients, antigen exposure stimulates production of allergen-specific IgE. This IgE attaches to mucosal mast cells. Subsequent exposure to the allergen leads to formation of antigen–IgE complexes on mast cells and basophils. The formation of antigen–antibody complexes triggers an acute-phase *degranulation* reaction, with release of histamine, kinins, prostaglandins, and esterases in concentrations proportional to the intensity of the antigen challenge. Hours later, a late-phase response can be demonstrated in persons with more severe disease, manifested by re-release of mediators (minus prostaglandins); an influx of leukocytes, eosinophils, and mononuclear cells; and increased responsiveness to antigenic and nonantigenic stimuli. With continued allergen exposure, there is heightened mucosal responsiveness due to an increase in the population of mast cells.

In addition to environmental stimuli, genetic factors play a role. Antigen-specific responses are controlled by regulatory genes, and allergic rhinitis is much more common in persons with a positive family history. The relation of allergic rhinitis to reactive lower airway disease (asthma) remains a subject of debate, but it appears that allergic rhinitis is neither a cause nor consequence of it.

Clinical Presentation. Nasal congestion, sneezing, and profuse watery discharge dominate the initial clinical presentation. Itching of the nose, throat, and eyes is common, as is postnasal drip, tearing, and conjunctival injection. Often the nasal mucosa appears pale and edematous. Symptoms typically vary over the course of the day. They are most severe on arising in the morning, lessen in the afternoon, and may worsen again by evening. With continued allergen exposure, there is increased sensitivity both to allergens and to nonallergenic stimuli.

Onset of allergic rhinitis is usually during childhood but may occur at any age. Childhood cases frequently continue into adulthood. Often, the condition improves with time. The condition is *seasonal* when the antigen is a pollen ("hay fever") and *perennial* when the allergens are dusts, molds, or animal danders. Patients living in the northern half of the United States who are sensitive to tree pollen will become symptomatic in late March and early April and those sensitive to grasses, in mid-May to late June. Patients affected by ragweed and other summer weeds experience difficulty in late August until the first frost. Patients with seasonal allergic rhinitis outnumber those with perennial complaints by a ratio of about 10 to 1. Individuals may be allergic to a number of antigens.

In some instances, the patient has all the earmarks of allergic rhinitis but no evidence of IgE mediation, and skin tests for inhaled allergens are negative. Such patients have been designated as having *nonallergic rhinitis*, even though their nasal secretions often contain large numbers of eosinophils and they respond to corticosteroids.

Vasomotor Rhinitis. The pathophysiology is poorly understood but believed to involve abnormal autonomic responsiveness and vascular dilatation of the submucosal vessels. IgE levels are normal, and the number of eosinophils in nasal secretions is usually, but not always, normal. Abnormal autonomic reactivity is believed to account for the nasal stuffiness or rhinorrhea sometimes occurring with *emotional upset* and *sexual arousal*.

The condition may mimic perennial allergic rhinitis and is believed by some clinicians to be a diagnosis of exclusion when no allergen is identified. Others consider the condition a readily distinguishable entity characterized by a normal-appearing nasal mucosa and persistent nasal stuffiness without itching that is worsened by changes in ambient temperature and humidity. Although congestion is the most prominent symptom, a discharge may also be present. Sneezing is relatively absent.

Drugs. Overuse of topical *nasal decongestants* (e.g., oxy-metazoline, phenylpropanolamine, pseudoephedrine) can result in a worsening of symptoms (*rhinitis medicamentosa*). After more than 3 days of continuous use, response to these agents becomes blunted (tachyphylaxis), leading to increased use, often on an hourly basis. Cessation results in severe rebound nasal congestion presumably due to marked reflex vasodilatation. The nasal mucosa appears erythematous. The problem resolves in 2 to 3 weeks if topical decongestants are stopped. a-Adrenergic blockers can aggravate preexisting rhinitis and cause mild nasal congestion in normal patients.

Cocaine abuse is another important cause of drug-induced nasal congestion and discharge. Being a potent sympatho-mimetic, the pathophysiology is analogous to that of nasal decongestant abuse. Recurrent nasal use leads to ischemic mucosal injury, atrophy, and tell-tale septal perforation.

Hormonal Etiologies. *Hypothyroidism* and *pregnancy* may cause the turbinates to become pale and edematous, leading to nasal congestion. Hypothyroidism may otherwise be subclinical save for the chronic nasal obstruction. Symptoms resolve with correction of the hypothyroidism or with delivery.

Mechanical Obstruction. Unilateral congestion, discharge, and recurrent episodes of sinusitis are characteristic of mechanical obstruction due to tumor, polyp, or deviated septum. *Neoplasm* is rare but is suggested by a blood-tinged discharge. *Polyps* can occur in association with allergic and vasomotor rhinitis, chronic sinusitis, aspirin-induced asthma, cystic fibrosis, and drug use. The mechanism of formation is unknown. Polyps move freely because they are pedunculated and nontender and appear as soft, pale gray, smooth structures. Patients with asthma and nasal polyps are often hypersensitive to aspirin. Polyps do not regress spontaneously and may become large or multiple, causing considerable obstruction. A *deviated septum* is sometimes the source of obstructive symptoms. Most are developmental and not traumatic in origin. Associated sinus occlusion is rare.

Obstruction due to crusting is seen with *atrophic rhinitis*. The condition is of unknown etiology, appears mostly in women, and is characterized by dry atrophic nasal turbinates, mucosal crusts, and a foul or fetid greenish discharge referred to as ozena. The purulent discharge is believed due to secondary infection.

Chronic Inflammatory Disease. *Midline granuloma*, an uncommon illness of unknown etiology, causes ulcerative destruction of upper respiratory tract structures and may present as nasal stuffiness, crusting, and granulations. Steady progression leads to ulcers of the nasal septum. Most patients are over 50, many with a history of allergic rhinitis. *Wegener's granulomatosis*, an immune-mediated disease of middle-aged persons, may have a similar insidious presentation with nasal obstruction, rhinorrhea, or chronic sinusitis. Necrotizing granulomatous lesions and vasculitis are found in the upper and lower airway. *Sarcoidosis* may present as bilateral nasal obstruction (see Chapter 51).

DIFFERENTIAL DIAGNOSIS

The causes of nasal congestion and discharge can be organized pathophysiologically and are listed in Table 222.1.

Table 222.1. Important Causes of Chronic or Recurrent Nasal Congestion

WORKUP

Although it is important to rule out mechanical obstruction, chronic inflammatory disease, and drug-induced illness, the most common diagnostic task is to distinguish allergic from vasomotor disease.

History. The *timing* of symptoms can be helpful diagnostically. Nasal congestion that coincides with periods of pollination is virtually diagnostic of seasonal allergic rhinitis. Continuous waxing and waning of symptoms throughout the year, with exacerbations during the hay fever season, suggest a combination of perennial and seasonal allergic disease. When symptoms occur chronically without respect to seasons, one may be dealing with vasomotor rhinitis, perennial allergy, mechanical obstruction, or a chronic inflammatory condition. Perennial rhinitis is a possibility when the patient reports frequent "colds."

Aggravating and alleviating factors should be noted. Patients bothered by dusts are generally atopic, whereas those whose symptoms are aggravated by quick changes in temperature, emotion, or drugs fall into the vasomotor category. Use of antihypertensive agents and topical nasal decongestants needs to be explored, as does exposure to fur-bearing animals, feathers, other possible sources of animal danders, or chemical irritants. Pollutants are often more irritating to allergic patients but may also cause symptoms in nonatopic people.

Associated symptoms of potential importance include fever and a purulent nasal discharge, suggestive of an infectious etiology. A cold is the most likely cause of acute discharge, but chronic discharge that is fetid, foul smelling, and accompanied by crusting indicates secondary infection as in atrophic rhinitis, Wegener's granulomatosis, and midline granuloma. Bloody discharge and unilateral obstruction suggest tumor. Mechanical obstructions are often unilateral as well. The presence of asthma or aspirin sensitivity increases the likelihood of nasal polyps. Sneezing and postnasal drip are nonspecific and of little help in distinguishing among etiologies, but associated itching of the eyes, tearing, and conjunctival redness suggest an allergic mechanism.

Epidemiologic data need to be considered. Onset in childhood is typical of allergic disease, but onset of symptoms during adulthood does not rule out atopy. When chronic progressive nasal congestion develops in a middle-aged patient, particularly a woman, one must consider atrophic rhinitis or one of the necrotizing inflammatory diseases. The allergy histories of the patient's parents should be ascertained, because a positive family history strongly suggests allergic disease.

Drug use and *concurrent conditions* are important to review, including abuse of cocaine or nasal decongestants, hypothyroidism, sarcoidosis, and pregnancy.

Physical Examination. The nasal mucous membranes are inspected for erythema, pallor, atrophy, edema, crusting, and discharge. The presence of polyps, erosions, and septal perforations or deviations should be noted. A nasal speculum markedly improves visualization of the nasal cavity and should be used in every examination. Some findings are nonspecific. For example, a pale boggy appearance to the mucosa is allegedly a classic sign of allergic disease, but erythema sometimes occurs in allergy and its presence certainly does not rule it out.

Examination of the eyes for conjunctival erythema, tearing, photophobia, and papillary edema of the lids provides supportive evidence of an allergic mechanism. Transillumination and palpation of the sinuses, pharyngeal examination for erythema and discharge, a look in the ears for evidence of otitis, cervical node examination for adenopathy, and auscultation of the chest for wheezes complete the physical examination.

Laboratory Studies. Antigen challenge is sometimes helpful when the differentiation between allergic and nonallergic disease remains difficult. In vivo and in vitro methods are used. When history provides ready identification of allergens, there is little need for skin testing, but if drastic environmental measures are being contemplated, documentation of the specific allergens is indicated.

In Vivo Testing for Allergen-specific IgE (Skin Prick Testing). The procedure of choice for detection of allergen-specific IgE continues to be skin testing. For environmental allergens, an *epicutaneous (needle prick)* test is used. (*Intradermal* injection should not be used because it generates a high frequency of false-positives and risks severe systemic reactions.) Preparations of commonly inhaled allergens (dusts, molds, animal danders, and local pollens) are introduced by needle prick into the skin. A positive test is a wheal and flare reaction within 20 minutes. A positive reaction does not prove causation, only that there is sensitization to the allergen and allergen-specific IgE present. Correlation with history and physical examination is needed to establish an etiologic role for the antigen.

Antihistamines must be omitted for 12 to 24 hours before testing to avoid a false-negative result. Dermatographism is a common cause of false-positive results, occurring in 15% to 20% of the population and necessitating use of a saline control injection. Eczema and concurrent use of antipsychotic drugs can also interfere with interpretation. The size of the wheal and flare correlates well with the level of allergen-specific IgE. However, allergen preparations remain to be standardized, to avoid impairing interpretation and comparison of results.

Although many of the allergens tested by skin prick are inhaled, *inhalation challenge* remains predominantly a research method, used to evaluate nasal resistance after mucosal exposure.

In Vitro Testing for IgE and Other Markers of Allergy. When skin prick testing is not available, serum tests can contribute to diagnosis. Determination of total *serum IgE* is helpful if the level is markedly elevated, but test sensitivity is low because some cases of allergic rhinitis are not associated with high serum concentrations. The same is true for the *total eosinophil count*. A count at the time of an exacerbation that is in excess of 500 cells/mm^3 is suggestive of an allergic etiology, but the absence of peripheral eosinophilia does not rule out allergic rhinitis. *Radio allergoabsorbent testing* (RAST) is an in vitro means of identifying and quantitating an allergen-specific IgE. The test involves adding the patient's serum to a purified allergen absorbed to an inert particle. If the serum contains high concentrations of specific IgE antibodies to the allergen, it will give a positive test. The shortcomings of radioallergosorbent testing are its expense and only modest sensitivity (less than that of skin testing); however, specificity is high. The test is best reserved for patients whose skin tests are equivocal and for those who cannot undergo skin testing. *IgE immunoassays* represent an alternative in vitro means of testing for specific IgE antibodies; a positive test that correlates with symptoms on natural exposure is often sufficient grounds for initiating environmental therapy.

Other Studies. Examining *smears of nasal secretions* for eosinophils is of limited specificity because eosinophils may be present in both vasomotor and allergic rhinitis, but an abundance is more suggestive of an allergic etiology. The smears can be informative if infection is in question, because neutrophils should be present in large numbers. *Sinus films* are sometimes helpful if purulent discharge, sinus opacification, or tenderness suggests an accompanying sinusitis; however, a clinical diagnosis is usually sufficient for initiating therapy (see Chapter 219).

PRINCIPLES OF MANAGEMENT AND PATIENT EDUCATION

Allergic Rhinitis

The major components of the treatment include avoidance of responsible allergens (so-called environmental therapy), antihistamines and sympathomimetics for quick

symptomatic relief, topical corticosteroids or cromolyn for improved prophylaxis and control, and immunotherapy for control and prophylaxis in refractory cases.

Avoidance (Environmental) Measures. The appropriate avoidance procedures are a function of the responsible allergens and differ for seasonal and perennial disease.

Seasonal Allergic Rhinitis. Avoidance of long walks in the woods during the pollination period and staying indoors with the windows closed when symptoms are severe and the pollen count is high (e.g., hot, windy, sunny days) helps reduce allergen exposure. Some patients find air conditioners helpful, but its filter does little to remove pollen from the air. Air conditioning simply makes it more tolerable to stay indoors with the windows closed on a hot day. The outside air intake on the air conditioner should be kept closed to avoid bringing in more pollinated air. If ragweed is a problem, daisies, dahlias, and chrysanthemums should not be kept indoors. Preventing accumulation of excess dust in the bedroom and avoiding irritants such as tobacco smoke, chemical vapors, and strong perfumes lessen symptoms.

Perennial Allergic Rhinitis. Control of perennial disease requires particular attention to allergens in the home, but recommendations should be practical. Cleaning the house and especially the bedroom with a damp mop two to three times a week will reduce dust. Feather pillows should be replaced by Dacron or polyester ones, and mattresses should be covered with an elastic fabric casing. Use of special dust-impermeable covers for mattresses, pillows, and blankets does not appear to be any more effective than simpler, less expensive environmental measures. Areas where mold can collect, such as piles of old newspapers or furniture in a damp basement, should be cleaned up. A dehumidifier may prevent mold growth. Throwing out carpets and draperies is excessive, but new furnishings made of synthetic fabrics are preferable to cotton and wool to minimize dust collection. Humidification of air in winter also helps reduce dusts. Patients allergic to molds should avoid having African violets and geraniums in the home. No new fur-bearing pets should be obtained. Most pets usually have to be removed from the home entirely if symptoms are disabling. Simply keeping the pet out of the bedroom does not help sufficiently because the dander circulates in the air throughout the house.

Updated: 07/21/03

Pharmacotherapy. Patients who find allergen avoidance impractical or ineffective often request medication. The commonly used agents include oral antihistamines, which block mast-cell activation and the effects of histamine on end organs; inhaled cromolyn sodium and its analogues, which block degranulation of mast cells and basophils; topical cortico-steroids, which inhibit cytokine production, mast-cell proliferation, and other inflammatory mediators; and sympathomimetics, which decongest by means of vasoconstriction.

Antihistamines. The *first-generation* H_1-blockers (e.g., *chlorpheniramine, diphenhydramine, clemastine*) provide adequate control of mild-to-moderate symptoms, with itching, sneezing, rhinorrhea, and conjunctival irritation responding best, but nasal congestion often persisting. Bothersome sedation can be a problem in up to 15% of users, and some degree of psychomotor impairment can be demonstrated in most. *Second-generation* H_1-blockers (e.g., *loratadine, fexofenadine*) are less sedating and less inhibitory of psychomotor function because their protein-bound lipophobic structure prevents their crossing the blood–brain barrier. They also have little anticholinergic activity and thus avoid the annoying side effects of dry mouth and constipation sometimes associated with the use of first-generation agents. However, they are no more effective than first-generation antihistamines.

Rapid *absorption* occurs after oral intake on an empty stomach, with onset of action within 1 to 2 hours. Intake with food may slow absorption substantially. *Duration* of action ranges from 3 to 4 hours for nonsustained formulations of first-generation preparations to 12 hours for sustained-release preparations and 12 to 24 hours for second-generation H_1-blockers.

Antihistamine *cost* has become a major concern in an era of rapidly rising medical expenses. The second-generation antihistamines are extremely expensive, costing 20 to 45 times more than chlorpheniramine and as much as 7 times more than nasal steroids (Table 222.2). Demand for second-generation H_1-blockers has been greatly stimulated by direct advertising to patients. Approaches to *cost containment* in treatment of allergic rhinitis include

Table 222.2. Cost and Convenience of Drugs for Allergic Rhinitis

- Starting with a first-generation antihistamine and switching to a nonsedating preparation only if daytime sedation becomes a problem (tolerance to sedation commonly develops);
- Substituting an inexpensive first-generation preparation for the nighttime dose of a twice daily second-generation preparation;
- Prescribing the least expensive second-generation preparation (providing a 20% reduction in cost);
- Prescribing a nasal steroid preparation instead (see below).

Aside from sedation and anticholinergic effects, the first-generation H_1-blockers are well tolerated, as are most second-generation H_1-blockers. When prescribing daytime use of a first-generation agent, it is important to keep in mind that some degree of *psychomotor impairment* may occur even without noticeable *sedation*, an especially important consideration in persons who operate a motor vehicle, heavy equipment, or machinery. Reports of fatal *ventricular arrhythmias* (e.g., torsades de pointes) emerged with use of two second-generation agents (*terfenadine and astemizole*), leading to their withdrawal from the market. The episodes were related to drug-induced QT interval prolongation and occurred in situations that exacerbate prolongation of the QT interval (e.g., use of quinidine, disopyramide, or class IC antiarrhythmics; hypomagnesemia, hypokalemia) or interfere with hepatic antihistamine metabolism (e.g., concurrent use of antifungals or macrolide antibiotics). Fexofenadine, cetirizine, and loratadine do not appear to confer the same degree of risk for QT prolongation and ventricular dysrhythmias.

A topically active antihistamine (*azelastine*) has been developed for use as a *nasal spray*. About 40% of the nasal spray is absorbed systemically. Although similar in efficacy to other antihistamines, the drug's side effects (somnolence, bitter taste) and high cost make it less desirable than oral nonsedating antihistamines and inhaled steroids.

Sympathomimetics. Patients still bothered by marked nasal congestion despite antihistamine use may benefit from concurrent treatment with an oral sympathomimetic (e.g., pseudoephedrine). The vasoconstrictive action of adrenergic agents can help reduce edema and secretions and counter the sedative action of antihistamines. These properties make oral sympatho-mimetics a useful component in over-the-counter decongestant formulations, often in combination with an antihistamine such as chlorpheniramine. All sympathomimetics are effective decongestants, but those with some b activity in addition to their vasoconstrictor a-adrenergic action (e.g., *ephedrine, pseudoephedrine*) are preferred when drowsiness is a problem. *Phenylpropanolamine* has predominantly a activity. A typical regimen is pseudoephedrine, 60 mg, every 4-6 hours; lower doses may suffice in mild cases.

The addition of sympathomimetic therapy may provoke bothersome side effects (*headache, palpitations, nervousness*) or trigger harmful cardiovascular effects (e.g., *elevated blood pressure, increased heart rate*). Use, especially if continuous, in patients with hypertension, coronary artery disease, or heart failure is inadvisable. Empirical trials of various antihistamines and decongestants are often necessary to select the best agent(s) and dose(s). Combination preparations are convenient if the fixed doses match the doses needed; these preparations should not be used as initial therapy. Combination preparations containing a first-generation antihistamine and a sympathomimetic are available without prescription and popular with many patients, who find the combination less sedating and more effective than the antihistamine alone. Second-generation antihistamines are also available in combination with a sympathomimetic. Compared with single-agent therapy, the

cost of combination preparations can be high.

Topical sympathomimetic decongestant sprays have a limited role because of the risks of tachyphylaxis and rebound nasal congestion. They are best used for keeping the eustachian tubes patent in patients during airplane travel (see Chapter 219). A topical application of *phenylephrine* (Neo-Synephrine) or *oxymetazoline* (Afrin) spray every 3 to 4 hours while the patient is airborne should suffice, especially when preceded by an oral decongestant an hour before flight time. Rebound congestion may occur if sprays are used repeatedly for more than 3 days in a row.

Topical Corticosteroids. For patients with persistent symptoms of seasonal or perennial allergic rhinitis, regular use of a nonabsorbable topically active *intranasal corticosteroid* preparation (e.g., *flunisolide, budesonide, beclomethasone, fluticasone, triamcinolone, mometasone*) is becoming the treatment of choice. Nasal steroid therapy in such patients has proven to be clinically more effective and more cost effective than chronic use of oral antihistamines. Only symptoms of allergic conjunctivitis are better controlled by antihistamines. No significant benefit is afforded by combination therapy. Once and twice daily nasal steroid preparations are available; cost and convenience are the principal determinants of choice (Table 222.2). Patients with dryness and crusting of the mucosa may prefer a liquid formulation rather than a powdered one. Side-effect profiles and efficacies appear comparable, although some claims of enhanced safety (e.g., less hypothalamic-pituitary-adrenal suppression with mometasone) remain to be confirmed.

At recommended doses and frequencies, significant adrenal suppression does not occur with these topical corticosteroids, even when used chronically. No adverse effects on adult bone metabolism have been documented, although concerns about growth retardation in children remain. Unresolved is the effect of long-term nasal-steroid use on risk of developing cataracts and glaucoma, an association found in the elderly exposed to long-term high-dose use of inhaled and systemic glucocorticosteroids (see Chapter 105 and Chapter 208). Other adverse effects include mucosal irritation and friability, leading to an occasional *nosebleed*. Mucosal ulceration is rare. Application of the spray can cause transient burning and sneezing. Atrophic rhinitis is a risk of chronic use. Colonization of the nose with *Candida* has been reported.

Cromolyn Sodium has been found moderately effective, making it a reasonable nonsteroidal choice in persons with less severe disease. The agent is administered either as an inhaled powder or as a dissolved liquid up to six times per day. It works by preventing degranulation of mast cells and is most effective when used prophylactically before an anticipated allergen exposure. It benefits both the immediate and late phases of the allergic reaction and can diminish the severity of an ongoing allergic episode. Nasal congestion is reduced. Patients with very high IgE levels are most responsive; many others are not. The agent is very safe and well tolerated, which has led to its being approved for over-the-counter use.

Nedocromil is a newer topically active mast-cell stabilizer, structurally different from cromolyn and possessing antiinflammatory activity as well. Nonetheless, clinical efficacy in allergic rhinitis is similar to that of cromolyn, but only twice daily administration is required.

Immunotherapy (Hyposensitization) is indicated as a last resort in patients who face prolonged (more than 6 weeks) exposure to a known allergen and who remain incapacitated despite a year's trial of a full program of pharmacotherapy and environmental measures. Hyposensitization reduces IgE production and stimulates synthesis of IgG *blocking antibody*. It may also induce IgE suppressor lymphocyte activity or reduce mast cell and basophil responsiveness. Prevention of local reaction to pollens, cat dander, and dust mites has been demonstrated in patients with allergic rhinitis. Hyposensitization involves cutaneous administration of incremental doses of allergen extract, initially at intervals of 1 to 2 weeks, progressing to intervals of 3 to 6 weeks after several months of treatment.

Immunotherapy should be considered a complement to a medical therapy, because most responses are not dramatic. Skin testing for definitive identification of the causative allergen(s) is required, and frequent visits over a prolonged period mean considerable patient inconvenience and high cost. Assessment of response to immunotherapy (improvement in symptoms, reduction in medication requirements) should be made every 6 months, and therapy should be discontinued if substantial benefit is not evident after 12 to 18 months.

Recommended Approach to Treatment. Although the heavily promoted nonsedating H_1-blockers are very popular because they are well tolerated and reasonably effective in persons with mild to moderate disease, their uncritical chronic use violates most tenets of rational cost-effective prescribing. A more cost-effective approach would be to

- Implement avoidance and simple, practical environmental measures; there is no evidence that one needs to use special dust-impermeable covers for bedding. **Updated: 07/21/03**
- Start with a trial of a first-generation antihistamine, beginning with a twice daily dose of a long-acting preparation (e.g., sustained-release chlorpheniramine 8 to 12 mg). Add a small daytime dose of a shorter acting preparation (e.g., 4 mg chlorpheniramine) if needed and continue if well tolerated, but exert caution in persons whose work requires unimpaired psychomotor performance (e.g., those operating machinery, heavy equipment, or a motor vehicle).
- If sedation is a problem and short-term treatment will suffice, then consider short-term addition of a sympathomimetic (e.g., pseudoephedrine 60 mg); avoid if there is hypertension or underlying heart disease.
- If sedation is a problem and longer term therapy is needed for mild-to-moderate disease, then begin the least costly twice daily nonsedating antihistamine preparation (e.g., fexofenadine 60 mg every morning only); for nighttime use, recommend a nonprescription first-generation antihistamine.
- If control is inadequate, proceed to daily sustained use of a topically active, nonabsorbable, nasal steroid preparation (e.g., beclomethasone one to two puffs twice daily) or cromolyn.
- Consider immunotherapy only for those who have failed a year of all the above measures and in whom chronic unavoidable exposure to the offending allergen(s) is expected in the future.

Vasomotor Rhinitis

Vasomotor rhinitis is difficult to treat. Avoidance of tobacco smoke, rapid changes in temperature or humidity, and irritant chemical vapors is helpful. Humidification of the home in winter is also worthwhile. Cessation of nasal spray use is essential. A change in antihypertensive medications may be needed. A mild adrenergic agent with some a activity (e.g., pseudoephedrine) sometimes provides partial improvement. Addition of an antihistamine for its nonspecific drying effect may give some extra relief but is ineffective by itself. A reactive depression is common in such patients; use of an antidepressant with anticholinergic activity (e.g., amitriptyline) may be considering, both for its antidepressant and drying effects.

Immunotherapy and steroids are of no proven benefit. Patients severely bothered by nasal obstruction may benefit from cryosurgical treatment of the inferior and middle turbinates; profuse rhinorrhea is occasionally treated by sectioning the parasympathetic nerve supply to the nose. Consideration of surgical approaches should be reserved only for patients whose lives are seriously impaired by their symptoms, because chances of success are limited and risk of complications is substantial.

INDICATIONS FOR REFERRAL

For the patient with allergic rhinitis whose condition is inadequately controlled on a well-designed medical regimen, referral to an allergist for skin testing and consideration of immunotherapy is a reasonable step. An allergist can also be of help when an allergic etiology cannot be distinguished from vasomotor rhinitis and when the antigen(s) must be identified for management purposes. Referral to an ear, nose, and throat specialist is indicated for removal of polyps or foreign bodies, management of a suspected tumor, necrotizing inflammatory condition, or atrophic rhinitis and for correction of deviated septa. Referral might also be worthwhile for patients with incapacitating vasomotor rhinitis.

CHAPTER 223 APPROACH TO THE PATIENT WITH EXCESSIVE SNORING

Snoring is essentially a lay term for soft tissue airway obstruction during sleep. The complaint almost always originates from a spouse or household member whose sleep is being disturbed. Snoring may be an annoying but medically trivial problem, but when associated with daytime sleepiness and witnessed apneic episodes, it may be a manifestation of sleep apnea (see Chapter 46).

PATHOPHYSIOLOGY AND CLINICAL PRESENTATION

Pharyngeal size in snorers and patients with obstructive sleep apnea is reduced compared with that in nonsnorers, with sleep apnea patients having the smallest cross-sectional pharyngeal area. The sound of snoring originates in the collapsible portion of the airway, the soft tissue between the choanae and the epiglottis. Tone in the lingual and pharyngeal muscles may be inadequate due to use of sedatives or alcohol. Structural abnormalities may contribute and include redundant or thickened lateral pharyngeal musculature, a long uvula, thickened pharyngeal folds, and flaccid tonsillar pillars. Large tonsils, cysts, or neoplasms sometimes may obstruct the airway. Mild maxillomandibular abnormalities, such as a small chin, overbite, and high hard palate, have been found important in women. Obstructing nasal abnormalities (e.g., severely deviated septum, polyps, sinusitis, neoplasm) may create excessive negative pressure and cause collapse of the airway during inspiration.

Severe airway obstruction may lead to *sleep apnea*. Full obstruction interrupts ventilation and, if sufficiently prolonged, results in hypercarbia and hypoxemia. Restoration of breathing usually requires arousal from sleep. The nightly occurrence of multiple apneic episodes and disturbed sleep pattern causes daytime tiredness and hypersomnolence. Uncorrected, the condition may lead to cor pulmonale from chronic arterial desaturation. The condition is most common in obese patients but not restricted to them (see Chapter 46).

WORKUP

The history is most important, especially for recognition of sleep apnea. Habitual snoring, daytime sleepiness, history of motor vehicle accidents caused by falling asleep at the wheel, or witnessed apneas should trigger concern about sleep apnea. Although the condition is most common in men, women with sleep apnea often go unrecognized. Delay in diagnosis of sleep apnea is common, especially in women because symptoms are often ignored or the presentation may be atypical (fatigue, no associated obesity or daytime sleepiness, mild maxillomandibular abnormalities).

A careful examination of the mouth and upper airway is needed to search for obstructing anatomy. Referral for formal ear, nose, and throat evaluation may be helpful. For the patient with suspected sleep apnea, consideration of nocturnal oxygen saturation monitoring and a formal sleep study are indicated (see Chapter 46).

MANAGEMENT

The patient with annoying but physiologically benign snoring can sometimes be helped by simple advice. Loss of excess *weight* and avoidance of *alcohol* and *sedatives* may prove beneficial. Sleeping on one's side rather than on the back sometimes helps minimize upper airway collapse (an old trick is to tape a marble to the patient's back to discourage lying supine). Avoidance of the excessive *neck flexion* that comes from sleeping supine on several pillows can be achieved by limiting the patient to a cervical pillow placed under the nape of the neck or by elevating the entire head of the bed (as in management of reflux esophagitis). Any nasal obstruction from chronic rhinitis should be fully treated (see Chapter 222); anatomic obstruction may benefit from a trial of an external nasal dilator (e.g., a Breath Right Strip).

For patients with disturbingly refractory snoring, a more aggressive approach is to consider use of a continuous positive airway pressure (CPAP) device. The apparatus delivers CPAP through the nose and is usually reserved for those with sleep apnea (see Chapter 46), but may be worth a try in households where marital harmony and restful sleep are threatened by excessive snoring. The devices are sometimes awkward to use and not always acceptable but newer ones are more comfortable. Consideration of dental orthosis has proven useful in preliminary studies and may be worth a referral in cases where there is an overbite or other maxillomandibular pathology. Pulmonary consultation is indicated when there is concern about sleep apnea (daytime sleepiness, nocturnal apnea; see Chapter 46). An ear, nose, and throat consultation may prove useful when snoring proves intractable and appears associated with anatomic oropharyngeal pathology.

CHAPTER 224 MANAGEMENT OF APHTHOUS STOMATITIS

Aphthous stomatitis (canker sores) is a common self-limited ulcerative condition of the oral mucosa. About 20% of the population is affected at one time or another. The lesions can be disturbing in appearance and very painful. The primary physician should be able to differentiate them from more serious pathology and provide symptomatic relief.

PATHOPHYSIOLOGY, CLINICAL PRESENTATION, AND COURSE

Pathogenesis remains incompletely understood, but a heightened immunologic response to oral mucosal antigens appears to play an important role. There is a genetic predisposition and an increased prevalence among patients with such autoimmune diseases as Crohn's disease, chronic ulcerative colitis, Behçet's syndrome, and Reiter's syndrome. Contributing factors include deficiencies of iron, folate, and vitamin B_{12}; psychological stress; generalized physical debility; and trauma. In some women, flares occur premenstrually. Regardless of etiology, once mucosal breakdown has occurred, the lesions are invaded by mouth flora and become secondarily infected.

Clinical Presentation Aphthous stomatitis develops in four clinical stages:

1. *Premonitory*—tingling, burning, or hyperesthetic sensation, lasting up to 24 hours;
2. *Preulcerative*—lasting from 18 hours to 3 days, characterized by moderately painful erythematous macules or papules with erythematous halos;
3. *Ulcerative*—lasting 1 to 16 days, characterized by painful discrete ulcers 2 to 10 mm in diameter, occurring singly or in groups, covered by gray yellow membrane with a dusky erythematous halo; pain ceases during this stage;
4. *Healing*—usually without scarring unless lesions are very large, averages 2 weeks (range from 4 to 5 weeks).

Aphthous ulcers are classified according to size. Most are *minor* (i.e., less than 1 cm in diameter) and appear in crops of four or five. *Major lesions* are greater than 1 cm, solitary, indolent, and, as noted, may scar as they heal. Lesions are painful and may occur anywhere within the oral cavity. In two thirds of patients, recurrent lesions do not develop, but in one third, recurrences continue for up to 40 years.

DIFFERENTIAL DIAGNOSIS

Other causes of oral mucosal ulceration include pemphigus, herpes simplex, Behçet's syndrome, and hand-foot-and-mouth disease. *Pemphigus* is suggested by the presence of bullous lesions elsewhere on the body (although oral lesions may precede others by years) and a Tzanck smear from the base of the lesion showing acantholytic cells. Immunofluorescence studies may be necessary if there is recurrent disease. The ulcerated mucosal lesions of *herpes simplex* infection are limited to mucosal surfaces attached to bone, whereas aph-thous ulcers may occur anywhere in the oral cavity. The Tzanck preparation shows multinucleated giant cells. The ulcers of *Behçet's syndrome* are identical to those of aphthous stomatitis; genital ulceration and eye involvement help differentiate the condition from simple aphthous disease. In *hand-foot-and-mouth disease*, papulovesicular lesions with an erythematous halo appear on the hands, feet, and lips in addition to the mouth. The lesions ulcerate and then heal over 7 to 10 days. Because the condition is due to an enterovirus, the mucosal findings may be preceded by viral gastrointestinal symptoms.

PRINCIPLES OF MANAGEMENT

When the chief reason for seeking medical care is concern, reassurance that the lesions will heal spontaneously and that they do not represent more serious pathology will often suffice. For patients with large lesions and those bothered badly by the discomfort, additional measures are reasonable. In the presence of extremely painful lesions, use of a topical anesthetic agent (e.g., viscous lidocaine) before meals may allow the patient to eat. Avoidance of abrasive foods also helps. *Tetracycline liquid* (250 mg four times a day) used as a mouthwash that is held in the mouth for several minutes before expectorating is easy to use. *Topical corticosteroids* impregnated into a paste vehicle (e.g., Orabase) help apply the steroid to the mucous membrane and may provide some added relief. *Carbamide peroxide* gel is an oxidizing agent that has some bactericidal effect against many mouth organisms and is a mild debriding agent. In the presence of extremely painful lesions, use of *topical anesthetic agents* (e.g., viscous lidocaine) before meals may allow the patient to eat. Avoidance of abrasive foods also helps. *Levamisole*, which stimulates immune response, has been used experimentally and reported efficacious in about two thirds of cases, but the unknown long-term safety of this agent limits its use for this self-limited condition. Topical use of sucralfate liquid may provide some mucosal protection.

Women with a definite premenstrual flare may be helped by estrogen-dominated oral contraceptives. Identification and correction of an existing deficiency of folate, vitamin B12, or iron may cure aphthous stomatitis. For lesions precipitated by emotional stress, attention to the underlying problem may help (see Chapter 226). Chemical cauterization by means of silver nitrate sticks ($AgNO_3$) is used by some practitioners to treat acute lesions, but this involves the distinct possibility of destroying normal tissue and should not ordinarily be used.

PATIENT EDUCATION

Besides reassurance, patient education should include recommendations for avoiding mucosal trauma and maintaining good nutrition and oral hygiene. Use of a soft-bristled toothbrush and avoidance of foods with sharp surfaces, salt, and talking while chewing can be helpful. Patients with vitamin or mineral deficiencies can be prescribed a supplement. The possibility of recurrence in one third of patients should be explained.

CHAPTER 225 MANAGEMENT OF TEMPOROMANDIBULAR JOINT DYSFUNCTION

Temporomandibular joint (TMJ) dysfunction has received much attention in the lay press as a cause of chronic headache and facial pain (see Chapter 165). Although severe cases may require dental or oral surgical intervention, most can be managed conservatively by the primary physician.

PATHOPHYSIOLOGY AND CLINICAL PRESENTATION

Most TMJ dysfunction is psychophysiologic in origin, the consequence of chronic *bruxism* (nocturnal jaw clenching and teeth grinding). This tension-relieving oral habit develops in response to situational and intrapsychic stresses and can lead to masticatory muscle fatigue and spasm. In most instances, the problem remains *extracapsular*, with little or no internal derangement of the TMJ. However, severe prolonged bruxism may cause *intracapsular* joint derangement, resulting in degenerative disease of the joint. *Sinovitis* from connective tissue disease, infection, or trauma is another form of intracapsular pathology.

Symptoms of TMJ dysfunction include chronic, dull, aching unilateral discomfort about the jaw, behind the eyes and ears, and even down the neck into the shoulders. Jaw pain, clicking sounds, and difficulty opening the mouth widely, especially in the morning, are characteristic. Chewing may exacerbate symptoms. Locking of the jaw is common. Masticatory muscle tenderness, mandibular hypomotility, clicking, and joint deviation on opening are noted on physical examination. Molar prominences may be flat from chronic grinding. A subset of patients with symptoms referable to the TMJs also experience pain and dysfunction that extend far beyond the TMJs.

A subset of patients with TMJ complaints exhibit features characteristic of patients suffering from a chronic pain syndrome (see Chapter 236). They present to multiple doctors with refractory pain complaints, often extending beyond the TMJs. Not only is health care utilization high as such patients search repeatedly for a "cure," but physician frustration is also high as nothing seems to work. Any suggestion by the physician of a "psychological" cause clashes with the patient's etiologic view and leads to a dissonant doctor–patient relationship. Such patients often seek the comfort "TMJ" support groups.

DIAGNOSIS

The hallmark of TMJ dysfunction is chronic unilateral jaw or facial pain exacerbated by jaw movement. Other causes of jaw pain worsened by jaw movement include *acute otitis media* and *parotitis*. These are distinguished by their acute onset and associated inflammatory manifestations. More subtle is the jaw claudication from *temporal arteritis* (see Chapter 161). Intracapsular TMJ disease may be differentiated clinically from extracapsular dysfunction by the presence of markedly limited jaw movement, jaw deviation on opening of the mouth, and presence of crepitus and clicking on jaw movement. However, there is much overlap of symptoms between internal and extracapsular TMJ disease; jaw clicking may even be noted in normal persons.

Confirmation of internal derangement requires radiologic study. *Magnetic resonance imaging* (MRI) of the TMJ provides the best visualization of bony and soft tissue structures. It has become the test of choice, being more sensitive than conventional or computed tomography and free of radiation exposure. MRI test expense can be reduced substantially by imaging only the TMJ. Imaging is indicated only when internal derangement is suspected, conservative measures have failed, and more aggressive therapy is being considered.

Patients with refractory TMJ complaints that extend well beyond the TMJs and disproportionately interfere with daily functioning should have the possibility of an underlying chronic pain syndrome explored (see Chapter 236).

PRINCIPLES OF MANAGEMENT

Nonsurgical Measures. Because TMJ dysfunction is largely a psychophysiologic condition, treatment may begin with the primary physician inquiring into sources of stress and tension and offering counseling. Often, *cognitive/behavioral therapy* is more effective than insight-oriented approaches to psychotherapy (see Chapter 226). Most persons improve without formal psychiatric care. Less etiologic but helpful symptomatic measures include dietary advice, local physiotherapy, analgesics, minor tranquilizers, and sometimes antidepressants.

Dietary advice includes cutting food into small pieces and using a diet that minimizes hard repetitive chewing (e.g., no chewing gum or biting into big submarine sandwiches). *Physiotherapy* in the form of local heat and massage to the muscles of mastication helps relieve muscle spasm and the accompanying pain. Some persons achieve relief with application of *ultrasound* of *cold packs*. Analgesics such as aspirin and low doses of nonsteroidal antiinflammatory agents are also helpful when pain is prominent. Short-term use of a *minor tranquilizer* at bedtime (e.g., 2 mg of diazepam as needed for 35 days) can help reduce nocturnal muscle spasm and complement analgesic therapy. However, long-term tranquilizer use should be avoided due to the risk of dependence (see Chapter 226). The so-called muscle relaxants (e.g., Robaxin, Soma) are of no proven advantage. Patients with more refractory pain may respond to a trial of a sedating *tricyclic antidepressant* (e.g., nortriptyline 25 mg as needed). Patients with severe grinding may benefit from nighttime use of a custommade *splint* or bite guard.

A regimen that incorporates all these measures into a comprehensive treatment program has a success rate of over 75%. Patients who report refractory pain may have suffered joint damage and require consideration for regrinding or surgical intervention. When the clinical presentation is one of refractory pain accompanied by more global musculoskeletal dysfunction and disproportionately little evidence of TMJ destruction, then approaching the condition as a chronic pain syndrome may be the wisest course (see Chapter 236).

Regrinding and Surgical Therapies. Only the patient with severe malocclusion leading to marked joint trauma is a candidate for regrinding of the teeth. It is a therapy of limited efficacy, requiring careful patient selection. Many patients without objective malocclusion and significant joint injury are subjected needlessly to regrinding or surgical therapy. Surgical intervention is a consideration only when conservative measures have failed to provide relief *and* there is clinical evidence of internal joint derangement and secondary degenerative arthritis (see above). Under these circumstances, an MRI of the TMJs should be obtained and referral made if important degenerative changes are found.

Incapacitated patients refractory to conservative therapy yet found to have marked degenerative changes clearly linked to symptoms are potential candidates for surgery. They should be referred for consultation to an oral surgeon experienced in treating TMJ disease. There are almost no large-scale, prospective, randomized studies to guide choice of surgery for TMJ disease. Arthroscopic approaches appear promising. They are reported to provide significant symptomatic relief, are minimally invasive, and have a low incidence of complications; however, long-term benefit remains to be established.

PART 15 PSYCHIATRIC AND BEHAVIORAL PROBLEMS

CHAPTER 226 APPROACH TO THE PATIENT WITH ANXIETY

JOHN J. WORTHINGTON III AND SCOTT L. RAUCH

Anxiety disorders are prevalent (estimated lifetime prevalence of 25% in the general population) and a frequent precipitant of visits to the nonpsychiatric physician. Evaluation and management can be challenging because patients present with feelings of distress and concern about disease in the absence of objective evidence. Suffering no less from the subjective nature of their ailment, they fear something is amiss with their bodies and persistently seek an acceptable explanation and relief. The autonomic arousal accompanying anxiety may affect many organ systems and imitate physical disease. Moreover, anxiety and anxiety-like symptoms may be consequent to a variety of medical ailments and their treatments.

Anxiousness is a normal human affect. Distinguishing it from pathologic anxiety and anxiety disorders often requires systematic evaluation and a thorough understanding of the individual patient's physical and psychological status. Unrecognized and untreated, anxiety disorders increase the cost of medical care and render patients vulnerable to further morbidity, including demoralization, hypochondriasis, depression, and varying degrees of disability. A comprehensive and empathic assessment of the anxious patient by the primary care physician permits a reasoned and often therapeutically effective approach to the difficult problems presented.

PATHOPHYSIOLOGY AND CLINICAL PRESENTATION

Definitions. *Anxiety* is the distressing experience of dread, foreboding, or panic accompanied by a variety of autonomic—primarily sympathetic—bodily symptoms. The distress, therefore, is both psychic and physical. Patients vary considerably in their tolerance to it. The new onset or exacerbation of anxiety often occurs in response to emotional or physiologic stimuli. Most persons meet the challenge of universally anxiety-provoking situations with their own personal strengths and styles of coping. When a patient's capacity for coping is overwhelmed, excessive anxiety may emerge. *Pathologic anxiety* is distinguished from the normal by its occurrence in the absence of an appropriate stimulus and by its duration or intensity.

Neurotransmitter Mechanisms. Several monoamine and neuropeptide neurotransmitters are implicated in the neurobiology of anxiety. *Norepinephrine* plays a prominent role in mediating anxiety states centrally. The locus ceruleus of the pons serves as the chief noradrenergic nucleus. Abnormal firing patterns in the locus ceruleus have been implicated in the pathophysiology of some anxiety conditions, such as panic disorder. In contrast, the inhibitory neurotransmitter *gamma-aminobutyric acid*, ubiquitous throughout the brain, is implicated as serving an anxiolytic function within the limbic system. The resultant somatic manifestations of anxiety are principally mediated by the *sympathetic nervous system*.

Classification and Basic Components of the Clinical Presentation. The classification of anxiety disorders is largely based on clinical features (Table 226.1). In both its normal and pathologic forms, anxiety's manifestations consist of affective, cognitive, behavioral, and somatic components. The *affective component* is characterized by the experience of dread, foreboding, or panic countered by *cognitions* that make sense of or seek to neutralize the distress. A variety of *behaviors* reflect the anxious state or evolve in response to it (e.g., avoidance). Typical psychological presentations might include complaints of apprehension, motor tension or agitation (restlessness, edginess, jitteriness), and heightened arousal (including hypervigilance, distractibility, impaired concentration, and insomnia). The *somatic complaints* are mostly those of autonomic hyperactivity and include systemic, cardiopulmonary, gastrointestinal, urinary, and neurologic symptoms (Table 226.2).

Table 226.1. Anxiety Disorders and Defining Features

TYPE	SPECIFIC SYMPTOMS
General	Fatigue, weakness, diaphoresis, insomnia, flushing, chills
Neurologic	Dizziness, paresthesias, derealization, near-syncope, tremulousness, restlessness
Cardiac	Palpitations, chest pain, tachycardia
Respiratory	Dyspnea, hyperventilation, choking
Gastrointestinal	Dry mouth, diarrhea, nausea, vomiting
Urinary	Frequency, urgency

Table 226.2. Somatic Symptoms of Anxiety

Adjustment Disorder with Anxious Mood. Most presentations of anxiety within the medical setting are normal reactions to anxiety-provoking situations. For a limited time period, a patient may suffer symptoms similar to those of a generalized anxiety disorder (see below). When a patient's capacity for coping is overwhelmed, excessive anxiety may transiently emerge until the patient is able to adjust. This state is termed *adjustment disorder with anxious mood* and typically resolves in less than 6 months. Adjustment disorders may likewise be heralded by other manifestations, including depressed mood and misconduct.

Generalized Anxiety Disorder. This common condition is characterized by anxiety lasting longer than 6 months and worry extending beyond a specific subject. Typically, the patient is ruminating with worries over a variety of concerns and may have been this way for several years with a waxing and waning course.

Generalized anxiety disorder also includes an array of physical concomitants, including restlessness, fatigability, poor concentration, irritability, muscle tension, and insomnia. In addition to the persistent anxious state, the patient may describe more discrete episodes of acute anxiety.

When sudden spells of extreme anxiety occur with prominent symptoms of sympathetic activation, they may be accompanied by feelings of impending doom, fear of dying, the sensation of panic, and the impulse to flee. Such symptoms characterize *panic attacks*, which may occasionally be experienced by patients with generalized anxiety disorder, although they are a more prominent feature in panic disorder.

Panic Disorder. This anxiety disorder is characterized by *recurrent unexpected panic attacks*, with at least one attack followed by no less than a month of persistent concern about having additional attacks, worry about the implications of the attack or its consequences (e.g., losing control, having a heart attack), or a significant change in behavior related to the attacks. Panic disorder is more common in females and in those with a positive family history of panic. Emergence of anxiety symptoms early in life, including a history of separation difficulties during childhood, also represent risk factors for panic disorder.

Many patients become disabled by anticipatory fear of subsequent panic attacks and by phobic *avoidant behavior* patterns. They avoid places with restricted escape (e.g., crowds, theaters, tunnels, elevators), fearful of being trapped during an attack. In its most extreme form, *agoraphobia* (literally, "fear of the market place"), avoidant behavior may reach the point where a patient is afraid to leave the safety of the home or to be left alone. In rare situations, agoraphobia has also been reported to occur in the absence of panic disorder. (More commonly, the patient whose family describes them as "never leaving the house" has depression with loss of interest in doing their activities as a prominent symptom.)

The course of panic disorder includes times of frequent panic attacks interspersed with periods of less frequent episodes, complicated by phobic avoidance and anticipatory anxiety. The paroxysmal nature of panic attacks and the prominence of autonomic symptoms may mimic cardiac or neurologic disease, causing some patients to become hypervigilant, convinced of a serious underlying medical disorder, and "doctor shoppers" in search of such a diagnosis. Such persons may become demoralized, depressed, and debilitated. Suicide risk appears to be increased in panic disorder, especially in patients with concurrent depression.

Specific Phobias. A phobia is an irrational fear related to a specific stimulus. On exposure to that stimulus, the patient almost invariably manifests an anxiety response. A patient may suffer from a specific phobia of any specific stimulus. Although specific phobias commonly generate circumscribed symptoms, they may interfere with some aspect of a patient's functioning due to avoidance of the phobic stimulus or perseverance in the face of great discomfort (e.g., fear of flying leading to difficulty with travel).

Social Phobia (Social Anxiety Disorder). Patients with social phobia develop anxiety in situations where they are the focus of attention or might be scrutinized publicly. The individual fears they will act in a way (or show anxiety symptoms) that will be humiliating or embarrassing. Such patients may experience *performance anxiety* or "stage fright" but also exhibit distress in more ordinary social settings. In the generalized type, the fear includes *most social situations* (participating in small groups, dating, initiating or maintaining conversations, speaking to authority figures, attending parties, etc.). Social phobia is to be distinguished from the more limited form of normal performance anxiety, which occurs in universally acknowledged anxiety-provoking situational settings (e.g., performing in front of a very large audience or as part of a very important event).

Obsessive-Compulsive Disorder. More common than previously recognized, obsessive-compulsive disorder (OCD) affects up to 3% of the population. It is characterized by obsessions and/or compulsions that are sufficiently severe to cause patients substantial distress or impair their ability to function.

Obsessions are unwanted intrusive thoughts of a bizarre, senseless, or extreme nature. The subject of obsessions typically includes sexual or violent themes that are very distressing to patients and may lead them to fear that they are "going crazy." The recurrent and persistent thoughts, impulses, or images themselves become a source of anxiety.

Compulsions refer to repetitive behaviors that are performed in a stereotypical or ritualized fashion, usually in response to obsessions, sometimes in an effort to neutralize them. Resisting the drive to perform compulsions causes escalating anxiety, whereas succumbing and performing them is accompanied by feelings of transient relief, followed by feelings of shame. Characteristic compulsions include hand washing (to neutralize contamination obsessions), checking behaviors (e.g., doorlocks and stove burners to counteract obsessions of uncertainty), and counting (to neutralize anxiety associated with other obsessions).

The relationship between the compulsions and obsessions may also be nonsensical or irrational. Usually patients retain insight regarding the nonsensical or extreme nature of their thoughts and behaviors, distinguishing them from psychotic persons.

Because of the *shame* associated with the symptoms of OCD, it is not uncommon for patients to hide the disorder from friends, family, and doctors. OCD may come to the attention of primary care physicians when patients' obsessions involve preoccupations with their bodily functions (e.g., urinary or bowel obsessions) or susceptibility to disease (e.g., obsessions with contamination or fear of AIDS). Rarely, the compulsions may be performed to such extreme as to pose medical risk or sequellae (e.g., dermatologic complications of hand washing).

The *onset* of OCD is variable, with a bimodal distribution of age at onset, a peak in the preteen years, and another peak in the third decade of life. There is a disproportionate representation of males in the early peak and a disproportionate representation of females in the later peak. The *clinical course* is similarly variable; symptoms may arise at any age, wax and wane, and become exacerbated in times of stress.

The etiology and underlying pathophysiology of OCD are poorly understood. It has been related genetically to Tourette's disorder and commonly occurs with *depression*. Associated disorders include *body dysmorphic disorder* (i.e., preoccupation with a defective body image) and *trichotillomania* (compulsive hair pulling).

Posttraumatic Stress Disorder. Hours to months after a traumatic exposure (e.g., combat experience, natural disaster, physical assault, rape), the posttraumatic stress disorder (PTSD) patient reports *persistent reexperiencing* of the traumatic event, via intrusive thoughts, vivid dreams, or "flashbacks." Other requisite characteristics include *avoidance* of stimuli associated with the trauma, *hyperarousal* (e.g., increased startle response), and persistence of symptoms for more than 1 month. In many cases, the symptoms may continue for years. Rarely, the syndrome emerges more than 6 months after the traumatic exposure and in such cases is designated "*PTSD with delayed onset.*"

Patients may present for medical assistance with primary complaints of anxiety or with concerns and questions regarding the neurologic underpinnings of their symptoms. Alternatively, PTSD may develop as a consequence of medical illness or procedures (e.g., amputation), which by their nature represent profound trauma. Medical settings may serve to trigger reexperiencing phenomena. It is important to be aware of the entity and sensitive to the needs of its sufferers.

Substance Abuse. Anxiety is often poorly tolerated, leading some patients to seek relief through use or abuse of anxiolytic substances. A patient's reliance on *alcohol, benzodiazepines* (BZDs), or any other sedating medication may reflect an unrecognized underlying anxiety disorder. Chronic use of sedating substances can lead to neural irritability and can cause or exacerbate anxiety after withdrawal. It often becomes difficult to differentiate the cause and effect relationship between substance abuse and anxiety. Patients with anxiety disorders are 50% more likely to be alcoholic, and similarly, the prevalence of anxiety disorders is 50% higher in alcoholics.

DIFFERENTIAL DIAGNOSIS

The medical differential diagnosis of the symptoms and signs associated with anxiety includes many conditions in which there is stimulation of the sympathetic nervous system (Table 226.3). Some reports suggest that undiagnosed medical ailments are responsible for a significant number of psychiatric referrals for "anxiety." Unrecognized arrhythmias, endocrinopathies, and medication reactions may mimic anxiety disorders and vice versa.

TYPE OF CAUSE	SPECIFIC CAUSE
Cardiovascular	Angina pectoris, arrhythmias, congestive heart failure, hypertension, hypovolemia, myocardial infarction, syncope (of multiple causes), vascular disease, vascular collapse (shock)
Dietary	Caffeinism, monosodium glutamate (Chinese-restaurant syndrome), vitamin-deficiency diseases
Drug related	Akathisia (secondary to antipsychotic drugs), anticholinergic toxicity, digitalis toxicity, hallucinogens, hypertensive agents, stimulants (amphetamines, cocaine, and related drugs), withdrawal syndromes (alcohol or sedative-hypnotics)
Hematologic	Anemias
Immunologic	Anaphylaxis, systemic lupus erythematosis
Metabolic	Hyperadrenalism (Cushing's disease), hyperkalemia, hyperthermia, hyperthyroidism, hypocalcemia, hypoglycemia, hyponatremia, hypoparathyroidism, menopause, porphyria (acute intermittent)
Neurologic	Encephalopathies (infectious, metabolic, and toxic), essential tremor, intracranial mass lesions, postconcussion syndrome, seizure disorders (especially of the temporal lobe), vertigo
Respiratory	Asthma, chronic obstructive pulmonary disease, pneumonia, pneumothorax, pulmonary edema, pulmonary embolism
Secreting tumors	Carcinoid, insulinoma, pheochromocytoma

Table 226.3. Medical Causes of Anxiousness

Among the psychiatric disorders to be considered in the differential diagnosis of anxiety are the *depressive disorders*. They are among the most critical to recognize, because they are common, treatable, carry a high risk of morbidity and mortality when untreated, and frequently coexist with symptoms of anxiety (see Chapter 227). Other psychiatric conditions presenting with anxiety as a prominent component include *psychosis, dementias, and drug-related disorders*.

WORKUP

The primary care physician's evaluation of anxiety needs to include assessment for medical causes and psychiatric diagnoses.

Assessment for Medical Causes. The list of possible medical causes is much too extensive to enable a workup that includes every possibility. A reasonable alternative is to focus on any medical conditions for which the patient is already under treatment. This includes a review of the patient's concerns, fears, and ongoing therapies. In addition, attention is directed toward the most important disorders commonly linked with anxiety, such as dysrhythmias (see Chapter 25), hyperthyroidism (see Chapter 103), and drug reactions or withdrawal (see Chapter 229 and Chapter 235). If the patient has a single prominent symptom or constellation of symptoms that implicate a single organ system, it is worthwhile to medically evaluate that focus in detail. However, the presence of multiple physical symptoms (six or more), high patient rating of symptom severity, low patient rating of health status, physician perception of the patient encounter as difficult, and age less than 50 years are important clues for an underlying anxiety or depressive disorder. Such easily identified clinical features have been shown to be independent predictors of underlying psychopathology in patients presenting to primary physicians with bodily symptoms. Because there are effective treatments for anxiety disorders, a diagnostic trial of an antianxiety therapy might help resolve a difficult diagnostic situation, but suppression of anxiety symptoms does not rule out a medical disorder and may even worsen it (e.g., use of BZDs for anxiety accompanying a severe asthma attack).

Assessment for Psychiatric Disorders. The physician should recall that anxiety symptoms are typically conceptualized in three dimensions: psychological, somatic, and behavioral.

Psychological. Patients suffering from an anxiety disorder may complain of somatic manifestations of anxiety but may omit history pertaining to the psychological experience. Therefore, it is important to inquire specifically about psychic manifestations such as fear, panic, the sensation of impending doom, or the impulse to flee. Reviewing the features of the various anxiety disorders sometimes helps the patient to construct a clearer clinical picture, but care must be taken not to prejudice the patient's responses or appear too eager to make a psychiatric diagnosis.

Somatic. One also needs to determine the *onset, quality, intensity, and duration* of symptoms, being certain to include a compassionate inquiry into recent life events and situational stressors present at the time that symptoms emerged.

Behavioral. Identifiable *stimuli or exacerbating factors* should be noted and settings that create apprehension. Development of *avoidant behaviors* should be ascertained. If a particular precipitant is identified, it is helpful to inquire into its origin (e.g., a phobia of dogs arising from a remote history of a dog bite or avoidance of elevators as a consequence of having had a panic attack in one). Often, symptoms may have arisen spontaneously, contributing to the sense that they are autonomous (as in panic disorder or OCD).

Also useful is inquiry into *strategies* used to alleviate the symptoms. This may uncover additional history about substance use, avoidance, or compulsive behaviors. *Family history* is reviewed for similar symptoms, known anxiety disorders, and related disorders such as depression or substance abuse. *Past history* of childhood school phobia or early patterns of timidity may be informative. Finally, a thorough physical examination is essential, checking for undisclosed sequelae of repetitive behaviors.

PRINCIPLES OF MANAGEMENT

The treatment strategies for anxiety include psychotherapeutic and pharmacologic interventions; a combined approach yields the best results.

Psychotherapy

Psychotherapeutic treatments for anxiety help to alleviate symptoms through insight, education, support, and the reconditioning of behavioral patterns. Supportive, insight-oriented, and behavioral psychotherapies may be used individually or jointly.

Supportive Psychotherapy. The hallmark of this approach is empathic listening, education, reassurance, encouragement, and guidance. The primary care practitioner frequently performs these functions, whether or not the intervention is labeled as supportive psychotherapy. In the case of anxiety, *empathic listening* helps patients to feel that another human being can appreciate their suffering and, as importantly, not judge them harshly because of their condition. Patients with anxiety often feel ashamed, characterizing themselves as "weak" or "silly" because of their fears and behaviors. Empathy helps to cut through the shame and loneliness. Listening and encouraging them to relate their histories can have a cathartic effect. Many patients with anxiety disorders have hidden some or all of their suffering for years.

In addition to empathic listening, *patient education* is crucial. It begins by informing the patient of the diagnosis and explaining its origins, prognosis, and treatment plan. Increased knowledge and understanding is empowering because it promotes a sense of command and confidence while reducing feelings of uncertainty, helplessness, and isolation. Such changes themselves are anxiolytic. Fears of serious somatic illness, "going crazy," and incurable disease are alleviated.

Reassurance in the form of "there is nothing serious," even if given in a sympathetic nonpatronizing manner, will be demoralizing and disappointing if offered perfunctorily. Although a negative medical workup may be reassuring to some patients, the patient with an anxiety disorder is often not relieved, because he or she is still experiencing distinctive, intrusive, and distressing symptoms. Reassurance serves to heal only when it addresses what is wrong and what can be done. It must be offered in concert with true empathy and education.

Once a strategy has been developed to manage the patient's anxiety, *guidance and encouragement* are helpful to the patient in negotiating treatment trials and supervening situational stresses.

Insight-oriented Psychotherapy. The objective is to guide the patient to an understanding of the association between circumstances, emotions, and symptoms. By exploring feelings, relationships, and actions (both past and present), the patient may develop new insights into his or her inner emotional makeup. This can help reduce the symptoms of anxiety and reframe the meaning of anxiety symptoms when they do occur. Insight therapy typically requires frequent and lengthy sessions for optimal results and the skill of a good psychotherapist.

Behavioral therapy is especially effective for anxiety patients. It consists of reconditioning or modifying patients' behaviors or the association between a stimulus and

response. Techniques include general relaxation-response training (for tolerating anxiety symptoms), *in vivo* exposure and desensitization (for phobias and avoidant behaviors), cognitive therapy (for panic and obsessions), and exposure-response prevention (for OCD). The effectiveness of each of these behavioral techniques is augmented if the patient's anxiety can be held in check. For this reason, the behavioral therapies may be particularly well suited for combination with pharmacotherapies. As with insight-oriented psychotherapy, behavioral therapy is best conducted by professionals specially trained in this approach.

Relaxation techniques are of benefit to almost anyone who suffers from anxiety. Deep muscle relaxation, autogenic exercises, and diaphragmatic breathing are taught (see Appendix). Together, these techniques help to minimize the escalating anxiety that results from autonomic dyscontrol. Their use allows patients to better tolerate moderate anxiety states, abort panic episodes and use more aggressive behavioral techniques.

Exposure and desensitization entail gradual *reconditioning* of patients by exposing them to feared stimuli in controlled settings that minimize and allow habituation to their anxiety response. In this way, the feared stimuli become better tolerated and avoidant behaviors are eradicated, as the association with the anxiety response is weakened. Similarly, the exposure-response prevention paradigm is used in treating OCD patients. After being exposed to a provocative stimulus, they are helped to resist the urge to perform their compulsions in response to that stimulus. Although tolerating the anxiety, they may use sanctioned relaxation techniques. Gradually, the compulsions are reduced.

Cognitive-behavioral therapy. Preoccupation with physical symptoms and misinterpretation of their meaning characterize persons with panic disorder and hypochondriasis. Cognitive-behavioral therapy consists of addressing and correcting the patient's beliefs in conjunction with teaching behavioral techniques to help patients cope with their anxiety. The approach has been particularly successful when applied in the setting of noncardiac chest pain. Referral should be directed to therapists experienced in this method, because considerable skill is required to implement it successfully.

Pharmacotherapy

Treatment outcomes for psychotherapy are often enhanced when pharmacotherapy is incorporated into the program. The primary goal of drug therapy is sufficient diminution of symptoms to enable performance of tasks previously impaired by anxiety, including an enhanced ability to benefit from behavioral therapy. Patients should be informed that treatment will be of limited duration and will reduce their symptoms but not eradicate them. BZDs are the most widely used of anxiolytics. Antidepressants, b-adrenergic blocking agents, buspirone, and neuroleptics are also used.

Benzodiazepines. For rapid specific relief of anxiety symptoms, the BZDs are regarded as the anxiolytic of choice, superior in efficacy and safety to the barbiturates and the nonbarbiturate sedatives such as meprobamate, ethchlorvynol, and glutethimide. For some patients, BZDs offer substantial or complete relief of anxiety symptoms. For others, they attenuate severe anxiety pending response to other antianxiety therapies. There is wide individual variation in clinical response, plasma levels, and dosage requirements.

Ensuring Proper Use. Overuse and drug seeking from multiple sources occur in a small percentage of patients, although rarely with the intensity and risks associated with opiates, barbiturates, and other sedatives. Nevertheless, the physician should know the patient well before prescribing BZDs and be alert for signs of concurrent alcohol or drug dependence (see Chapter 228 and Chapter 235). The efficacy of treatment should be evaluated regularly by follow-up visits, with special attention to proper use. The physician should avoid prescribing by phone, calculate exact quantities required, and remain wary of "lost prescriptions" or other signs of medication misuse. To justify continued treatment, the patient should demonstrate a decrement in anxiety, with enhanced performance or decreased avoidant behavior. Requiring the patient to be seen in person for an appointment at least every 3 months is a good guideline, as is stopping the prescription of the BZD if there is a problem with compliance (e.g., attendance at appointments). BZD overuse is uncommon in the absence of a past history of alcohol or drug abuse but can be a serious problem, at times a consequence of careless prescribing practices and inadequate patient education about proper drug use. If dose requirements escalate, especially if accompanied by addictive behaviors, referral is advised to the specialist experienced in treating this problem.

Side Effects, Tolerance, and Dependence. Side effects include *sedation* (especially in combination with alcohol or other sedative agents), *impaired memory* acquisition (including amnesia reported with single-dose triazolam use), and, rarely, *disinhibition* characterized by increased hostility or aggression. Alcohol and cimetidine slow hepatic BZD metabolism and increase risk of toxicity.

Daily use of BZDs over time leads to receptor adaptation (*tolerance*) and the development of *physical dependence*. Physicaldependence does not, however, imply misuse, abuse, or even loss of benefit. Rather, dependence denotes that a discontinuation syndrome will follow abrupt cessation of therapy. *Withdrawal* is usually accompanied by only mild symptoms but may include rebound anxiety, involuntary movements, insomnia, psychomotor restlessness, and perceptual changes.

Severe withdrawal symptoms are unlikely unless high doses or a high-potency preparation (especially a short-acting one) has been used daily for a prolonged time period and then halted abruptly. In such cases, a *delirium tremens*–like syndrome may develop. *Seizures* have been reported after sudden discontinuation of alprazolam after as short a time as 1 to 2 months of maintenance therapy. For less potent or long-acting BZDs, the risk of a severe abstinence syndrome is less. Chronic daily treatment is best discontinued by tapering doses over several weeks.

Selection of Agent. The available BZDs appear equally effective for the management of generalized anxiety symptoms when equipotent doses are used. In the future, one may see new BZDs with greater treatment specificity, because heterogeneity of brain BZD receptors has been demonstrated. For now, the essential differences among BZDs are in potency and pharmacokinetics (Table 226.4). These factors determine suitability for single-dose and maintenance use and risk of physical dependence and withdrawal.

DRUG	APPROXIMATE DOSE EQUIVALENCE (mg)	RELATIVE RAPIDITY OF EFFECT	HALF-LIFE (hr)
Alprazolam (Xanax)	0.5	Fast/Intermediate	12–15
Chlordiazepoxide (Librium)	10	Intermediate	5–30
Clonazepam (Klonopin)	0.25	Fast/Intermediate	15–50
Clorazepate (Tranxene)	7.5	Fast	30–200
Diazepam (Valium)	5	Fastest	20–100
Lorazepam (Ativan)	1	Intermediate	10–20
Oxazepam (Serax)	15	Slower	5–15

Table 226.4. Pharmacokinetic Properties of Commonly Used Benzodiazepines

For *single-dose use*, the desirable pharmacokinetic properties are rapid rate of onset and offset. Speed of absorption from the gastrointestinal tract is the most important factor determining onset. Capacity to traverse the blood–brain barrier is also a factor; the more lipophilic, the more quickly the drug enters the central nervous system. Lipophilicity also governs rate of clinical offset by determining how rapidly the drug is redistributed into lipid stores after a single dose. Serum half-life is not relevant to duration of action of single-dose use. *Diazepam* is rapidly absorbed and very lipid soluble, giving rapid onset and offset when used in single-dose fashion. Relatively rapid onset is usually desirable in situations in which single-dose use is prescribed.

For *maintenance use*, a drug's serum half-life is the pertinent parameter, affected by liver function and whether hepatic metabolites are active or inactive. Drugs with a short half-life are simply converted to water-soluble glucuronides and rapidly cleared by the kidneys. Their disadvantage is the potential for anxiousness and even mild withdrawal symptoms between doses. The longer half-life agents are more likely to accumulate. However, because of the development of drug tolerance, there is little additional risk of clinically important central nervous system suppression among most users of long-acting agents. The exceptions are the elderly and those with hepatocellular disease, in whom use of long-acting agents can lead to overwhelming drug accumulation that causes excessive sedation, drowsiness, and psychomotor impairment.

Determination of Dosage. Dosage must ultimately be determined empirically on a case-by-case basis. It is most prudent to begin with low doses and titrate up as

necessary. Most patients suffering from anxiety of lesser intensity than panic will not benefit from doses greater than 8 mg/d of lorazepam or its equivalent. Starting doses should typically not exceed the equivalent of 4 mg/d of lorazepam in young otherwise healthy adults who are BZD naive. In the elderly, starting and maximum doses should be approximately halved (see below). Steady state takes longer to achieve using drugs with a long half-life, an important consideration when deciding how often to adjust dose. A clinically useful rule of thumb is that steady state is 90% achieved after five drug half-lives.

Antidepressants. *Serotonin selective reuptake inhibitors* (SSRIs) are often used as first-line agents in the treatment of anxiety. They are among the most effective agents at eradicating the core symptoms of such anxiety conditions as *panic disorder, social phobia, generalized anxiety disorder, PTSD, and OCD.* As in depression, their beneficial effects are usually delayed for several weeks (see Chapter 227). *Tricyclic antidepressants* (TCAs) and the *monoamine oxidase inhibitors* (MAOIs) are generally used in the treatment of refractory patients.

Initiation of Therapy. Although the antidepressants are "first line" in terms of their efficacy, therapy is often initiated with BZDs to offer some immediate relief. Concurrently, or after anxiety symptoms are attenuated, antidepressant medication may be added. Once the antidepressant agent has become effective, some patients become entirely asymptomatic. In such instances, the BZD may be tapered down and even discontinued. In anxiety disorders, antidepressants are initiated with low doses (e.g., imipramine, 10 mg/d; fluoxetine, 10 mg/d), because brief symptom exacerbation may occur in some patients. Full antidepressant doses, if tolerated, are usually necessary. The recommended dose, for example, of paroxetine in the treatment of panic disorder is 40 mg/d.

Use in Specific Conditions. Two SSRIs (*sertraline and paroxetine*) have received U.S. Food and Drug Administration (FDA) indications for the treatment of *panic disorder*. There is a growing body of evidence supporting the use of the other SSRIs as well. *TCAs and MAOIs* have a long history of effectiveness in panic disorder. SSRIs may also be of utility in the treatment of *generalized anxiety disorder*, especially if panic attacks are present. Patients with *PTSD* respond best to initial use of antidepressants, with continuation based on treatment response and the constellation of symptoms. *OCD* patients respond especially well to SSRIs. There is some suggestion that the obsessions respond preferentially, whereas compulsions are best addressed through behavioral interventions combined with medications. Like the other anxiety disorders, *social phobia* has been shown to be effectively treated by most of the SSRIs, with several in the process of becoming FDA approved. Again, MAOIs have a long history of being particularly effective for social phobia, although their safety and side-effect profile restrict their use to treatment-resistant cases.

Buspirone is a non-BZD anxiolytic that acts as a partial serotonergic agonist and has mild anxiolytic and antidepressant effects. Because of its benign side-effect profile (nonaddicting and no withdrawal), buspirone is a reasonable alternative to BZDs in cases where *chronic anxiolysis* is required, especially when substance abuse or noncompliance is a concern. Risk from overdose is low, and the drug is well tolerated. Its anxiolytic effects are modest compared with those of the BZDs, and onset of action may take weeks, rendering the drug ineffective for single-dose use and of little help to patients with severe symptoms. Some efficacy has been reported in OCD. As a mild anxiolytic that may be taken frequently and safely, it may benefit patients with mild generalized anxiety or adjustment disorders. Treatment is initiated at doses of 5 mg three times a day and adjusted weekly in dose increments of 5 mg/d. In patients requiring more than 20 mg three times a day, referral to a specialist is recommended.

Beta-Blockers. b-adrenergic blocking agents blunt the peripheral catecholamine-mediated manifestations of anxiety. As such, they are very useful on a short-term as-needed basis for *performance anxiety* and stage fright (e.g., propranolol 10 to 20 mg as needed). In the case of a special performance, it is suggested that the patient try a test dose a few days earlier to determine both efficacy and side effects. Large doses may blunt psychomotor responses. For generally anxious patients with prominent somatic manifestations of adrenergic excess (e.g., tremor, palpitations), longer acting beta-blockers (e.g., atenolol 50 mg/d) facilitate symptom control when used alone or in combination with BZDs. They should be used with caution, if at all, in patients with asthma, heart failure, or heart block (see Chapter 32 and Chapter 48). Moreover, they may worsen symptoms if there is an underlying depression (see Chapter 227).

Anxiolytic Pharmacotherapy in the Elderly. Because drug metabolism is slowed in the elderly, excessive sedation is a risk with anxiolytic therapy, especially with use of long-acting agents.

Benzodiazepines. In most instances, nighttime use of a short-acting agent that has no active metabolites and in patients whose metabolism is relatively unaffected by aging is preferred. *Lorazepam and oxazepam* fulfill these requirements. Their elimination by hepatic conjugation to a water-soluble glucuronide for renal excretion changes little with age. Lorazepam is the faster in onset; oxazepam's onset is gradual. Their disadvantages include the need for frequent dosing if continuous anxiolysis is desired and rebound anxiety and insomnia if discontinued abruptly after prolonged use. Initial oxazepam dose is 10 mg; for lorazepam, it is 0.5 mg. Both are usually given before bed. Intake should be limited to short (5- to 10-day) courses or occasional as-needed use.

For more sustained anxiolysis, a BZD with a longer effective half-life may be required (Table 226.4). However, elimination of active drug metabolites lengthens with age, markedly prolonging drug half-life (e.g., from 20 to 90 hours for diazepam). Accumulation of active metabolites can cause diminished alertness and impair memory acquisition, mimicking dementia. Excessive sedation may cause a fall with serious injury—risk of hip fracture rises markedly with use of long-acting BZDs in the elderly. Initial doses should be small (e.g., the equivalent of 2 to 5 mg/d of diazepam) and increased slowly and cautiously. It may take up to 2 weeks to achieve steady-state levels after a change in dosage.

Antipsychotics. In the elderly, anxiety accompanied by agitation or specific psychotic manifestations may require short-term antipsychotic therapy. The *atypical antipsychotics* have become first-line agents, including *olanzapine* (Zyprexa), *risperidone* (Risperdal), *quetiapine* (Seroquel) and *clozapine* (Clozaril). A small dose of a high-potency typical antipsychotic such as *haloperidol* (Haldol) or *fluphenazine* (Prolixin) is another option. Lower potency agents (e.g., chlorpromazine, thioridazine, perphenazine) necessitate use of higher doses and increase the risk of hypotensive, cardiovascular, and anticholinergic side effects.

Antidepressants. Of the antidepressants, SSRIs are the best tolerated (see Chapter 227). Of the TCAs with anxiolytic activity, those with low anticholinergic and antiadrenergic side effects (e.g., nortriptyline) are preferred. Because antidepressant metabolism slows with age, one should start with half the usual dose and titrate up slowly.

Beta-Blockers. Beta-blocker use requires particular caution, given the prevalence of congestive heart failure, heart block, and obstructive lung disease in the elderly and their susceptibility to such side effects as cognitive blunting, nightmares, and depression.

THERAPEUTIC RECOMMENDATIONS AND INDICATIONS FOR REFERRAL

General Guidelines

- Begin with supportive psychotherapy that includes explanation, empathic listening, meaningful reassurance, guidance, and encouragement.
- Teach relaxation techniques for the patient willing to use them (see Appendix).
- Consider referral for insight-oriented therapy when there is emotional upheaval or disabling symptoms.
- Supplement psychotherapeutic measures with anxiolytic drug therapy to improve the patient's ability to perform daily activities previously impaired by anxiety. In most instances, use only in an adjunctive role for a limited duration. If BZD therapy is used, advise of the risk of physical dependence. Inform that drug treatment is likely to reduce symptoms but not eradicate them.
- Refer if there is evidence of substance abuse, either as an etiologic factor or as a mode of self-treatment.

Situational Anxiety and Adjustment Disorder

- Initiate supportive psychotherapy and behavioral therapy, including identification of specific provocative stressors and their association with the onset of symptoms.
- If distress from anxiety impairs daily functioning, begin a short course (up to 5 days) of BZD therapy (e.g., clonazepam 0.5 mg twice daily).
- If the distress represents one of many such episodes in a pattern of emotional upheaval, refer for insight-oriented therapy. Also refer if symptoms endure beyond the stressful period or worsen despite treatment.

Generalized Anxiety Disorder

- Initiate supportive psychotherapy and consider insight-oriented therapy to help diminish the role of psychosocial stressors.
- Consider a short course of BZD therapy for periods of exacerbation (e.g., alprazolam 0.5 mg three times a day for up to 5 days).

- Prescribe an SSRI if there is a history of associated panic attacks or depression (e.g., begin with venlafaxine–extended release [Effexor-XR] 37.5 mg twice daily and advance dose as tolerated to 150 mg twice daily).
- Avoid chronic BZD therapy due to risk of dependency. If the patient is coming off long-term therapy, taper over several weeks according to the patient's ability to tolerate decreases. Monitor for any withdrawal symptoms (e.g., tinnitus, perceptual changes, involuntary movements).
- Consider a trial of buspirone if chronic anxiolytic therapy is desired. Begin with 5 mg three times a day and gradually advance to a maximum of 60 mg/d. Risks of physiologic dependence and withdrawal are nil, but potency is low and it may take weeks to notice any effect.
- Refer patients with disabling chronic anxiety for psychiatric care.

Panic Disorder

- Use pharmacologic therapy to achieve control and minimize phobic avoidance and depression.
- Screen for suicidality (see Chapter 227), especially if patient is despondent; refer urgently if there is concern. Otherwise, begin therapy with a low dose of a serotonin reuptake inhibitor (e.g., paroxetine 10 mg daily). If agitation is not increased, proceed gradually to full antidepressant doses (e.g., paroxetine 40 mg/d; sertraline 150 mg/d).
- In situations where the cost benefits of a generic TCA override the better tolerability of an SSRI, start with a small "test" dose (e.g., imipramine 10 mg q.h.s. and proceed gradually as tolerated to 100 to 200 mg q.h.s.). The added costs of cardiac monitoring and blood levels of the TCAs must be factored into the cost-benefit equation.
- Alternatively, an MAOI antidepressant may be prescribed, but dietary restriction and expertise in its use are required (see Chapter 227).
- If rapid relief is sought due to presence of disabling phobic behavior, start with a potent BZD (e.g., alprazolam 0.25 to 0.5 mg four times a day or clonazepam 0.5 mg q.h.s. or twice daily), pending onset of benefit from antidepressant therapy.
- After a period of well-being, taper BZD medication to the lowest possible maintenance dose or proceed to discontinuation.
- Weigh continued BZD use against risk of dependence. Use of potent BZDs poses risks of dependence and severe withdrawal. Taper slowly over several weeks when discontinuing therapy that has been continuous for more than 6 weeks.
- Refer patients with prominent phobic behavior and those with suicidal ideation.
- For patients requiring longer term maintenance therapy, it is important to continue the antidepressant medication at its full acute-phase dose.

Social Phobia

- Refer for behavioral therapy.
- Prescribe a BZD on an as-needed single-dose basis to help attenuate anxiety, decrease avoidance, and facilitate daily functioning and behavioral therapy.
- Prescribe a low-dose SSRI (e.g., paroxetine 10 mg q.h.s.) and proceed gradually to full antidepressant doses (paroxetine 40 mg q.h.s or fluoxetine 20 to 40 mg q.a.m.).
- For patients whose performances are compromised by ordinary "stage fright," consider a trial of a beta-blocker (e.g., propranolol 10 mg, up to 20 mg four times a day) on an as-needed basis. Give a preperformance trial dose to be sure performance is not compromised by the medication.

Specific Phobias

- Refer for behavioral therapy.
- Consider rapidly acting single-dose BZD therapy (e.g., alprazolam 0.25 to 0.5 mg or diazepam 10 mg) on an as-needed basis to provide symptomatic control in anxiety-provoking situations and to facilitate behavioral therapy.

Obsessive-Compulsive Disorder

- Refer for behavioral therapy.
- Initiate pharmacologic therapy with an SSRI.
- Refer to an experienced psychopharmacologist for further management of the drug treatment program.

Posttraumatic Stress Disorder

- Refer to a psychiatrist specializing in the treatment of such persons. Most programs begin with an SSRI. Mood stabilizers may be helpful for prominent irritability or anger. BZDs may sometimes be helpful in the short term but must be used with caution because of the risk of substance abuse in this vulnerable population of patients.
- Refer to an experienced psychotherapist. Three psychotherapy techniques—exposure therapy, cognitive therapy, and anxiety management—are considered to be the most useful in the treatment of PTSD. Expert therapists make distinctions among the techniques depending on which specific type of symptom presentation is most prominent. Insight-oriented psychotherapy helps to overcome emotional memories of the traumatic event; behavioral techniques may also be of benefit.

Treatment of the Elderly

- Reduce starting doses of medications by one half of the usual adult dose.
- When using BZDs for short-term anxiolysis, prescribe lorazepam or oxazepam. For chronic anxiolysis, use longer half-life agents with caution and at reduced doses and dose intervals.
- If antidepressants are indicated for anxiolysis, consider an SSRI (e.g., fluoxetine) or an MAOI (see Chapter 227).
- If agitation, "sundowning," or psychotic features accompany anxiety, prescribe small doses of an atypical neuroleptic (e.g., risperidone 0.5 mg once or twice daily).

CHAPTER 227 APPROACH TO THE PATIENT WITH DEPRESSION

JOHN J. WORTHINGTON III, SCOTT L. RAUCH

INTRODUCTION

Most patients with depression present to primary care physicians, often complaining of somatic symptoms. The frequency, treatability, and potentially serious consequences of depression make its diagnosis and management high priorities for the primary care physician. Unfortunately, the diagnosis is often not made. Sometimes it is not evident because the symptoms may masquerade as a variety of psychiatric or somatic conditions. Moreover, the stigma of psychiatric diagnosis can impede recognition of depressive illness by both patients and physicians. A pair of simple questions about mood ("down, depressed, or hopeless") and anhedonia ("little interest and pleasure") in the prior 2 weeks can be an effective screen. It is incumbent on the primary care physician to be vigilant in asking about such symptoms of depression.

Updated: 6/27/03

PATHOPHYSIOLOGY AND CLINICAL PRESENTATION

Mechanisms

The purported mechanisms of depression include psychodynamic, cognitive, genetic, neuroendocrine, and neurotransmitter determinants. Depression most likely represents a complex combination of these elements. Genetic factors and/or early childhood experiences may render persons more susceptible to depression. Neurotransmitter and neurohumoral elements probably serve as important effector pathways for development of symptoms.

Psychodynamic origins are believed to involve difficulties with formation and maintenance of self-esteem, which may occur from having hypercritical parents or being abused. In addition, growing up in an emotionally unresponsive environment may compromise learning ways to effectively cope with situational stresses. Suffering loss or failure as an adult is likely to be difficult, poorly responded to, and capable of reawakening prior painful feelings of inadequacy and worthlessness that lead to depression. Rigid dysfunctional defenses may be erected in an attempt to minimize the chances of loss or failure.

The cognitive perspective views depression as the consequence rather than as the origin of negative or distorted thinking. Subscribing to inflexible rules of conduct and unattainable goals can be a setup for failure and loss of self-esteem. Setbacks are viewed as a reflection of one's unworthiness and inadequacy.

Genetic determinants have been discovered from studies of twins, chromosomes, and pedigrees. In some pedigrees, there appears to be a dominant gene with incomplete penetrance. A family history of affective disease is commonly elicited. Major depression is up to three times more common among first-degree relatives of people with the disorder than in the general population.

Neurotransmitter basis of depression began with the finding that reserpine could induce depression and monoamine oxidase inhibitors could reverse it. This led to the identification of altered neurotransmitter metabolism as an important biochemical concomitant of depression and to the discovery of new antidepressant drugs, each increasing the availability of a major central neurotransmitter (e.g., norepinephrine, serotonin, or acetylcholine), usually by selective inhibition of reuptake.

Neuroendocrine hypotheses derive from the observation that most neurovegetative manifestations of depression (changes in appetite, libido, diurnal rhythms) involve hypothalamic functions. In addition, links between neurotransmitter release and neurohormone activity have been identified. Corticotropic-releasing hormone is believed to play an important role, resulting in hypercortisolism. Early morning awakening, reflecting an abnormal advance in circadian rhythm, may be one consequence.

Psychological and Somatic Manifestations

Depression's clinical presentation includes a host of psychological and bodily complaints.

Psychological Manifestations. Sadness is a very common symptom. Irritability, discouragement, loss of interest, worry, frustration, and decreased libido comprise the major dysphoric manifestations and may occur in the absence of overt sadness (Table 227-1). Some patients become preoccupied with physical complaints, such as pain or bowel dysfunction. Others exhibit changes in memory, concentration, or self-image. Diurnal mood variation is characteristic, with symptoms often worse in the morning and improving as the day progresses.

Psychological Symptoms and Signs
Mood sad, "blue," and "down"
Depressed affect
Anxiety
Irritability or anger
Anhedonia (lack of pleasure)
Loss of interest in environment
Loss of interest in activities
Loss of interest in sex (decreased libido)
Social withdrawal
Guilt (may be delusional)
Poor self-esteem
Self-deprecatory thoughts
Poor concentration or indecisiveness
Rumination or obsessive thoughts
Feelings of helplessness or hopelessness
Recurrent thoughts of death or suicide
Psychotic symptoms (e.g., delusions or hallucinations)
Multiple physical complaints or hypochondriacal fears

Neurovegetative Symptoms and Signs
Sleep disturbance (frequently early morning awakening)
Decreased energy
Appetite disturbance (usually decreased)
Diurnal mood variation (usually worse in morning)
Psychomotor retardation or agitation

Table 227-1. Clinical Presentation of Depressive Syndromes

Depressed affect can be subtle, at times only noticed when sadness ensues from talking with the patient. As depression worsens, psychomotor abnormalities may appear. Although psychomotor retardation, with slowed speech and a long latency before the patient answers questions, has been thought of as the classic presentation of depression, in fact, anxiety is the much more common symptom. Nearly three fourths of patients with a depressive disorder have worry, psychic anxiety, or somatic anxiety as one of their presenting symptoms.

Somatic Manifestations Distinctive neurovegetative symptoms include *disturbed sleep* (most commonly *early morning awakening*), *lack of energy*, and *decreased appetite*. Neurovegetative symptoms are predictive of responsiveness to psychopharmacologic intervention. In what is termed an *atypical depression*, patients may exhibit *increased sleep and increased appetite* (hypersomnolence and hyperphagia).

Diagnostic Classification (Based on the Diagnostic and Statistical Manual, 4th edition)

Although no single classification system is universally accepted, the current standard of diagnosis in the United States is the American Psychiatric Association's

Diagnostic and Statistical Manual, 4th edition (DSM-IV) (Table 227-2).

Table 227-2. Classification of Depressive Syndromes

Major Depression (Unipolar Depression) This is the DSM-IV term for serious depression that is accompanied by neurovegetative symptoms. Lifetime risk of developing a major depression is estimated to be one in four for women and one in eight for men. Dysphoric mood typically dominates the clinical picture and is persistent. Four or more of the major neurovegetative symptoms dominate the clinical picture and are present for a minimum of 2 weeks, including appetite disturbance, sleep disturbance, psychomotor retardation or agitation, anhedonia, loss of energy, feelings of worthlessness or guilt, decreased concentration, and suicidal thoughts.

Onset is variable. Symptoms usually develop over weeks to months, but they may develop suddenly. Situational factors surrounding the onset of the illness have no bearing on the diagnosis. Historically, distinctions were made between *endogenous and reactive depression*, but an identifiable precipitant is no longer considered pertinent with respect to diagnosis. Frequency of episodes appears to increase with age. At least half of patients have recurrent episodes. A family history of a major affective disorder (major depression or bipolar disorder) is common. The relationship between alcoholism and depression remains controversial.

Major Depression with Psychotic Features. A subclassification of major depression, this disorder has the additional features of delusions, hallucinations, bizarre behavior, or disorganized thinking.

Major Depression in the Elderly. In the elderly, depression can mimic dementia. The patient may appear withdrawn, unkempt, inattentive, or even confused. The condition may be due to depression alone or to a combination of depression and dementia.

Bipolar Disorder–Depressed Phase. The presentation of a depressive episode in a bipolar (manic-depressive) patient is identical to that of major depression, except there is a history of prior manic or hypomanic episodes. *Mania* is manifested by periods of elation or expansive mood, increased energy, decreased need for sleep, inflated self-esteem, and overinvolvement in activities, accompanied by a decreased concern for the consequences. Its diagnosis requires adequate severity to substantially impair level of functioning. If the hallmark symptoms of mania exist, but the patient shows no decrement in functioning, the patient is described as *hypomanic*.

Distinguishing between unipolar and bipolar depressions is very important in determining treatment (see below).

Dysthymic Disorder. This category denotes a chronic low-grade depression, characterized by pervasive dysphoric mood for at least 2 years. Some complain of life-long feelings of depression. Symptoms are less severe than those of major depression and neurovegetative symptoms are fewer. Depression appears as an integral part of personality or their character (hence the older term *characterologic depression*). Such patients can be frustrating to treat because of chronic dysphoria, self-pity, and development of irrational patterns of negative thinking (e.g., "things always go wrong for me"). The physician typically develops feelings of helplessness and may unconsciously communicate a wish that the patient would go away.

Typically, onset is in adolescence or early adult life and accompanied by other symptoms of a *personality disorder*, such as a history of difficulty with interpersonal relationships, manipulativeness, feelings of emptiness, and lack of an identity. A subpopulation of dysthymic patients seems to have an attenuated chronic form of major depression with onset later in life after a period of good functioning. Neurovegetative symptoms may be more prominent.

Dysthymia and major depression can coexist in a given patient (so-called "*double depression*"), when a major depressive episode evolves in the context of preexisting dysthymia. However, incomplete recovery from a major depression should be described as major depression in partial remission rather than dysthymia.

Cyclothymic Disorder. This state resembles bipolar illness, but the mood swings are less severe. These patients have a chronic mood disturbance characterized by periods of depression alternating with periods of elevated mood. Neither are of sufficient severity or duration to meet the criteria for major depressive or manic episodes. Interspersed may be periods of normal mood lasting as long as several months.

Seasonal Affective Disorder. This depressive variant is distinguished by its seasonal pattern, characteristically beginning in the fall and ending about 5 months later. It has been linked to lack of light exposure and is more common in northern latitudes. Alterations in serotonin activity have also been noted. As in other forms of depression, sadness is the dominant affect, and fatigue and decreased libido are common. Atypical features include tendencies to overeat and oversleep. In the United States, women are more commonly affected than men (ratio, 3:1). Age of onset is typically in the 20s.

Adjustment Disorder with Depressed Mood. This occurs after a *significant life stress*. Patients usually present with depressed mood associated with feelings of hopelessness, helplessness, worthlessness, and anxiety. Their thoughts are often dominated by the problems that precipitated the episode. Sleep and appetite disturbances are common but are less severe and less persistent than in major depression. The condition is usually self-limited, lasting less than 6 months and improving when the stress is removed or the individual evolves a more adaptive coping mechanism. It is important to note that any patient with symptoms severe enough to meet the criteria for major depression (described above) should receive that diagnosis regardless of the history of a precipitant. The message that the primary care physician should gather from this chapter is that evaluating the depressive symptoms, regardless of a *suspected precipitant*, is crucial, and possibly life saving, in initiating antidepressant treatment.

DIFFERENTIAL DIAGNOSIS

It is important to consider organic causes of depression, including *drug-related* etiologies, which are among the most common (Table 227-3). Chronic feelings of fatigue and dysphoria are nonspecific symptoms common to multiple medical conditions whose differential diagnosis includes *chronic fatigue syndrome, Lyme disease, fibromyalgia, rheumatoid disease, and endocrinopathies* (see Chapter 8). Patients experiencing domestic violence may present with frank major depression or multiple bodily complaints (e.g., headache, gastrointestinal symptoms, premenstrual difficulties, sexual dysfunction) mimicking depression. In addition, several psychiatric disorders can masquerade as depression.

Table 227-3. Organic Etiologies of Depression

Uncomplicated Bereavement. Symptoms of normal grief may initially be identical to those of depression. The question of a superimposed depression should be raised if mourning continues for more than 6 months, if neurovegetative symptoms are particularly severe, if there is severe impairment in the patient's ability to function, or if psychotic symptoms emerge.

Alcoholism and Drug Dependence. Many alcoholic patients appear depressed. It is not possible to delineate which symptoms are due to alcohol and which, if any, might be due to a primary affective disorder until the patient has been fully detoxified. Other substance abuse disorders may mimic depression, especially abuse of sedative-hypnotics or withdrawal from psychostimulants.

Personality Disorders. These patients frequently complain of depressive symptoms, with periods of severe dysphoria, but their affective symptoms often fluctuate markedly with environmental changes (especially with changes in interpersonal relationships). Poor impulse control, histories of unstable relationships, and a striking quality of manipulativeness or entitlement are other clues to primarily characterologic pathology.

WORKUP

The possibility of depression should always be considered in patients who present with fatigue, poor sleep, appetite disturbances, multiple bodily complaints, and expresses feelings of hopelessness or poor self-esteem. The onset of depressive symptoms and signs in patients with chronic debilitating disorders or chronic pain can be slow and subtle and should not be overlooked. When depression is suspected, specific inquiry into its manifestations is needed. However, before proceeding with the inquiry, it is useful to complete a detailed medical history for "organic" etiologies (including elicitation of specific patient concerns) and to follow later with a detailed physical examination, especially in patients who present complaining of somatic symptomatology. Not to do so risks alienating the patient, who wants his or her medical complaints taken seriously. Also useful are a few words to explain the rationale for considering depression (e.g., "it's a serious treatable condition and listed as one of the important causes of the symptoms bothering you"). These few simple measures facilitate patient understanding and impart a sense of seriousness and thoroughness to the workup. In addition, they help reduce the stigma of considering a psychiatric diagnosis.

History

Strategy. The dimensions to explore include neurovegetative symptoms, multiple bodily complaints, psychosocial history, and past psychiatric history of patient and family. It is helpful and often less threatening to ask first about neurovegetative symptoms such as sleep, appetite, and energy. If the responses are suggestive of depression, one can proceed to inquire about mood and any loss of interest in sex, family, job, and other sources of interest or pleasure. In addition, the patient should be queried about self-opinion and any self-critical feelings. With every depressed patient, it is critical to ask about suicidal thoughts and intentions (see below). Also useful in the exploration of multiple bodily complaints is consideration of systemic illness that might mimic depression.

Screening for Neurovegetative Symptoms. Specific inquiry into these characteristic symptoms is facilitated by the mnemonic *SIG E CAPS* ("prescribe an energy capsule"):

S—Is your *sleep* disturbed?

I—Have you noted a loss of libido or *interest* in your usual activities?

G—Are you feeling *guilty* or having self-deprecatory thoughts?

E—Have you noticed a decrease in your *energy* level?

C—Have you been having trouble *concentrating*?

A—Have you experienced changes in your *appetite* and weight?

P—Have been physically slowed down or sped up (i.e., experienced *psychomotor* abnormalities)?

S—Have you had thoughts of *suicide*, feelings of hopelessness, or preoccupation with issues related to death? (See below for more detail.)

Checking for Multiple Bodily Complaints and Ruling Out Organicity. Patients with low energy, dysphoria, and multiple bodily complaints out of proportion to physical findings are likely to have depression, but, as noted earlier, they still require careful consideration of conditions that may present in similar fashion, such as *chronic fatigue syndrome, Lyme disease, fibromyalgia, rheumatoid disease, vasculitis, and endocrinopathies* (see Chapter 8 for details of workup). In addition, depression or multiple bodily complaints may be the clinical presentation of *domestic violence*. Screening for this condition can be as straightforward as asking: "At any time, has a partner ever hit you, kicked you, or otherwise physically hurt you?"

Confusion and alterations in level of consciousness strongly suggest organicity, although they are not always present. When they are, drug-induced etiologies are important to consider. Onset is usually temporally related to medication use and should be sought. Worth noting are any use of *antiarrhythmics, antihypertensives, sedative-hypnotics, and corticosteroids*, as well as over-the-counter agents and substances of abuse. The relation of *beta-blockers* to depression remains inconclusive, but risk appears greatest for those that are lipophilic and readily cross the blood–brain barrier. The elderly are particularly susceptible to adverse central nervous system (CNS) effects from drugs that cross the blood–brain barrier.

Primary neuropathology should be sought when depression is accompanied by an alteration of neurologic function. *Left frontal lobe* involvement by a *mass lesion or stroke* may trigger a depressive syndrome. Inquiry into focal signs and symptoms help to differentiate a structural lesion from a functional affective disorder.

In some medical illnesses, depression may dominate the early clinical picture. *Pancreatic cancer* is the archetypal example. Important associated findings should be sought, including profound weight loss, vague upper abdominal discomfort, and onset of painless jaundice (see Chapter 58). *HIV infection* and emergence of *AIDS* are frequently associated with depression. In such cases, the diagnosis may be obscured by comorbid medical illness (see Chapter 13). Also, depressive features may mistakenly be conceptualized as normal grief in response to the medical diagnosis and surrounding tragedy.

Psychosocial History. This should focus on the patient's current home environment and means of financial and emotional support. Does the patient live alone? If not, is the family environment accepting or, conversely, contributing to the patient's discomfort? The availability of responsible family members to observe and supervise the patient might mean the difference between outpatient treatment and hospitalization if the patient is very depressed or debilitated. What are the patient's

daily responsibilities and what secondary stressors arise if the patient cannot meet these obligations?

Psychiatric History of the Patient and Family. Once the issue of medical etiologies has been put to rest, one should return to eliciting a past psychiatric history. Given depression's tendency to recur, the patient should always be asked about similar episodes in the past. If there is a history of depressive or manic disease, it is important to obtain the details of treatment and treatment response. A history of prior psychosis or suicidality is also important to elicit, because of their risks for recurrence.

Family history can be difficult to elicit because of shame about any mental illness in the family. It helps to explain that depression is thought to run in families because of hereditary biochemical factors, not defects in character. A family history of major depression, bipolar disorder, or suicide supports a diagnosis of depression in the patient. The genetic predispositions for unipolar depression and bipolar illness are distinct.

A family history of other psychiatric diagnoses must be interpreted in the context of changing nomenclature and diagnostic criteria. In the past, mania was frequently misdiagnosed as schizophrenia. "Nervous breakdown" or "going insane" were common nonspecific terms. If family psychiatric history is present, it is worth reviewing symptoms and attempting a tentative retrospective diagnosis.

Physical Examination

The importance of a careful and detailed physical examination cannot be overemphasized, especially because most depressed patients presenting to primary physicians harbor concerns about medical illness. Specific patient concerns elicited during the history should be explicitly checked for during the physical examination to facilitate the provision of meaningful reassurance. (See Chapter 8 for description of the pertinent physical examination.)

Mental Status Examination. Much of the mental status examination can be performed by taking note of the patient's appearance, affect, behavior, and responses during the history. Has the patient's condition interfered with grooming and self-care? Is there sadness, tearfulness, despondency, apathy, irritability, anxiety, or anger? Is there psychomotor retardation or agitation? Does the patient offer anything spontaneously, or is there a long period of hesitation before answering (i.e., speech latency)? Is the speech slow? Is normal inflection present?

The patient should also be asked explicitly to describe his or her *mood*. Thought is assessed for form and content. Is the patient's thought pattern clear and coherent or is it tangential, circumstantial, or nonsensical? Are there ideas of worthlessness, helplessness, hopelessness, guilt, suicidal thought, or homicidality?

Is the patient able to maintain *attention*? Distractibility may occur in depression, delirium, dementia, or severe anxiety and will interfere with the patient's overall cognitive performance. Any inattention is worth documenting by testing ability to recall a series of random numbers (digit span). Patients should be able to repeat a series of at least five to seven numbers without error. "I don't know" answers are reflective of apathy or lack of energy associated with depression. Tests of memory, calculation, abstractions, and other higher cortical functions should be performed.

Although psychotic depression is uncommon in primary care settings, it is important not to miss this very serious condition. It should be noted whether the patient appears guarded or expresses paranoid thoughts or delusions. Inquiry into any unusual experiences, such as hearing voices or seeing things that other people do not see, provide further evidence of a thought disorder. However, unusual smells, tastes, and tactile experiences suggest an organic brain syndrome.

Evaluation for Suicidality. Depression is a potentially fatal illness. Assessment of suicide risk is an integral part of the workup of every depressed patient. About 15% of patients with major affective disorders take their lives; diagnosing and treating depression can be a life-saving medical intervention by the primary care physician. With proper intervention, most suicides can be prevented. Concurrent conditions that increase the risk of suicide include chronic alcoholism, personality disorders, and both functional and drug-induced psychoses; delusional beliefs or hallucinations may lead to self-destruction. Predicting a suicide attempt is difficult, even among patients who complain of suicidal thoughts. Assessment of risk is facilitated by specific inquiry.

Technique. Assessing risk of suicide requires attention to the patient's *thoughts* (ideas, wishes, motives), *intent* (the degree to which the patient intends to act on the thoughts), and *plans*. Inquiry necessitates a calm empathic approach that allows expression of feelings and is free of any implied criticism. On any expression of hopelessness, helplessness, or suffering, one might begin with a rather indirect query (e.g., "Are you feeling so badly that sometimes you would prefer not to go on living?"). A positive response is followed by more direct questions about self-destructive thoughts and plans. A well worked out, realistic, and potentially lethal plan suggests great risk, as does the act of putting one's affairs in order.

Asking patients about suicide does not put the idea into their heads. Pitfalls include failure to ask specifically about suicidal thoughts and feelings and premature interruption of the patient who mentions suicide. Any mention of suicide must be taken seriously, and *every* depressed patient must be asked about suicide. It is an error to avoid the subject for fear of doing so. Truly suicidal patients usually are relieved to be asked about it.

Mental status, especially the patient's ability to resist suicidal thoughts, is important to consider. An extremely impulsive, psychotic, or intoxicated patient has no meaningful internal controls and will require hospitalization.

Assessment of Risk. There is no simple formula for precisely assessing suicide risk. Attention to thoughts, intent, and plans is essential, facilitated by consideration of mental status and pertinent psychosocial and demographic predictors (Table 227-4). Patients expressing suicidal thoughts, especially if accompanied by intent and plans, or who lack reliable internal controls to resist suicidal impulses require emergency psychiatric consultation. Such patients should be closely supervised and not allowed to transport themselves. Patients with severe or worsening depression who have thought about suicide but steadfastly deny intent or plans should be given a prompt confirmed appointment with a psychiatrist. Depressed patients with no suicidal thoughts, intent, or plans; a normal mental status examination; and external social supports can be treated by the primary care physician, as long as frequent visits can be arranged and the depression responds to treatment. Patients with suicide potential should never be given more than 1 g or a week's supply of a tricyclic antidepressant (see below).

History of prior attempts
Depression
Psychotic features present (especially command hallucinations)
Substance abuse
Positive family history of suicide
Living alone
Age: in males, risk increased with age peaking at 75; in females, the peak for completed suicide is 55–65.
Sex: females attempt suicide three to four times more often than males, but males are successful two to three times more often than females.
Marital status: at great risk are those who never married; are widowed, separated, or divorced; or married without children; those married with children are at least risk.
Employment: unemployed are at greater risk than employed; unskilled are at greater risk than skilled.
Physical illness: 50% of all patients who attempt suicide have a physical illness. At highest risk are those with chronic pain, diagnosed chronic disease, recent surgery, or a terminal illness.

Table 227-4. Risk Factors for Suicide

Laboratory Studies and Use of Diagnostic Instruments

There are no laboratory tests for depression. For a time there was interest in urinary catecholamine metabolites and the overnight dexamethasone suppression test, but shortcomings in sensitivity and specificity compromised clinical utility. Depression remains a clinical diagnosis. Nonetheless, medical causes of depressed mood and neurovegetative symptoms must be ruled out (see Chapter 8).

Written Diagnostic Instruments for In-Office Evaluation. Validated diagnostic instruments are sometimes useful supplements to the clinical evaluation. The *Beck Depression Inventory* and the *Hamilton Depression Scale* (HAM-D) help to assess severity and can be used to follow response to therapy and clinical course. The Beck Depression Inventory is a 21-item self-administered questionnaire. The Hamilton Depression Scale is a 21-item instrument that must be clinician administered.

Both take approximately 15 minutes to complete and score. The higher the score, the more severe the distress.

PRINCIPLES OF MANAGEMENT

Overall Strategy

Depression is a potentially life threatening yet treatable condition. Most depressed patients (particularly those with major depression) can be treated as outpatients by their primary care physician. *Antidepressants and psychotherapy* represent the basic treatment modalities, adapted to the specific type of depressive order encountered. *Psychiatric referral* should be considered in severe cases and in those with psychotic, bipolar, or characterologic qualities.

Major Depression. The cornerstone of treatment for major depression (unipolar depression) is antidepressant medication. Psychotherapy plays a very important adjunctive role.

Bipolar Disease. Psychiatric referral is required for management of bipolar disease, which responds well to a combination of a mood-stabilizing agent and antidepressant therapy.

Psychotic Depression. Neuroleptics are required as well as psychiatric consultation. If there is an organic cause (*secondary depression*), one treats the causative medical illness and discontinues potentially offending medications. Only if the medical condition responds slowly or is intractable are trials of an antidepressant or supportive psychotherapy indicated.

Characterologic Depression/Dysthymic Disorder. A characterologic depression responds best to psychotherapy, but, when neurovegetative symptoms are prominent, a trial of antidepressants would be helpful. Dysthymia has recently been shown to be responsive to selective serotonin reuptake inhibitors (SSRIs). A patient with untreated dysthymia is five times more likely to subsequently develop an episode of major depression.

Adjustment Disorder with Depressed Mood. This can be treated by the primary care physician with supportive psychotherapy. If moderate sleep and appetite disturbances are present (as they commonly are), an antidepressant can provide symptomatic relief.

Management of major depression has two facets, psychotherapeutic and medical. The primary care physician needs to become skilled in providing supportive psychotherapy and using first-line antidepressants.

Psychotherapy

Treatment begins with establishing a strong patient–physician relationship (see Chapter 1.1) and providing psychological support. More intensive psychotherapy may also be beneficial. The addition of antidepressant medication improves prognosis. Psychotherapy and medication are often synergistic.

Psychological Management (Supportive Psychotherapy). Patients with major depression benefit from supportive psychotherapy, much of which can be provided by the primary care physician. A clear, empathic, hopeful manner helps to forge a therapeutic alliance and facilitates treatment. A detailed explanation of the diagnosis combined with reassurance that depression is eminently treatable do much to calm a fearful patient and family. When patients feel hopeless or undeserving, it is useful to point out that these are the characteristic symptoms of depression and they will gradually improve.

While conveying hope and optimism, the physician must take care not to dismiss as insignificant the patient's fears, pains, and negative feelings. Many feel overwhelmed by life stresses. It is important to identify these stresses. Empathic listening and thoughtful comment can help the patient devise strategies for coping. At the outset of treatment one should see the patient every 1 to 2 weeks for about half an hour. Appointments can then be spaced out according to the patient's needs. If a patient becomes severely depressed, agitated, or psychotic, emergency psychiatric referral should be made.

Cognitive-behavioral therapy has shown promise in depressed patients with medical problems, helping to reduce the depression accompanying the problem and improving control of the underlying medical condition through improved compliance.

Social and Environmental Interventions. A caring family willing to monitor the severely depressed patient can make the difference between outpatient management and hospitalization. Members can ensure medication compliance and follow-up appointments and minimize social isolation. Also helpful is identifying stressful elements in the patient's environment so that they might be modified. Worries about the consequences of taking time off from work and issues of confidentiality must be addressed. Helping the patient deal with these important concerns is essential and greatly appreciated.

Psychopharmacologic Therapy

The SSRIs serve as first-line antidepressants. Tricyclic antidepressants (TCAs) can be effective in patients who do not respond to initial trials of SSRIs. The monoamine oxidase inhibitors (MAOIs) and lithium are reserved for special situations.

Selective Serotonin Reuptake Inhibitors. As their name implies, the SSRIs (e.g., *fluoxetine [Prozac], sertraline [Zoloft], paroxetine [Paxil], fluvoxamine [Luvox], and citalopram [Celexa]*) affect CNS serotonin metabolism. All require 3 to 4 weeks of continuous use before clinical improvement becomes evident. For mild to moderate depression, they appear to be equal in efficacy to the TCAs and better tolerated. For severe depression, there has been controversy as to whether the SSRIs are as effective as the TCAs. Unlike the TCAs, many of which are sedating, many SSRIs have *energizing* or "activating" side effects, a factor favoring their selection in patients suffering anergy, apathy, and psychomotor retardation. They have become the antidepressant of first choice, especially in circumstances where avoidance of tricyclic side effects is desired. Randomized controlled trials have found the major SSRIs to be similar in efficacy, safety, and side effects. However, a period of trial and error is often necessary to determine the optimal agent and best dose for a particular patient.

Updated: 2/13/02

Side Effects. These activating agents can exacerbate agitation, anxiety, and insomnia, making them problematic for depressed patients already troubled by such symptoms. The motor *restlessness* (including tremor), initial *anxiety*, and *agitation* with insomnia can be the most distressing side effects of SSRIs. Concerns about exacerbation of suicidality with SSRI use proved unfounded after detailed investigation. Nonetheless, it is always crucial to remain vigilant and inquire specifically about suicidal thoughts, even as patients begin to show improvement (see below).

Paradoxically, up to 20% experience some *sedation*. Unlike the TCAs, with their associated anticholinergic and alpha-blocking activity, there is little risk of orthostatic hypotension, tachycardia, heart block, blurred vision, or dry mouth. *Sexual dysfunction* has been reported, including impotence in men and decreased lubrication in women. Decreased libido and anorgasmia may occur in both men and women. These effects are reversible, but a common cause of discontinuation of therapy (see below). Some weight gain from appetite stimulation may occur, but not to the extent associated with TCAs. *Headache, nausea, and diarrhea* have also been reported. All SSRIs can cause a life-threatening reaction if taken concurrently with an *MAOI*. At least 2 weeks should pass before starting an MAOI after SSRI use and 5 weeks after fluoxetine use.

Some SSRIs (fluoxetine, paroxetine, and fluvoxamine) *inhibit liver cytochrome P-450 enzymes*, slowing hepatic drug metabolism and prolonging the effects of warfarin, phenytoin, and other drugs that are hepatically metabolized. Although SSRI use in *pregnancy* does not increase the risk of birth defects or retard development of intelligence, there is some increase in risk of perinatal complications when treatment is continued during the third trimester.

Dosage. *Fluoxetine* is available in 10- and 20-mg capsules. Some patients with prominent anxiety symptoms do better to start with the lower dose. A liquid form enables even smaller starting doses. In nonelderly patients, fluoxetine can be initiated at 20 mg daily. Dosage may be advanced by 10 to 20 mg/d every 4 weeks. Usually, 20 or 40 mg/d suffices. The Physicians' Desk Reference maximum dose is 80 mg/d, although higher doses are used to treat obsessive-compulsive disorder (see Chapter 226). Because of the drug's long serum half-life (2 to 3 days), less frequent dosing is possible for elderly persons needing less than 20 mg daily (e.g., 20 mg every 2 to 4 days).

Sertraline is started at 50 mg/d and gradually increased to therapeutic dosages in the range of 100 to 250 mg/d. *Fluvoxamine* is also started at 50 mg/d and gradually

increased to therapeutic dosages in the range of 100 to 250 mg/d. *Citalopram and paroxetine* are administered in doses comparable with those of fluoxetine. All other SSRIs have shorter half-lives than fluoxetine, but dosing is still once daily. Paroxetine is also available in a liquid form.

Tricyclic Antidepressants. The TCAs are a reasonable choice for antidepressant therapy in selected persons who fail SSRI treatment. The low cost per tablet of the generic formulations weighs in their favor (although brand formulations are very expensive) (Table 227-5). When use in properly selected patients, TCA therapy can reduce the cost of therapy by an order of magnitude, but only when used in persons who can readily tolerate the side effects. Primary care physicians should become comfortable with using at least one sedating and one nonsedating TCA compound. These agents appear to act predominantly on norepinephrine metabolism, inhibiting reuptake at CNS synapses. Some TCAs also affect serotonin and, to a lesser extent, dopamine metabolism. A large number of tricyclics are available. All are equally effective. The major differences are in the degree of *anticholinergic and sedative side effects*. All require 3 to 4 weeks of continuous use before clinical improvement becomes evident. Drug choice for a given patient is determined by attention to the side effects of available agents (Table 227-5). Patient comfort and compliance are facilitated by avoiding drugs with marked anticholinergic activity.

Table 227-5. Antidepressants

Selecting among Tricyclics. In general, the TCAs tend to be sedating. Patients with severe *insomnia* might do best with a strongly sedating drug, such as *doxepin* (Adapin or Sinequan) given at bedtime. The very sedating drug *amitriptyline* (Elavil) has long been popular with physicians, but because of its strong anticholinergic side effects, it is probably not an optimal first-choice agent unless low doses suffice. The elderly and those with prostatic hypertrophy do best with a nonsedating tricyclic that has relatively mild anticholinergic activity (e.g., *desipramine* [Norpramin] or *nortriptyline* [Aventyl or Pamelor]). Nortriptyline has the advantage among tricyclics of causing the least postural hypotension. Persons bothered by anergy and psychomotor retardation are best treated with a nonsedating slightly activating TCA (e.g., desipramine) or an SSRI (as per above).

The prescribing of a *fixed combination* preparation containing a tricyclic plus a *neuroleptic* (e.g., Triavil) or a *benzodiazepine* (e.g., Limbitrol) is irrational and should be avoided. Combinations make it difficult to achieve therapeutic levels of the tricyclic without administering too much of the other compound. Moreover, except for the depressed patient with psychotic symptoms, *typical antipsychotics* have no place in the treatment of depression. Occasionally, *atypical antipsychotics* are used for augmentation purposes in treatment-refractory patients.

Adverse Effects. Tricyclics can have *lethal* cardiovascular toxicity when taken in overdose due to severe cumulative *anticholinergic and alpha-blocking* effects. One should never write a prescription that dispenses more than 1 g of a tricyclic to a potentially suicidal patient or to a patient one does not know well. At therapeutic doses, *postural hypotension* can occur, especially in the elderly, leading to falls, fractures, and head injury. If postural hypotension is a problem, nortriptyline or an SSRI should be used. If the hypotension is always worse in the morning, it may be useful to give the nortriptyline in three divided doses. Patients should be instructed to be careful when rising from recumbency or sitting.

Before benefit is noted, patients may want to stop TCA therapy because of *dry mouth, lassitude, constipation, or mental clouding*. Such symptoms are common with use of TCAs but may also result from depression. They often pass or abate with continued therapy, a reassuring fact that helps patients to continue TCA treatment. *Weight gain* is another complaint. It results from TCA-associated stimulation of appetite.

Rarely, more severe dose-related anticholinergic symptoms occur, especially in the elderly. These include *ileus, urinary retention, and dysrhythmias*. In all patients over 40, it is good practice to obtain a baseline electrocardiogram before starting a tricyclic. At therapeutic levels, tricyclics exert anticholinergic effects on the heart, which could cause a *rise in heart rate and conduction delay*. In patients with bundle branch block, atrioventricular block, or sinus node disease, there is an increased risk of higher degrees of heart block. In patients without underlying conduction system disease, tricyclics rarely cause conduction problems.

Very rarely, a full *anticholinergic syndrome* develops in patients taking TCAs, characterized by agitation, delirium, and fever. The most common precipitant is simultaneous use of more than one anticholinergic drug. Most often implicated is concurrent use of thioridazine (Mellaril), anticholinergic antiparkinsonian drugs, antihistamines, antispasmodics, and over-the-counter sleep medications containing antihistamines. The number of anticholinergic compounds should be closely monitored, especially in the elderly.

Dosage. Tricyclics are started at a low dose with gradual increases until the therapeutic dose-range is achieved (Table 227-5). After that, trial and error is often required. Drug *serum levels* can be used to determine compliance and achievement of therapeutic serum concentrations in nonresponders. Blood levels vary widely among patients for any given oral dose due to individual differences in drug absorption and metabolism. Therapeutic serum levels have been established for imipramine, desipramine, amitriptyline, and nortriptyline (Table 227-5). For other TCAs, serum levels are useful only to ascertain compliance. Many clinical laboratories are unreliable in measuring these compounds. One should seek an experienced laboratory.

The most common cause of treatment failure is inadequate dosage. In healthy nonelderly adults, a typical *starting dose* is the equivalent of 50 mg of desipramine. (Nortriptyline has twice the milligram potency of most tricyclics; thus its starting dose is 25 mg.) The daily dose is best taken at bedtime to facilitate compliance and minimize side effects. Dosage can be increased by 50 mg every 3 to 4 days to a dose of 150 to 200 mg at bedtime. Dosages are reduced by 50% in the elderly (see below). The final dosage chosen is one that provides a therapeutic response without intolerable side effects. The usual *maximum dosage* is 300 mg of desipramine or the equivalent (150 mg for nortriptyline). This is easier said than done. In recent reviews, relatively few patients whose depression was diagnosed received a therapeutic dose of a TCA.

Atypical Antidepressants. These agents have slightly different mechanisms of action than those of the first-line SSRIs, providing them with potential benefits in selected circumstances where SSRIs do not suffice. They are mostly the province of the psychiatrist, and unless familiar with their use, the primary physician should not prescribe one of these agents in preference to a first-line drug. However, some knowledge of their characteristics is helpful when managing patients who have been prescribed an atypical antidepressant.

Venlafaxine. Venlafaxine (Effexor) is a selective inhibitor of both serotonin and norepinephrine. It is typically started at 37.5 mg twice daily (due to its short half-life) and gradually tapered up to therapeutic dosages in the range of 75 to 150 mg twice daily. At its higher doses, it has more effect on norepinephrine uptake inhibition, and some studies have suggested that it has a higher response rate.

Nefazodone. Nefazodone (Serzone) inhibits serotonin reuptake, it is unique in blocking 5-HT $_2$ receptors and mediating 5-HT-1A transmission. It is usually started at 50 mg twice daily and gradually tapered up to therapeutic dosages in the range of 150 to 300 mg twice daily.

Mirtazapine. Mirtazapine (Remeron) is associated with an increased release of both serotonin and norepinephrine. By mediating 5-HT-1A transmission and blocking 5-HT$_2$ and 5-HT$_3$ receptors, it may account for its antidepressant and *anxiolytic* effects. It is usually started at 15 mg q.h.s. and gradually tapered up to therapeutic dosages in the range of 30 to 45 mg q.h.s.

Bupropion. Bupropion (Wellbutrin) appears to work by downregulating postsynaptic b-noradrenergic receptors. Unlike the SSRIs, there is no adverse effect on

sexual functioning. It may be especially helpful in patients who do not respond to the SSRIs. It is now available in a sustained release form, reducing its risk of seizure to that of other antidepressants. However, even the sustained release form is still contraindicated in patients with a known seizure disorder or eating disorder. It is usually started at 150 mg SR q.a.m. and gradually tapered up to therapeutic dosages in the range of 150 to 200 mg SR twice daily.

Trazodone. Trazodone (Desyrel) is a nontricyclic with efficacy similar to the TCAs but generally better tolerated. The drug is sedating and particularly helpful for those who cannot sleep or tolerate anticholinergic side effects. *Postural hypotension* can be a problem in the elderly. Other common side effects include indigestion, nausea, and headaches. *Priapism*, a painful medical emergency, has been reported. Males prescribed trazodone must be warned that a sustained painful erection requires immediate medical attention. Trazodone is usually started at 50 to 100 mg q.h.s. as a sleep inducer. To be used as an antidepressant, it needs to be gradually tapered up to therapeutic dosages in the range of 200 to 600 mg q.h.s.

Monoamine Oxidase Inhibitors. MAOIs are quite useful in treating the elderly (see below), being well tolerated by virtue of their lack of anticholinergic side effects. However, they do have other side effects that bear noting.

Side Effects. The primary ones are *hypotension and insomnia*. Hypotension is unrelated to dose and may occur up to a month after starting the drug. It rarely necessitates stopping the drug. Insomnia can be minimized by giving the last daily dose no later than 4 p.m. *Hypertensive crisis* is the most serious adverse effect, caused by ingesting a large amount of tyramine. Dietary and drug precautions must be given. A *low-tyramine diet* is required, necessitating avoidance of foods such as fermented cheese, large amounts of yogurt, excessive caffeine, and chocolate, beer, and red wine. Patients can drink white wine, vodka, gin, and whiskey. A blanket warning to avoid all alcohol is not only unwarranted but may also compromise compliance. *Sympathomimetics* should be avoided. They are found in many over-the-counter medications including combination cold tablets, nasal decongestants, and appetite suppressants. *Amphetamines* are also not permitted. Treatment of a hypertensive crisis involves prompt cessation of MAOI use and initiation of antihypertensive therapy with an alpha-blocker or a direct vasodilator. (*Phentolamine*, 5 mg given slowly intravenously, is recommended.) Fever is managed by means of external cooling. Severe life-threatening reactions can also occur as a consequence of interactions between MAOIs and SSRIs or *narcotic analgesics*. A several week period between cessation of SSRI therapy and initiation of MAOI use is required, as is consultation before starting the MAOI.

Tranylcypromine (Parnate) is the preferred MAOI in the elderly because its effects last no more than 24 hours. Starting dose is 10 mg once or twice daily and gradually increased as needed over a few weeks. Usually 20 to 30 mg daily will suffice, but occasional patients require as much as 80 mg/d.

Other Agents. The benzodiazepine *alprazolam* (Xanax) has excellent antianxiety effects and *mild* antidepressant action. However, prolonged use is associated with significant risk of dependency (see Chapter 226). *Buspirone* (BuSpar) is similarly purported to have combined anxiolytic and *mild* antidepressant effects and has the advantage of a more benign side effect profile, without risk of physiologic dependence (see Chapter 226). These agents are reasonable in cases of adjustment disorders with depressive and anxiety features, but they are not indicated for the treatment of major depression.

Some nontricyclic second-generation antidepressants have fallen from use because of severe adverse effects (e.g., seizures with *maprotiline*; tardive dyskinesias with *amoxapine*). These agents are of limited safety and should be avoided.

Selection of Antidepressant for Major Depression. Choice is best made by taking into account disease severity, age, degree of psychomotor retardation and sleep disturbance, and ability to tolerate anticholinergic, cardiac, and postural side effects. *Costs* should also be considered, because these drugs are likely to be used for prolonged periods of time. The newer antidepressants are quite expensive, but so are brand-name TCA formulations (Table 227-5). Although the generic TCAs are less costly on a pill per pill basis, their requirements of cardiac monitoring, blood levels, and possibly more frequent office visits to manage their side effects can all contribute to a higher total cost in patients especially vulnerable to their side effects.

In the elderly and others with cardiac disease, prostatic hypertrophy, postural hypotension, or glaucoma, the SSRIs may be better tolerated. Some clinicians believe the SSRIs are not as effective as the TCAs for severe depression. When sedation without anticholinergic activity is desired, trazodone is a reasonable choice, particularly in the elderly. For anergic, hypersomnic, or motor-retarded patients, an activating agent is best (e.g., an SSRI or bupropion-SR or desipramine). For patients with a mixture of neurovegetative symptoms, nortriptyline is reasonable, being well tolerated and free of excessive sedating, activating, anticholinergic, or antiadrenergic effects.

Monitoring and Duration of Therapy; Failure to Respond. Monitoring response to therapy can be readily accomplished by carefully reviewing symptoms and activity level. The questionnaire instruments used for assessment of disease severity (see above) can also be used. If a patient shows little or no response to antidepressant therapy after 4 weeks at full dosage (which may be 6 weeks from initiation of therapy), then the drug trial should be considered a failure. If there is doubt as to adequacy of dosage or compliance, a serum drug level can be obtained. Failure to respond is an indication for psychopharmacologic consultation to explore whether augmentation therapy (i.e., adding a second agent, usually from a different class) or switching to another agent is the best approach. Sometimes augmentation can be the more rapid approach to achieving control, but consultation is advised.

It may also be important to reassess the patient's use of alcohol. It has long been known that patients who meet criteria for alcohol abuse or dependence are less likely to respond to antidepressant treatment. In a recent report, it was shown that a group of depressed outpatients who drank an average of 1.0 ounces of alcohol per day had a lower rate of response to an 8-week course of fluoxetine. This mild to moderate level of alcohol use was enough to decrease their chance of acutely responding to their antidepressant. Thus, patients should be encouraged to either abstain from drinking alcohol while on their antidepressant or limiting their alcohol use as much as possible.

If the response to initial therapy was promising but limited by intolerance to drug side effects, then switching to another agent in the same class with a more favorable side effect profile might suffice (e.g., switching from amitriptyline to nortriptyline for postural hypotension).

If depression successfully remits, antidepressant medication is maintained for at least 6 to 9 months or longer among patients who have experienced moderate to severe depression and who are judged to face a high risk of recurrence, perhaps because of a history of previous episodes. Continuation-phase medication should be maintained at the same dosage as was used in the acute-phase treatment. It has been shown to reduce risk of recurrence by 70% for as long as 36 months after the acute episode. When it is time to discontinue treatment, the dosage can be slowly tapered over a period of 4 weeks while watching for the reemergence of depressive symptoms. Should symptoms recur, the dosage is returned to its prior level and maintained for at least another 6 to 9 months. Major depression is a medical illness with a high rate of recurrence. After a single episode, 50% of patients subsequently have a second episode. After two episodes, the chance of having a third is approximately 80%. For patients with two or more episodes, maintenance therapy for probably 3 to 5 years is indicated. Patients with a family history of depression or bipolar disorder should also be closely evaluated for long-term maintenance therapy.	Updated: 03/20/03

Discontinuation of Therapy Due to Drug-Associated Sexual Dysfunction. An important and commonly cited cause of discontinuation of antidepressant therapy is antidepressant-associated sexual dysfunction. Manifestations include decreased libido, erectile dysfunction, and delayed orgasm. It is estimated that 30% to 70% of patients taking SSRI antidepressants experience this side effect. The finding is prevalent even among patients who achieve remission of depression with SSRI therapy. The problem typically occurs early in treatment and tends to persist, although it may wax and wane. Among the treatment approaches studied are addition of sildenafil or buspirone, addition of or switching to a nonSSRI antidepressant (such as bupropion, nefazodone, or mirtazapine), dose reduction, and dose holiday. Evidence of efficacy is strongest for addition of sildenafil in persons who achieve remission of their depression with SSRI therapy. More than 50% of male subjects in one randomized, placebo-controlled trial achieved significant improvement in most dimensions of sexual function with use of a 50-mg dose taken 1 hour before sexual activity. Libido is the least responsive to sildenafil therapy. Because data are available only from short-term studies in men, results in women and long-term safety and efficacy remain to be established.	Updated: 2/13/03

Prevention of Suicide

The best prevention is proper screening for suicidality and prompt referral at the time of initial evaluation. However, some patients are at greatest risk for suicide at the time when they are initially responding to antidepressant medication. Dysphoria may still persist as energy lifts, perhaps giving the patient with suicidal thoughts adequate energy to formulate a plan and follow it through. Continuous vigilance is required, as well as care in choice and amount of antidepressant prescribed. If there is a question of suicide risk, either a nontricyclic should be selected or no more than 1 g of a tricyclic dispensed at a time.

Treatment of Depression in the Elderly

Depression is the most common psychiatric disorder of the elderly, affecting close to one million older Americans. Primary treatment modalities include antidepressants and, for severely affected patients, electroconvulsive therapy (ECT). Age-related changes in drug metabolism and susceptibility to drug side effects must be taken into account in the design of the treatment program.

Choice of Antidepressant. When anergy and psychomotor retardation predominate, the activating effects of *SSRIs* make them attractive. Similarly, SSRIs are an excellent first choice if there is heart block, a dysrhythmia, or postural hypotension. Of the SSRIs, sertraline and citalopram are the least likely to interfere with hepatic drug metabolism and preferred in patients taking drugs that are metabolized by the liver (e.g., digoxin, warfarin, phenytoin). The sedating, anticholinergic, cardiac, and postural side effects of many *TCAs* make their use in the elderly especially problematic. Before starting therapy, postural signs and an electrocardiogram should be performed and particular note taken of the patient's somatic symptoms and degree of psychomotor retardation. *Amitriptyline and imipramine* are among the most difficult to use; *nortriptyline and desipramine* are better tolerated. If sedation is desired, *trazodone* is a reasonable choice, being free of anticholinergic activity.

Initiating and Monitoring Therapy. One starts with a *very low dose* of medication (e.g., 10 mg of fluoxetine, 25 mg of desipramine, 10 mg of nortriptyline, or 50 mg of trazodone). The dosage can be raised slowly every 5 to 7 days, while monitoring subjective response and heart rate and watching for anticholinergic, cardiovascular, and CNS side effects. One slows the increase in dose if tachycardia, excessive sedation, agitation, or orthostatic hypotension develops.

Often the patient is the last to recognize improvement, and family members commonly report that the patient is sleeping and eating better before the dysphoria resolves. An adequate trial may take twice as long in the elderly as in younger patients. Several studies have demonstrated elderly patients not showing their response until 8 to 10 weeks.

Failure to Respond. If there is little improvement after a reasonable trial at therapeutic doses, consultation is warranted to consider use of an alternative antidepressant (e.g., MAOI) or ECT.

Use of a Monoamine Oxidase Inhibitor. MAOIs have been used sparingly in the elderly because of concern for adverse reactions. Actually, MAOIs have no anticholinergic activity and are relatively well tolerated. Many older patients who do not respond to other antidepressants improve with MAOIs. MAOI therapy should be selected and started by a psychopharmacologic consultant, but management can then shift to the primary care physician, who needs to be familiar with drug actions and side effects (see above).

Use of Electroconvulsive Therapy. Elderly patients who are psychotically depressed, severely incapacitated, refractory or unable to take drug therapy, or in need of a rapid response should be referred for consideration of ECT. The best predictors of response are psychomotor retardation and delusions. Efficacy and safety have been well documented. Attainment of generalized seizure activity is required to achieve benefit. Customizing electrical dose to the patient's seizure threshold may help maximize efficacy and minimize adverse effects. Electrode placement appears to be more important than electrical dose as regards amnesia, with unilateral electrode placement associated with a lower risk. Amnesia occurs for events just before and up to a few weeks after treatment. More long-term cognitive functioning is no different than that for patients treated with antidepressants. Relapses occur with high frequency, making ECT an acute treatment. Maintenance ECT is not uncommon these days. Quite often an SSRI or TCA is prescribed for life-long maintenance treatment in an elderly patient.

Treatment of Seasonal Affective Disorder

Light therapy is the first line of treatment. Exposure to 10,000 lux of ordinary white fluorescent light for 30 to 45 minutes at a time once or twice a day is effective. Improvement often occurs within the first week or two of therapy. Patients typically sit about 50 cm from a light box and read for the period of treatment, with the light coming in at a 45-degree angle. Improvement has been noted both with morning and nighttime treatments, though the latter may cause insomnia. Elaborate forms of lighting that more closely simulate the spectrum of sunlight are no more effective than light from a standard white fluorescent source. The intensity of light appears to be the key determinant of efficacy. SSRIs are probably as effective as light therapy. Some clinicians use both. Efficacy of prophylactic therapy early in the winter is under study.

INDICATIONS FOR REFERRAL AND ADMISSION

Patients who should be referred for psychiatric consultation include those with refractory or disabling major depression, bipolar illness, psychosis, or substantial risk for suicide. Patients who fail to respond after 1 to 2 months of appropriate antidepressant treatment should have a psychiatric consultation. Many of these patients can be referred back to their primary care physician for follow-up after one or two psychiatric appointments.

Psychiatric hospitalization is indicated for high suicide risk, lack of reliable social supports (if the depression is severe), history of previously poor response to treatment, or symptoms that are so severe that the patient requires constant observation or nursing care.

PATIENT EDUCATION

Detailed patient education is a central component of supportive psychotherapy (see above). Patients who come from backgrounds that stigmatize mental illness or oppose psychotropic medication are comforted by learning of depression's "organic" pathophysiology, which helps them to comply with treatment. Compliance with antidepressant therapy is often compromised by side effects or mistaken attributions. Some stop their medication after only a few days if they do not notice an immediate improvement or use it only "as needed." Before initiating therapy, it is critical to review likely side effects and delayed onset of improvement. The importance of prolonged regular use must be emphasized. If the patient already has a tendency toward constipation, the prescription of a stool softener may make a tricyclic more tolerable. Patients should be instructed to report side effects rather than stopping the medication on their own and to call promptly if suicidal thoughts develop or if depression markedly worsens.

The educational process should include family and other household members. Enlisting their help in decreasing stress at home is helpful. With elderly or severely depressed patients, the family should be taught about the proper use of antidepressants and asked to monitor compliance.

THERAPEUTIC RECOMMENDATIONS

- If a depressive syndrome is identified, try to make a specific diagnosis and assess suicide risk.
- If the patient appears to be at risk for suicide, has psychotic symptoms, severe depression with no social supports, or is unable to care for him or herself, arrange prompt psychiatric consultation with a view to possible hospitalization.
- For other patients, begin supportive psychotherapy and make any social and environmental interventions that may help. Especially with elderly or severely depressed patients, involve the family in the treatment.
- For patients who have major depression (or patients with other subtypes who have neurovegetative symptoms), antidepressant medication is indicated.
- For elderly patients and those with suspected cardiac disease, obtain a baseline electrocardiogram to rule out conduction system abnormalities and check for postural hypotension prior to initiation of therapy.
- SSRIs have become the first-line treatment for depression. The rationale includes their safety during overdose and generally good tolerability. The most common side effects of the SSRIs are nausea, headache, insomnia, sedation, lack of appetite, and sexual dysfunction.
- Choice of SSRI can be based on cost when when minor differences in side effect profiles are not clinically important. Chosing a generic TCA is the least costly on a per-pill basis, but cost of monitoring and side effects can add substantially to cost.
- Patients who fail a 4- to 6-week trial of an adequate dose of an SSRI should be considered for referral to a psychiatrist.
- Initial doses of antidepressants in the elderly should be half to one third the standard starting doses noted here.
- If the patient responds to the antidepressant, it should be continued for at least 6 to 9 months or longer if depression was moderate to severe and there is appreciable risk of recurrence, and then slowly tapered.
- Never prescribe more than a week's supply or a total of 1 g of a tricyclic if there is suicidal risk.
- Explain to patients that antidepressants must be taken regularly, that they may take 4 weeks to work, and that there may be mild side effects that do not warrant discontinuation of the drug.

- Prescribe a generic formulation.

CHAPTER 228 APPROACH TO THE PATIENT WITH ALCOHOL ABUSE

ELEANOR Z. HANNA

The primary care physician is uniquely positioned to detect and treat harmful patterns of alcohol use and to prevent alcohol-use disorders and a host of related medical and social problems. Timely recognition is critical. Alcoholism encompasses two distinct conditions: *alcohol abuse* and *alcohol dependence*. Abuse is formally defined as a maladaptive pattern of use leading to impairment in one of several sociobehavioral domains for a 1-year period. Dependence is formally defined as a maladaptive pattern of use characterized by at least three of seven symptoms that include tolerance, withdrawal, preoccupation with and recurrent use of alcohol despite adverse consequences in important areas of life. Most problem drinkers are employed, employable, or in families, indicating that the scope of the problem extends far beyond those who meet formal diagnostic criteria.

National surveys suggest a very high prevalence of alcohol abuse, dependence, or both, approaching 8% or nearly 14 million adults. Alcohol use among youth aged 12 to 17 has increased dramatically, and the rates of abuse and dependence in persons 18 to 29 years are twice those for the nation as a whole. The overall estimated societal costs in terms of health problems, lost productivity, crime, accidental deaths, and fire are staggering (in excess of $165 billion). The estimated direct cost of treatment for alcohol problems and medical consequences approaches $20 billion, with more than $15 billion for medical care alone.

Screening for alcohol problems long before they become disabling and more difficult to manage should be a routine part of every primary care practice. One first identifies and then helps the patient understand and acknowledge the consequences of drinking, the presence of a problem, and the need for intervention. The objective then shifts to negotiating and carrying out an acceptable treatment plan, one that is personalized and multifaceted.

CAUSES OF ALCOHOL ABUSE

The etiology of alcohol abuse remains incompletely understood but is clearly multifactorial. Biogenetic, sociocultural, psychologic, and behavioral elements have been elucidated. No single model accounts for all manifestations, but each is helpful in understanding the problem.

Biogenetic Model. Genetic factors appear to influence the metabolism of alcohol and the effects of alcohol on neurotransmitters, receptors, and cell membranes. The A1 allele at the D_2 dopamine receptor gene and the G1 allele of the GABAA$_A$ receptor b3 have been identified as independent contributors, with a more robust risk for disease when combined. Alcohol abuse is clearly multigenetic in origin and more genetic risk factors are likely to be characterized.

Sociocultural Model. External factors such as poverty, socialization patterns, and cultural differences in the rules governing alcohol use are emphasized. Parental and peer values, attitudes, and behaviors regarding alcohol all contribute. This model may explain the increasing use of alcohol among women and youth and use patterns of ethnic minorities, despite an overall national decline in consumption.

Psychologic-Psychodynamic Model. In this model, underlying psychopathology (e.g., dependency conflict, depression, excessive need for power or sensation seeking, gender identification problems) is viewed as predisposing a person to drink excessively, either to mask or solve a psychologic problem. Drinking is viewed merely as a symptom.

Learning Theory/Behavioral Model. Alcoholism is seen as a learned behavior that is reversible, time limited, on a continuum with normal drinking behavior and established by a series of learning and reinforcement experiences. Social interactions, emotional stress, guilty or negative thoughts, and need for sleep or pain relief serve as precipitants and maintainers of drinking behavior. Any of these precipitants coupled with learned expectations about the effects of alcohol or deficits in social skills will initiate and maintain the drinking behavior.

CLINICAL PRESENTATION AND COURSE

Use of alcohol in moderation is characterized by varying consumption and beverage according to internal cues and external circumstances. If one chooses to drink, one does so in drinking-appropriate circumstances and rarely exceeds one or two drinks. The moderate drinker is neither likely to drive under the influence (might have a drink on arrival at a party and switch to something nonalcoholic later) nor likely to drink in order to deal with problems, escape, or get drunk.

With the caveats that a given dose of alcohol affects different people differently and that average daily consumption neglects the pattern of drinking, drinking in moderation may be defined quantitatively as two or less drinks per day for men and one or less for women and the elderly. The figure is lower in women and the elderly because they experience a higher blood alcohol level per drink due to smaller volume of distribution and decreased first-pass metabolism of alcohol. (A standard drink is assumed to contain roughly 12 g, 15 mL, or 0.5 oz of alcohol, which is the approximate content of 12 oz of beer, 5 oz of wine, or 1.5 oz of liquor.)

Alcohol misuse ranges from social drinking with a tendency for occasional excess to constant intoxication. Orderly progression is not assumed. The most commonly encountered presentations include

- The *social drinker*, who consumes alcohol in amounts and circumstances that appear socially acceptable but may develop a serious alcohol problem if there is a propensity to overindulge or to occasionally use alcohol to cope with stress.
- The *heavy social drinker*, who drinks in socially appropriate circumstances but actively seeks a life of occasions for drinking (through job or social life); has more than two drinks every day, continuously seeks out situations in which to drink, and may often overconsume but not exceeding the consumption of peers; and may never appear drunk or seem affected in social or work routines, but as drinking escalates, it becomes increasingly tied to seeking physical or psychological relief. Problem drinkers emerge from this population. Neither the person nor acquaintances suspect an alcohol abuse problem.
- The *problem drinker*, who meets the criteria for heavy social drinking, gets drunk on occasion and also exhibits medical, legal, social, or psychologic consequences of excessive alcohol consumption; makes or thinks of making attempts at cutting down or quitting; functioning may vary from seemingly intact behavior to difficulty coping; may deny a drinking problem and attribute blame to external events or persons; denial is common even among those with multiple arrests for drunk driving.
- The *alcohol-dependent patient* who tries to consume the same excessive amount of alcohol regardless of mood or situation, although external circumstances might constrain drinking for a time. Most continue to work; some even in high positions. Alcohol is given top priority in all situations (e.g., one goes to a party to drink, not to socialize). Tolerance to alcohol develops, and withdrawal symptoms (mood disturbance, tremor, nausea, sweats) may be noted during the work day when the blood alcohol level drops. Drinking at lunch and cocktail hour are needed to relieve symptoms. The patient is aware of the compulsion to drink but is difficult to reach unless family or employer notes a problem or serious medical complications develop.
- The *severely deteriorated patient* who maintains a constant state of intoxication, having no care for his or her person or surroundings; undergoes periodic hospitalizations for detoxification and for medical care necessary after alcohol-related trauma or organ damage.

Groups at increased risk include professionals; executives; young people; women, especially those of childbearing age; and the elderly as are those presenting with depression, other drug use, or a family history positive for alcoholism. Seemingly high functioning *executives and professionals* who manage their own schedules have ready access to both alcohol and drugs, the use and consequences of which remain hidden until serious sequellae become obvious. Eighty percent of *young people* drink as high school seniors and 24% binge drink, a pattern that continues and increases to 34% among college students. Adults who began drinking or smoking regularly in their early teens suffer the most serious alcohol, drug, and psychiatric problems and often manifest the greatest proportion of familial alcohol problems. *Women*, as a result of social change, are consulting clinics at double the former rates. *Elderly* patients may begin to use alcohol excessively for stress,

especially in reaction to loss of a loved one or because of sleep difficulties. A peak period for onset for new alcohol-related problems is 65 to 74 years of age.

Natural History and Clinical Course. There is considerable individual variation. Onset ranges from an initial phase of social drinking to immediate heavy drinking. Prognosis remains relatively favorable until dependence sets in. Once the addiction becomes psychologic or physiologic, it is difficult to break in the absence of treatment and the clinical course is often progressive. (This makes it imperative to detect alcohol misuse long before the patient meets formal criteria for diagnosis of alcohol abuse.) At the point of addiction, continued drinking may punctuated by periods of abstinence or controlled drinking but followed by relapse and progression, especially if there is no expert intervention. Controversy continues regarding whether or not total abstinence is required to halt progression.

Medical Complications. The risk of organ damage is related in part to the dose and duration of alcohol exposure, with some conditions (e.g., *alcoholic cardiomyopathy, fatty liver*) manifesting reversibility with abstinence, and others (e.g., *cirrhosis*) seeming to progress inexorably once severe hepatocellular damage has occurred. Risk appears to be a function of a genetic predisposition and alcohol dosage and chronicity of exposure. Although cardiovascular benefits may accrue from up to two drinks a day in white men (one in women and black men), consumptionof more than three drinks a day is associated with increased risk for hypertension, among other risk factors for more serious disease.

Persistent *impotence* and *loss of libido* reflect impaired gonadotropin release and accelerated testosterone metabolism that occur as consequences of chronic alcohol excess; they predate end-stage liver disease. *Alcoholic hepatitis, pancreatitis, and gastritis* may follow binge drinking. *Fatty liver and esophagitis* ensue from chronic use. Late-stage complications include *cirrhosis, oral cancers, cardiomyopathy, Wernicke's encephalopathy, and Korsakoff's dementia*.

Fetal alcohol syndrome occurs in infants born to mothers who drink heavily during pregnancy. Features include permanently stunted growth, mental retardation, musculoskeletal abnormalities, poor coordination, and cardiac malformations. Incidence approaches 33% among pregnant women who drink more than 150 g (6.25 oz) of alcohol per day. Another third of children born to such women will have mental retardation or severe behavior disorders. Serious maternal and infant health problems and increased infant and fetal deaths accrue among women who report drinking even as little as one drink a week during pregnancy.

DIAGNOSIS

The Diagnostic and Statistical Manual of Psychiatric Disease, 4th edition (DSM-IV), specifies the most widely used criteria for the formal diagnoses of alcohol abuse and alcohol dependence (Table 228.1).

Table 228.1. Criteria for Substance Abuse and Dependence according to DSM-IV

WORKUP

Formal diagnosis involves identification of excessive quantity and duration of consumption, physiologic manifestations of ethanol addiction, loss of control over drinking, and chronic damage to physical health and social functioning. In late stages of illness, these clinical findings are readily evident. *Detection before marked abuse or dependence has developed remains the major diagnostic challenge.*

The high prevalence of alcohol abuse, its serious consequences, and good response to early intervention argue for routinely screening all adolescents and adults who come for primary care. In addition, a high index of suspicion for alcoholism is indicated for the patient who presents with a family history positive for alcoholism, anxiety, insomnia, recurrent infection, an illness that is potentially alcohol related, child abuse, domestic violence, multiple psychosomatic problems, suicidality, depression, inability to articulate feelings, or interpersonal, occupational, financial, or legal problems.

Screening. For the patient in whom there is no clinical evidence or suspicion of alcohol abuse, the *CAGE questions* (Table 228.2) are the screening test of choice. In primary care settings, sensitivity for a score of 2 (the standard cutoff) ranges from 70% to 85% and specificity from 85% to 91%. In the *elderly*, where prevalence of alcoholism is increased but clinical presentation may be harder to ascertain, sensitivity falls to 50%, whereas specificity remains above 90%. Including questions on the quantity and frequency of drinking improves detection in the elderly.

Have you ever felt the need to Cut down on drinking?
Have you ever felt Annoyed by criticism of drinking?
Have you ever had Guilty feelings about drinking?
Have you ever taken a morning Eye opener?

(Mayfield D, McLead G, Hall P. The CAGE questionnaire. Am J Psychiatry 1974;131:1121.)

Table 228.2. The CAGE Test

A 10-item self-administered questionnaire, the *Alcohol Dependence Scale* is another popular research and screening toolin clinical settings. It can be incorporated into a previsit life-style screen to assess severity. Its benefits are high reliability and validity. A cutoff score of 5 will identify patients suitable for brief intervention in the physician's office. Other popular tests used in clinical and research settings are the *Michigan Alcohol Screening Test* (Table 228.3) and the *Alcohol Use Disorders Inventory*.

Table 228.3. The Michigan Alcoholism Screening Test (MAST)

A detailed drinking history is in order for all patients suspected of having an alcohol problem on the basis of any of the following:

- A positive Alcohol Dependence Scale, CAGE, or Michigan Alcohol Screening Test test;
- A family complaint or a history of alcoholism in the family;
- A daily drinking pattern of two to three drinks accompanied by seemingly innocuous complaints that might be related to drinking (e.g., frequent nonspecific illness, accidents);
- A life-style that will perpetuate increased prolonged drinking, including tobacco or drug use;
- The occurrence of intrapsychic or interpersonal problems or actual changes in life events;
- Suggestive manifestations on physical examination, such as alcohol on the breath, spider angiomata, plethoric facies, tremor, ecchymoses;
- Abnormal liver function tests; macrocytic anemia.

Taking an Alcohol History. Except under overwhelming circumstances, patients do not volunteer drinking problems and request help. Denial is likely to be strong. Consequently, one has to use an interview technique that is kind and supportive yet firm and even confrontational when there are serious clinical concerns, especially when there is question about ability to function. Where indicated, family members, friends, and even the employer may facilitate both history taking and therapy.

The Drinking Profile. In taking a drinking history, it is critical that one go beyond issues of quantity, frequency, and development of tolerance. A profile of the patient's drinking behavior over a given time period will prove most useful and should include attention to

- Setting: time, place, and occasion for drinking;
- Social network: the people involved with the drinking and their relationship to the patient;
- Consumption: quantity, frequency, and rate of consumption as it relates to that of others in the drinking context and as it relates to the patient's expected consumption;
- Pressures (internal or external) to drink;
- Other activities related to drinking.

The physician should suspect anyone *who drinks* and is in a *drinking context on a regular basis*—that means most patients. Not only will a drinking profile help characterize an alcohol abuser or alcoholic, it will also identify those not suspected of having a problem. The profile is an effective tool for confronting the resistant patient, treating a willing patient, and educating a person with a potential problem. It also permits one to make any standard manualized treatment approach personal, and thus more effective, with patient-specific examples.

Causes for Missing the Diagnosis. These include subtlety of presentation, use of definitions of alcoholism that do not encompass early manifestations, the view that the patient is normal so long as he or she can perform daily activities, societal acceptance of dangerous levels of alcohol intake, and general expectations of alcohol consumption at most social occasions. There may be unintentional collusion with the patient in denying the problem, especially if the patient is of similar or higher social status, has similar habits and life-style, or is attractive, verbal, and intelligent.

PRINCIPLES OF MANAGEMENT

Management is most successful when it is multifaceted, personalized, and long term. Often, the primary care physician remains the one constant medical figure and the most trusted person in the patient's life. Whether one intends to personally care for the alcohol abusing patient or refer them to a specialist, the primary physician has the important initial task of assisting the patient in acknowledging the drinking problem and accepting a treatment program.

Getting Started

Dealing with Denial. One should first listen carefully to how the patient explains the findings. If the problem appears likely to be accepted internally, but the patient does not want to reveal it externally, then it is best to help the patient discover the problem for him or herself. One might suggest keeping a journal or weekly log of drinking events for reviewing links between drinking and particular environmental, interpersonal, or psychologic precipitants. This also helps determine exactly how much the patient drinks without direct confrontation and, in itself, constitutes a brief intervention.

The same technique, with some additions, can be used for the patient who is hiding the problem from him or herself. Here, one reviews the evidence on how alcohol directly affects the patient's health. Use of screening instruments (see above) and presenting the findings in terms of a specific diagnostic classification system sometimes helps to objectify the diagnosis. If the patient continues to resist, then one can bring in family, friends, or employer to present the patient with their evidence of how destructive the drinking is to him or herself and them. Again, these sessions should be factual nonjudgmental discussions of the relationship of alcohol to the patient's health and behavior and its impact on those important to him or her.

Dealing with Resistance to Treatment. Patients who agree they have a problem yet continue to refuse help or to relinquish alcohol should be handled similarly, but with more focus on their fears and resistance. The hostile or belligerent patient should be dealt with firmly, but in a manner that enhances ability to objectify and control anger (e.g., by identifying the sources of anger).

Often those who resist treatment must first fear the loss of something very important (e.g., spouse, job) before seeking help. The so-called *tough love approach*, in which loss is seriously threatened or actually carried out unless the patient goes for treatment, must be sustained for an indefinite and prolonged period because many patients return to old habits once danger of losing a loved one or job passes. The approach is not always effective and should therefore be used sparingly. It is pointless to force the patient into treatment when no medical emergency exists. It is better to present the options available, continue exploring the issue, and provide health education while treating the patient's medical problems and awaiting willingness to undergo treatment.

Should the patient agree to seek treatment, it is important to keep the waiting period brief and helpful to remind the patient a day or two ahead of the appointment.

Patient Selection for Management by the Primary Physician. The doctor–patient relationship can be used to change life-style, identify and restructure destructive patterns, and learn new coping skills. Effective care requires being available on a regular basis to provide the necessary monitoring, instruction, and support. If such support is beyond the scope of the individual primary physician or a trained assistant in the practice, then a proper and smooth referral for specialized care is indicated. Brief physician office interventions have proved effective in reducing the alcohol consumption of nondependent patients.

Long-term management by the primary care physician is best for those patients with

- Medical complications as the foremost concern;

- A strong personal tie to the primary physician;
- Good social stability;
- Only minor psychopathology;
- Intelligence and pragmatism;
- Great faith in physicians;
- An intact and supportive social network.

It is important to remember that the treatment will be long and arduous and that the patient's behavior is sick and often will be directed at the primary physician or therapist in either a covert or overtly hostile manner. The ultimate goal is to help the patient gain self-control, regulation, and a sense of responsibility. One must not counterattack.

If and when the physician finds him or herself unable to cope, the patient should be referred to a specialist, with the primary physician remaining as the coordinator of care.

Determinants of Successful Treatment. *Early detection and prompt initiation* of treatment are essential to success, with success rates of 50% to 90% attained in patients abusing alcohol but without physical or social impairment. Success rates also depend on the *length of time* a person stays in treatment, *patient involvement* in goal setting and treatment planning, and continued attachment to *family* or an integrated *social network*. Very brief *physician interventions* have also proved effective, with the key being continued health care provided by the physician serving as the advisor/monitor.

Involving family members or significant others in the confrontation and treatment assists and supports the life-style changes that must be made, particularly when the problem drinker is a woman or young person. This ensures that the patient goes for and remains in treatment.

Other determinants of successful treatment include use of a *personalized multifaceted* plan, an *active role* for the patient, and continuous *review*. Controversy continues regarding whether or not *total abstinence* is required to halt progression. Cessation certainly is necessary to halt many of the medical complications.

Treatment Modalities

Therapies can be classified as biological, psychological, behavioral, or sociocultural. Selection is best done on an individualized basis to meet the patient's specific needs. Most programs use a combination of modalities. The biologic approach includes use of drugs. In general, drug therapy plays a supportive role in the outpatient care of the alcoholic patient, mainly providing a temporary respite from alcohol consumption sufficient to enable the patient to engage in a more comprehensive and durable treatment program.

Drugs to Decrease Alcohol Consumption and Prevent Relapse. Pharmacologic agents are prescribed to reduce the urge to drink, to blunt withdrawal symptoms, and to treat underlying psychiatric problems that may be contributing to alcohol abuse. As noted, the goal is to provide the patient with time to organize the supports necessary for achievement of long-term abstinence.

Disulfiram (Antabuse) is an aversive therapy. It achieves short-term improvement in alcohol consumption when used in a supervised comprehensive outpatient program that includes other rehabilitative measures. Success requires careful compliance and a stable life-style. Patients best suited are those who seek total abstinence, request the drug; have no underlying cardiovascular, depressive, or schizophrenic disease; and are willing to return monthly for evaluation of therapy.

The drug sensitizes the patient to the effects of alcohol by inhibiting hepatic aldehyde-NAD oxidoreductase. Within minutes of taking as little as 1 ounce of alcohol, the patient experiences an increase in serum acetaldehyde concentration that leads to palpitations, flushing, tachypnea, tachycardia, and shortness of breath. Nausea, vomiting, and headache develop if a greater amount of alcohol is taken. Symptoms last about 90 minutes and usually are self-limited. Occasionally, marked hypotension or a cardiac arrhythmia may occur. Fatalities from myocardial infarction and stroke have been reported. The agent can worsen depression and schizophrenia. Candidates require careful medical and psychiatric evaluation before initiating therapy.

Side effects include drowsiness and lethargy, which are countered by administering the drug before bed. The standard dose is 250 mg at bedtime. Important drug–drug interactions occur with antihypertensive agents (potentiation of hypotensive effect with intake of alcohol), benzodiazepines (BZDs; reduced intensity of the disulfiram reaction), tricyclic antidepressants and phenothiazines (potentiation of central nervous system effects), and drugs metabolized by hepatic microsomes (prolongation of their half-lives).

Disulfiram should not be considered an option for chronic use. *Duration* of therapy is individualized. Treatment should be terminated if the patient fails to keep appointments, resumes drinking, becomes pregnant or depressed, or develops abnormalities in liver function tests or cardiovascular status.

Naltrexone (Trexan), an opioid antagonist that appears to blunt the pleasurable effects of alcohol, is U.S. Food and Drug Administration–approved to reduce cravings and provides a new approach to pharmacologic therapy. In placebo-controlled randomized trials that include a program of concurrent comprehensive care, the drug significantly increases the abstinence rate to over 50%. Like other drugs for alcoholism, its role is as an adjunct. Recommended dosage is 50 mg/d for up to 12 weeks. The drug is well tolerated, with self-limited nausea and headache as the common side effects. High doses may cause hepatocellular injury, necessitating the monitoring of liver enzymes with use. It appears to work best in persons who describe intense cravings. Contraindications include opiate use and hepatocellular disease.

Acamprosate (calcium acetylhomotaurinate), which has specificity for NMDA and GABA receptors, is a competitive antagonist that reduces cravings. It is currently used abroad but is now under study in the United States.

Psychoactive Drugs. Pharmacologic treatment of underlying psychopathology has been proposed as a means of cutting down on drinking. Anxiolytic agents such as the BZDs have been used with a modicum of success in patients who drink because of an anxiety disorder. There is no evidence for long-term efficacy in reduction of alcohol use, but some data suggest a short-term reduction in anxiety that could enable a patient to engage in more comprehensive forms of therapy. BZDs have also been proposed as a means of reducing the desire to drink that might emanate from a postulated chronic withdrawal syndrome. Supporting data for both the syndrome and the efficacy of long-term drug treatment are minimal. *Buspirone* has been effective in short trials as a treatment for severely anxious patients, but more work is required to clarify its effectiveness. *TCAs and selective serotonin reuptake inhibitors* may be effective when there is an underlying depression, especially when it is accompanied by neurovegetative symptoms (see Chapter 227). *Lithium* has been tried with lesser success.

Drugs for Withdrawal. The acute withdrawal syndrome (tachycardia, elevation in blood pressure, tremor, hyperreflexia, increased irritability) and its severest manifestations and complications (seizures, hallucinations, and delirium tremens) are best prevented and treated by use of BZDs. The determinants for drug treatment of withdrawal include severity of symptoms, past history of withdrawal, and any comorbid medical conditions. The *Clinical Institute Withdrawal Assessment-Alcohol, revised* (CIWA-Ar), is the most validated instrument for objective assessment of withdrawal severity and risk (Table 228.4). It use is common in inpatient settings but may also be helpful in the office. A rough clinical estimate of severity must suffice in its absence. For those with mild symptoms (e.g., CIWA-Ar score less than 8), no treatment is necessary other than continued monitoring unless there is a history of severe withdrawal or comorbid disease, in which case pharmacologic therapy is needed. Patients with moderate symptoms (e.g., CIWA-Ar score of 8 to 15) benefit symptomatically from treatment; those with severe symptoms (scores higher than 15) require pharmacologic therapy because risk of seizures is very high.

SEVERITY OF WITHDRAWAL SYNDROME	REGIMEN
Mild (CIWA-Ar score <8)	Monitor every 4-8 hours until no worsening for 24 hrs; treat as for moderate or severe disease if prior history of severe withdrawal or if there is serious concurrent illness
Moderate (CIWA-Ar score 8-15)	Begin diazepam 10 mg q6h for 4 doses, then 5mg q6h for 8 doses, or chlordiazepoxide 50 mg q6h for 4 doses then 25 mg q6h for 8 doses; then halt and allow drug metabolism to achieve tapering
	For persons with concurrent liver disease, begin lorazepam 2 mg q6h for 4 doses, then 1 mg q6h for 8 doses
	Provide additional medication PRN when symptoms are not controlled
Severe (CIWA-Ar score >15)	Admit to inpatient facility and begin symptom-triggered regimen with hourly administration of diazepam 10-20 mg, chlordiazepoxide 50-100 mg, or lorazepam 2-4 mg and reassess hourly, repeating the dose if CIWA score >8-10

*After Mayo-Smith MF, et al. JAMA 1997;278:144.

Table 228.4. Treatment Regimens for Alcohol Withdrawal

The long-acting BZDs (e.g., diazepam, chlordiazepoxide) appear more effective in preventing withdrawal seizures and in achieving a smoother withdrawal with fewer rebound symptoms than the *short-acting agents*; however, they are more likely to cause sedation, particularly in the elderly and those with liver disease. The nonhepatically metabolized BZDs (*lorazepam, oxazepam*) are indicated for use in persons with hepatocellular disease, but they are shorter acting and necessitate close monitoring of the patient. Fixed-dose, loading-dose, and symptom-triggered BZD regimens have been developed and are effective when used as intended. Fixed-dose regimens are the standard approach to treatment. *Loading-dose programs* use a large dose of a long-acting agent (e.g., diazepam 20 mg) given at the outset and repeated until the patient is sedated. Normal drug metabolism results in tapering. *Symptom-triggered* therapy using chlordiazepoxide has been shown to decrease mean duration of therapy and amount of drug required compared with fixed-dose treatment, but it requires close monitoring of the patient, usually feasible only in the inpatient setting.

Beta-blockers (e.g., atenolol, 50 to 100 mg/d) can help control adrenergic symptoms and reduce BZD requirements, but they are not sufficient as monotherapy, because they do not prevent seizures, hallucinations, or delirium tremens. *Clonidine*, a centrally acting inhibitor of noradrenergic activity, is an effective alternative to BZDs in mild to moderate withdrawal syndrome when used in a tapered program.

Outpatient administration is appropriate for those with mild symptoms of withdrawal; inpatient supervision is indicated for those with more severe symptoms or a prior history of severe withdrawal.

Inpatient versus Outpatient Programs. As noted, inpatient care may be necessary for detoxification and treatment of withdrawal. For achieving long-term abstinence, randomized studies show no overall advantage for residential over nonresidential treatment programs. As a result, expensive long-term inpatient care is no longer the standard for treatment of alcoholism. Only one methodologically sound randomized trial has demonstrated an advantage for inpatient care, and this one was part of an employee assistance program, which is itself a well-recognized determinant of success.

The net result is the current emphasis on outpatient care, except for treatment of severe acute withdrawal syndrome. Inpatient care remains an option for people who have failed all other forms of treatment and who will not deal with the problems so long as they are in environments that maintain destructive drinking. It is a costly approach and should be used as a last recourse. For most patients, an outpatient program that combines psychotherapy and behavioral-cognitive approaches can be offered in primary care practices by the physician and/or staff after some training. A national randomized controlled clinical trial of a brief alcohol intervention program tailored to patients in a medical setting resulted in significant and increasing reductions in alcohol consumption between patients in the treatment and control groups over a 2-year period.

Outpatient psychotherapy places emphasis on psychic restructuring and removal of the presumed underlying psychopathology. Such treatment is important for the person whose interpersonal or psychologic problems outweigh the alcohol abuse. The best candidates are socially intact, intellectually curious, and eager to be involved in the process. If concurrent treatment of the drinking is included, this can be a successful approach to patients with comorbid psychiatric disorders.

Alcoholism is associated with special needs that require the therapist to take a much more active role than is typical in insight-oriented psychotherapy. One must provide structure, guidance, support, nurturance, and instruction in helping the patient control drinking while working on the underlying conflicts and dysfunctional defense mechanisms.

Behavioral-cognitive therapies are based on the notion that alcoholism is a learned behavior that can be extinguished and reshaped, with controlled drinking a possible outcome. For patients who are rigid or seek treatments with defined tangible end points, behavioral therapy is often useful, as it is helpful in dealing with problems involving role changes and behaviors in specific situations. *Aversive conditioning* is designed to either eliminate alcohol use or train patients to drink in moderation only. Alternative behaviors are taught via operant conditioning.

Cognitive therapy focuses on the observables of the drinking behavior (frequency, duration, quantity, time, place, activity, age, sex, and role-appropriate drinking behaviors). It attempts to identify the precipitants to abuse and the factors that maintain and perpetuate it. This method can be incorporated effectively into brief physician-based interventions.

Sociocultural treatment emphasizes altering external factors. It includes *residential care, halfway houses*, and direct social manipulation, such as *finding jobs*, helping with *shelter and money*, and removing a person from his family. This is a treatment appropriate for homeless, jobless, unstable persons whose social functioning is impaired; for repeated treatment failures; for young people; and for others with severe family problems. Any of these approaches and the community services that follow can be used as adjuncts to other treatments wherever necessary.

Community Services. *Alcoholics Anonymous* provides the critical elements of social support, caring, and structure, which are essential to many patients. The program has a quasireligious orientation, making it particularly useful to the religious person. Relatively superficial involvement (e.g., two to four meetings per month) is usually not effective as the sole means of therapy but can serve as a useful adjunct to other forms of treatment. However, the person willing to dedicate oneself to a lifetime of sobriety can achieve the goal in this carefully delineated manner. *Al-Anon and Al-Ateen* assist family members of the alcoholic. Other popular self-help groups are Women for Sobriety, which stresses individual responsibility to boost self-esteem, and Rational Recovery, which stresses using reason rather than spirituality.

Employee assistance programs can be very useful, because motivation is often high. Most large companies offer such programs, and their counselors can work in tandem with physicians. They may also offer family, marital, and financial help, as may programs available through social service agencies, community guidance centers, and even state or federal agencies. *Clergy and church organizations* can be very helpful to religious persons.

Prevention

Prevention involves more than warning people of the health hazards of alcohol abuse. It requires screening for early detection of alcohol abuse (see above) and providing patient-specific information. By taking a brief drinking history at the time of the yearly checkup, the primary physician can educate the patient and provide suitable guidelines for drinking behavior, just as one does for exercise and diet. A number of very brief physician interventions or trials of advice qualify as prevention or early intervention programs that can be easily offered in medical practice. Randomized trials have proved this an effective method in reducing harmful levels of alcohol consumption.

People who do drink need to know how alcohol can affect them, how to behave responsibly when drinking (especially in regard to driving), and how to drink to prevent drunkenness (Table 228.5 and Table 228.6). Individuals should know that their attitudes and behaviors will affect how their children/spouses drink. All should be cautioned that drinking is a dangerous way to deal with insomnia and emotional problems.

TIME ELAPSED SINCE FIRST DRINK (IN HOURS)	NUMBER OF DRINKS								
	1	2	3	4	5	6	7	8	9
1	0.01	0.03	0.05	0.08	0.10	0.13	0.15	0.17	0.20	0.22
2	0.00	0.02	0.04	0.06	0.09	0.11	0.14	0.16	0.18	0.21
3	0.00	0.005	0.02	0.05	0.07	0.10	0.12	0.14	0.17	0.19
4	0.00	0.00	0.01	0.03	0.06	0.08	0.11	0.13	0.15	0.18
5	0.00	0.00	0.00	0.02	0.04	0.07	0.09	0.11	0.14	0.16

*Determined by the number of drinks consumed in a circumscribed time period by a presumably normal 150-lb male. Females, because they are affected more quickly, require less alcohol to achieve these levels.

†Blood alcohol levels as a function of weight, time, and number of drinks consumed.

One drink = 1.5 oz 80-proof spirits (40% alcohol)
    3.0 oz fortified wine (20% alcohol)
    5.0 oz table wine (12% alcohol)
    12.0 oz beer (4.5% alcohol)

Table 228.5. Blood Alcohol Level[*]

BAL	BEHAVIORAL EFFECTS
0.05	Relaxation; possibility of thought, judgment, and self-control being affected
0.10	Obvious impairment of voluntary motor action; legally drunk in most states
0.20	Considerable motor impairment and loss of emotional control; definite intoxication
0.40–0.50	Unconsciousness and probable death resulting from respiratory failure

Table 228.6. Behavior Expected at Various Blood Alcohol Levels (BAL)

Waiting-room literature and hospital and community health-education programs can complement instruction. National campaigns focus on alcohol-related accidents, crime, concomitants of abuse, and birth defects.

INDICATIONS FOR ADMISSION AND REFERRAL

The patient who has medically decompensated because of a complication of alcohol abuse (e.g., heart failure, pancreatitis, gastrointestinal bleeding, and hepatitis) clearly requires prompt hospital admission. Other candidates include persons with evidence of severe withdrawal (tremor, agitation, hallucinations, seizures) and those unable to tolerate a severe withdrawal syndrome (prior history of severe withdrawal, concurrent medical or psychiatric illness, chronic and severe alcohol-related illness). A free-standing detoxification center may suffice for the otherwise uncomplicated patient.

Patients with major psychopathology, poor ties to the physician, or a disintegrated social network have serious drawbacks to successful treatment by even the most willing primary care physician. Such patients should be referred in a coordinatedway for specialized care, ensuring continuity and a personalized treatment program. The primary physician can perform a major service for these patients by understanding available specialized referral resources in one's community and matching them to the patient's needs.

RECOMMENDATIONS

- First establish rapport. Let the patient know you accept and understand them by approaching the problem in a respectful and comfortable manner.
- Offer appropriate and sufficient instruction and explanation as you go along, always engaging the patient in establishing realistic goals and not pushing beyond limits.
- Maintain a proper balance of support, caring, and limit setting; remain flexible and adaptable to the patient's needs.
- Think of treatment as a series of short-term programs to develop and increase the patient's sense of mastery.
- Never insist on immediate abstinence. This is a goal to be negotiated and accomplished in the context of harm reduction when there is resistance to abstinence. Only if all else fails should there be confrontation and control in this area.
- If serious health problems will result from any alcohol intake and you must ask the patient to abstain, do it in the context of a supportive educational-advice session to ensure their return.
- If a patient comes to a session drunk, kindly and calmly explain why it would be pointless to have a session and reschedule the appointment. If this behavior continues, the treatment agreement should be renegotiated to include rules about it.
- Keep motivation high, not only by using the patient's fear of losing his or her health, something, or someone very important, but by getting him or her to seek and define his or her own reinforcers.
- Help the patient to identify, objectify, and deal with anger and other emotions to enhance emotional control.
- When the patient is ready, help pinpoint the actual behaviors to be changed and work on them progressively. One may need to provide information, modeling, practice, feedback, and homework as the patient learns to handle feelings and to develop new social skills, the tools necessary to assess and modify behavior.
- Encourage self-monitoring of drinking behavior via logs, teaching the patient to detect causes, consequences, and maintaining factors and thus helping to learn alternate ways of coping with the people, places, situations, and feelings associated with heavy drinking.
- Select those components of available specialized treatment programs that match to the patient's needs, wants, and ability to cope. The standard formula of detoxification—disulfiram and Alcoholics Anonymous—is no longer either the recommended or the most acceptable treatment for alcoholism.
- For spree and binge-drinking patients, whose interpersonal and psychologic problems are likely to be predominant, consider outpatient psychotherapy if they are socially intact, intellectually curious, and psychologically minded.
- For patients strongly motivated to attain total abstinence and specifically requesting disulfiram therapy, begin 250 mg qhs and renew on a monthly basis, reevaluating the need for continued drug therapy while working on psychosocial interventions that will sustain long-term abstinence. Treatment is contraindicated in those with underlying psychiatric illness or cardiovascular disease. Consider naltrexone 50 mg/d for those who relapse because of intense craving for alcohol. Use drug treatment only as a complement to and a means of participating effectively in a comprehensive program of care.
- For patients who are rigid, repressed, and resistant to open-ended therapies, consider behavioral-cognitive methods. Brief physician intervention that is personalized can be effective.
- For patients willing to dedicate themselves to a lifetime of sobriety or who will benefit from peer counseling, consider Alcoholics Anonymous, especially if there is a religious interest.
- For patients who are homeless, jobless, or have other serious social problems, refer to a community social service agency for direct aid.
- For patients who have failed outpatient treatments, can afford the time, and need to be taken out of their environment to cease drinking, consider an inpatient alcohol program.
- For treatment of withdrawal, consider outpatient management if the patient is reliable, has no or only mild symptoms, no active underlying medical illnesses, no prior history of severe withdrawal and who has a supportive family that can provide supervision. Prescribe a long-acting BZD (e.g., a fixed-schedule program of diazepam 10 mg every 6 hours for four doses, then 5 mg every 6 hours for eight doses); achieve tapering by normal drug metabolism. Unstable patients and those with other medical conditions or with symptoms suggesting potentially severe withdrawal (e.g., tachycardia, tremor, hallucinations, increased irritability) should be promptly admitted for treatment.

CHAPTER 229 APPROACH TO THE PATIENT WITH SEXUAL DYSFUNCTION

LINDA C. SHAFER

There is an important relationship between one's sexual life and emotional and physical well-being. With the advent of sildenafil (Viagra) to treat erectile dysfunction and the increased interest in pharmacologic agents to treat female sexual disorders, the frequency of sexual dysfunction complaints in primary care care practice has risen to nearly 15% to 20% of visits. However, the incidence of sexual problems in any medical practice is a function of the frequency with which physicians take a sexual history. Approximately 43% of women and 31% of men report some specific sexual dysfunction when questioned. Therefore,the primary care physician needs to know how to take a sexual history, perform an appropriate medical evaluation (see Chapter 115 and Chapter 132), and carry out basic types of sexual counseling and supportive therapy. Over 80% of sexual complaints can be treated successfully in the primary care setting.

DEFINITIONS

Disorders are classified as "*primary*" when there has never been a period of satisfactory functioning and "*secondary*" when the difficulty occurs after adequate functioning had been obtained.

Male Disorders

Erectile dysfunction (impotence) is defined as the inability of a male to maintain an erection sufficient to engage in intercourse and is considered a problem if it occurs in over 25% of attempts. Premature ejaculation is the loss of voluntary control of the ejaculatory reflex. Masters and Johnson have defined the condition in terms of the inability to satisfy the female partner at least 50% of the time. However, this presupposes that the female has no problem with orgasm. *Premature ejaculation* is most often defined as ejaculation that occurs in less than 2 minutes after penetration or on fewer than 10 thrusts. *Retarded ejaculation* is the inhibition of the ejaculatory reflex. There is a persistent failure to ejaculate in the presence of a satisfactory erection. *Retrograde ejaculation* is a physical impairment of internal vesical sphincter activity.

Female Disorders

Frigidity is a term applied to a wide variety of conditions in the female, from complete lack of any sexual response to various inadequacies in orgasmic response. Because it is nonspecific and has a derogatory connotation, the term has been eliminated from most recent classifications. It has been replaced by two more precise terms: *female sexual arousal disorder (excitement phase dysfunction)* and *orgasmic dysfunction*. Female sexual arousal disorder (excitement phase dysfunction) is defined as the inability to respond to sexual stimulation with lubrication and genital vasocongestion. Orgasmic dysfunction refers to the inability to release the orgastic reflex and have an orgasm, despite ability to enjoy sexual intercourse and have normal sexual desire. There is no distinction between "healthy" vaginal and "infantile" clitoral orgasm. Some women who can have orgasm with direct clitoral stimulation find it impossible to reach orgasm during intercourse. This is a normal variant of sensitivity requiring the pairing of direct clitoral contact with intercourse. Vaginismus is an involuntary spasm of the musculature of the outer third of the vagina, making penile penetration impossible.

Both Sexes

Dyspareunia is a condition defined as painful intercourse leading to avoidance of sexual contact. *Hypoactive sexual desire disorder (low libido)* is defined as an absence of sexual fantasies and lack of desire to engage in sexual activity. *Sexual aversion disorder* is defined as an active avoidance of genital sexual contact with a sexual partner.

PSYCHOLOGICAL MECHANISMS AND CLINICAL PRESENTATIONS

Organic conditions are responsible for between 50% and 85% of sexual problems in both sexes (see Chapter 115 and Chapter 132). This figure represents a dramatic shift in the understanding of the causes of sexual disorders that were once thought to be primarily of psychogenic origin. Organically based sexual dysfunctions are usually compounded by psychologic issues. *Depression* as a cause of or result of sexual dysfunction must be ruled out in every case. Although there are no rigid correlations between developmental factors and dysfunctional syndromes, sexual disorders can be related to *prior experiences*. Early sexual attitudes may be negatively shaped by parental communication that sex is bad, dirty, or sinful; by inadequate information about sex; or by myths and misconceptions such as the ever-ready penis or mutual climax. Other negative experiences range from unpleasant sexual encounters to childhood sexual abuse and rape. *Intrapsychic conflicts* extend from fear of sexual failure to concerns about sexual identity and profound depression.

Interpersonal issues of a sexual and nonsexual nature sometimes interfere with sexual functioning, especially in the setting of inadequate communication and lack of cooperation between partners. Sexual problems may develop from such nonsexual factors as *situational stress and financial pressures*. Finally, sexual difficulty may occur in the context of the anxiety generated by an organic illness, such as fear of death after a heart attack.

Once a sexual problem ensues, regardless of the cause, a vicious cycle of fear of failure, anxiety, and guilt is likely to ensue and remain self-perpetuating.

Clinical presentations can be quite complex. In addition to sexual dysfunction, there may be somatic complaints with no apparent medical cause (e.g., headache, low back pain, urinary symptoms, generalized pelvic pain, vulvar pruritus).

Erectile Dysfunction. Most normal men experience occasional erectile failure due to fatigue, too much alcohol, or any number of transient unfavorable circumstances. In the United States, it is estimated that 10 to 20 million men have erectile dysfunction. True impotence has an incidence that ranges from 1% in men under 35, to 40% of men over 60, to 73% of men over age 80, with the age-related increase mostly due to physiologic factors. Prolonged impotence and primary impotence are much more likely to be associated with medical disorders or more serious psychologic issues, such as fears of intimacy, feelings of intense hostility toward women, and gender identity questions.

Premature ejaculation is the most common male sexual disorder, occurring in 30% to 40% of adult men. The psychologic causes of the disorder range from early conditioning to ambivalence and hostility toward women. Its increasing frequency has been associated with women wanting more sexual satisfaction, particularly orgasm. Once premature ejaculation occurs, it can easily be reinforced by the negative attitudes expressed by the partner. In addition, prolonged periods of no sexual experience seem to make the problem worse. If premature ejaculation occurs over a long period of time and remains untreated, secondary impotence may result. It is often easily treated in the context of a good relationship and has a very good prognosis.

Retarded ejaculation occurs most often in younger less sexually experienced men. The lifetime prevalence is 2%. Its milder form is often related to anxiety-provoking situations and has an excellent prognosis. When long-standing, the condition often signifies deeper seated psychopathology, such as significant fears of rejection involved with letting go. Issues of control and commitment may be involved as well as unconscious conflicts regarding female genitals or pregnancy.

Female Sexual Arousal Disorder. These women present with a complete avoidance of sexual activity or an aversion to sex, which is stoically endured. There is often a deep-seated conflict about sexuality, which makes the outcome less favorable. Concomitant depression and interpersonal problems and a history of medications or pelvic pathology (see Chapter 115) are other important factors.

Orgasmic dysfunction is among the most frequent female sexual complaint and occurs more often during the early years of sexual activity. The capacity for orgasm appears to increase with sexual experience and that includes the aging female. Again, the psychologic factors involved are variable and the prognosis for the condition is a function of which factors are responsible. These range from fears of loss of control and unrealistic expectations about sexual performance to poor partner communication. Depression must not be overlooked.

Vaginismus is associated with a high incidence of pelvic pathology (see Chapter 115). A careful gynecologic examination is always warranted and, in fact, is the only definitive way to make a diagnosis. Vaginismus is one cause of *dyspareunia*. When related to psychologic factors, vaginismus can be considered a conditioned response and treated behaviorally. There is often confusion about sexual anatomy and physiology, leading to fears of penetration and concerns about femininity. If the condition is long-standing, partners of these women can become seriously affected, developing secondary impotence. This disorder has been at the center of many cases of unconsummated marriages of long duration.

Dyspareunia. The overall prevalence for this condition is 20% (15% of women and 5% of men). Patients seek out medical treatment, but the physical exam is often unremarkable, with no genital abnormalities. The condition is usually chronic and results in avoidance of sex.

Hypoactive Sexual Desire Disorder. The prevalence of this condition is 40% for women and 30% for men. Low libido in one partner may reflect an excessive need for sexual expression in the other partner. Depression should be ruled out in all cases. Medical conditions causing pain, weakness, disturbance of body image, and concerns of survival may be important triggers.

Sexual Aversion Disorder. The exact incidence is unknown, but this is a common disorder. Primary sexual aversion is higher in men, and secondary sexual aversion is higher in women. About 25% of patients meet the criteria for panic disorder. These individuals may have marital problems and may avoid sexual situations by covert strategies such as going to sleep early, traveling, neglecting personal appearance, using substances, or being overly involved at work.

WORKUP

Sexual History. The sexual history should be an integral part of every medical evaluation, given the importance of sexual function to overall health, the central role that sexual dysfunction might play in somatic complaints and quality of life, and the need to review safer sexual practices. The history is most easily obtained in conjunction with performing the gynecologic and menstrual review of systems in women and the genitourinary review in men. In this way, sexual practices and concerns can be comfortably elicited in the context of routine history taking, especially if the physician displays an open, nonjudgmental, unembarrassed, and accepting attitude. One needs to take into account differences in social values, class, and age.

Helpful *screening questions* include "Does your present sexual functioning meet your expectations?" "Has there been a change in your sexual functioning?" "Would you like to change anything about your sexual functioning?" Additional routine questions to ask during the AIDS era are "Have you been sexually active (or involved) with a partner in the past 6 months? (With women, men, or both?)" "Do you practice safe sex?" Failure to ask AIDS screening questions may result in criticism of inadequate treatment or even lead to a malpractice suit.

If a sexual problem is uncovered, the chief complaint should be explored in detail. Ask patients to describe the problem in their own words, noting its duration, circumstances, possible precipitating and alleviating factors, and severity. A thorough description sometimes helps to distinguish an organic from a functional etiology (see Chapter 115 and Chapter 132). For example, in the impotent male, preservation of erectile function on awakening suggests a psychologic cause as does erection with attempts at masturbation.

Also try to elicit what type of treatment is viewed as potentially helpful, be it medicine, information, or support. Anything that tends to alleviate the problem, even if only temporarily, should be sought.

Physical Examination and Laboratory Studies. With improved understanding of the pathophysiology of sexual function and more sophisticated diagnostic testing, many sexual problems once thought to be purely psychogenic have been found to have an organic component as well. Take special note of sexual dysfunction as a common side effect of selective serotonin reuptake inhibitors, occurring in more than 30% of patients taking the medication. Even when psychological or interpersonal problems are believed to be the principal cause of sexual dysfunction, a careful medical evaluation that includes a detailed physical examination in conjunction with a few pertinent laboratory studies is always indicated (see Chapter 115 and Chapter 132).

PRINCIPLES OF TREATMENT

The primary care physician is often the first person consulted by a patient with a sexual problem. Even the physician without formal training in sex therapy can help many patients deal effectively with their sexual difficulties. When the problem stems from guilt and misinformation, the physician can use his or her position as an authority figure to give *permission and reassurance*, relabeling as "neutral" or "positive" sexual activities that the patient might fear are "bad" or "sinful."

Educating patients and correcting misinformation is a function that should not be overlooked or underestimated. Giving permission or providing information may be all that is necessary to help many patients. An essential part of modern sexual counseling is the teaching of safer sexual practices and review of risk factors for HIV infection (see Chapter 7 and Chapter 13).

Behavioral Methods and Medication. When the problem goes beyond misinformation, a trial of *behavioral methods* with specific suggestions to patient and partner can be helpful and is an appropriate next step. The objectives are to increase communication between partners, decrease performance anxiety and "spectatoring," change the goal of sexual activity toward feeling good and away from emphasis on erection or orgasm, and relieve the pressure to perform at each sexual encounter. A trial of such therapy is reasonable when there is no evidence of organic illness or significant underlying psychopathology.

Oral medication prescribed for specific sexual complaints of various etiologies may be given instead of or in conjunction with behavioral techniques. *Sildenafil* (Viagra) has revolutionized the treatment of erectile dysfunction and is effective in 46% to 73% of men. *Phentolamine* (Vasomax) and apomorphine also are efficacious in the treatment of erectile disorders and are currently under U.S. Food and Drug Administration review.

Premature ejaculation can be therapeutically treated with *antidepressant* medication, specifically clomipramine (Anafranil) and *selective serotonin reuptake inhibitors*, including fluoxetine (Prozac) and sertraline (Zoloft), which are associated with delayed ejaculation. Low libido or orgasmic dysfunction in postmenopausal women may respond to estrogen/testosterone compounds. The effectiveness of sildenafil in women to treat orgasmic dysfunction and arousal disorder is currently being studied. Topical impotence medication, including alprostadil cream (Topiglan), minoxidil solution, and nitroglycerine ointment, are under investigation. The steps described above will often lead to improved sexual function without the need for referral.

Although sildenafil (Viagra) is easy to prescribe, effective, and well tolerated, both physicians and patients must address the high cost of this drug (in excess of $10/pill). Insurance companies call for physicians to document why patients require this drug, setting strict payment guidelines and refusing payment when the drug is used only to enhance the quality of life. Similar issues may arise with other pharmacologic agents used to treat sexual dysfunction that are currently under investigation. How we spend our limited health care dollars is a matter of public health policy. Yet the physical and emotional suffering of people with sexual problems should not be underestimated or downplayed. Early studies suggest that patients with sexual disorders who are treated pharmacologically respond with increased self-esteem and greater marital happiness.

TREATMENT RECOMMENDATIONS: BEHAVIORAL TECHNIQUES

Erectile Dysfunction

- First educate the patient as to his ability to satisfy his partner without having penile-vaginal intercourse.
- Then begin "sensate focus" exercises, which start with nongenital massage and progress to genital massage. There should be a prohibition against intercourse, even if erections occur.
- After erection is obtained by genital massage, progress to attempting intercourse. In the female-superior position (female on top of male), the female may

manually stimulate the penis, and if erection is obtained, she may insert it into her vagina in a slow nondemanding fashion, relieving the male of any responsibility for insertion. This may also be done with a partial erection. Gradual movement is begun. There is an emphasis on the pleasures of vaginal containment.

Premature Ejaculation

- Educate the patient that his condition has little to do with the sensitivity of the penis but is usually the result of previous conditioning and anxiety.
- Suggest an increase in the frequency of sexual activity.
- Teach the Masters and Johnson "squeeze" technique. In this technique, the female manually stimulates the penis. When ejaculation is approaching the point of inevitability, as indicated by the male, the female squeezes the penis with her thumb on the frenulum, her index finger placed above, and her middle finger below the coronal ridge on the dorsal side of the penis. The pressure is applied until the male no longer feels the urgency to ejaculate (15 to 60 seconds). The squeeze technique should be repeated two or three times before ejaculation is allowed to occur.
- Once there are good results with the squeeze technique, the couple can try intercourse. In the female-superior position, the female remains motionless to accustom the male to vaginal containment. Gradual thrusting begins, using the squeeze technique as excitement intensifies.
- An alternative to the squeeze technique is the "stop-start" method. The female stimulates the male to the point of ejaculation, at which time she stops the stimulation. The erection may or may not subside. She then resumes stimulating the penis. After several stop-start procedures, the male may ejaculate.

Retarded Ejaculation (During Intercourse)

- The female stimulates the penis, asking for directions (verbal and physical) to enhance the feeling.
- Extravaginal ejaculation is obtained by continued stimulation. In the male's mind, the female should become associated with ejaculatory release.
- The female stimulates the penis manually until orgasm becomes inevitable. The penis is then inserted and the female thrusts demandingly. Manual stimulation is repeated if there is no successful ejaculation.

Female Sexual Arousal Disorder (Excitement Phase Disorder)

This disorder often results from more severe psychopathology and usually requires referral for treatment. However, on the practical side, suggestions regarding the supplemental use of lubrication such as saliva or KY jelly should be made.

Orgasmic Dysfunction

- Change the goal of sexual activity away from orgasm toward enjoyment of the experience.
- Give permission to the female to express sexual feelings.
- Begin sensate focus exercises, nongenital massage to genital massage. Use the back-protected position (male in a seated position with female between his legs with her back against his chest) with female in control to alleviate self-consciousness or spectatoring.
- Instruct the male in stimulative technique: He should not force responsivity but rather seek to accommodate desires;he should not approach the clitoris directly because of sensitivity.
- After success in manual genital stimulation, controlled intercourse in the female-superior position with the male making no demands comes next. This is followed by a lateral position that allows for mutual freedom of pelvic movement.
- For women who have never experienced orgasm, suggestions regarding self-stimulation are appropriate. The use of fantasy material is most helpful.
- For women who do have orgasms with masturbation but not intercourse, the "bridge technique" may be useful. After insertion of the penis, the male can stimulate the female (clitorally) manually or with a vibrator. This pairing can be helpful in achieving orgasm, and often after the female experiences orgasm in this way, the need for supplementary stimulation disappears.

Vaginismus

- Explain to the patient and her partner that this condition is involuntary and not willfully caused. Physical demonstration of the involuntary vaginal spasm may be done by inserting a gloved finger into the vaginal entrance.
- The couple is asked to refrain from intercourse during the early treatment.
- In a stepwise gradual fashion, the woman is encouraged to accept larger and larger objects into the vagina. This may be accomplished with the use of graduated Hegar dilators to be used in the office and at home or the woman may begin by using her fingers, first one and then several approximately the size of the penis. She may use her partner's fingers. Syringe containers of different sizes make good dilators.
- In the female-superior position, the woman gradually inserts the penis.

INDICATIONS FOR REFERRAL

Psychiatric Referral. After trying these medications and/or behavioral techniques, the patient's condition may still not be improved. This is often a sign that a referral to a psychiatrist or other mental professional trained in dealing with sexual problems is indicated and that the patient needs more intensive therapy. Often, direct referral to the specialist is indicated for patients with chronic psychopathology, such as those with " *primary" sexual dysfunctions, gender identity questions or homosexual conflicts, marked personality disorders* or significant past psychiatric history (especially of psychosis), or overt evidence of a clinical *depression* underlying the sexual complaint. Moreover, chronic severe problems in the relationship with one's partner signal the need for a referral.

Urologic Referral. For both organically based impotence and impotence refractory to psychologic treatment, it is appropriate to refer patients to urology. Treatments include a consideration of an intensive pharmacologic erection program, such as the injection of alprostadil (Caverject) into the base of the penis, the transurethral insertion of alprostadil (i.e., penile suppository) external vacuum pump therapy, and surgical penile implant (see Chapter 132). The success of any such treatment requires close collaboration between the urologist and the psychiatrist. On a case by case basis, referral to gynecology, endocrinology, and/or neurology may be warranted.

PATIENT EDUCATION

Early in one's practice, it becomes clear that patients have many sexual questions and concerns. Inadequate or inaccurate information about sexual anatomy, physiology, and practices is the basis for many sexual problems. Therefore, sex education should not be overlooked. Patients can sometimes obtain supplemental information from suggested reading material. Several time-honored books include *For Yourself: The Fulfillment of Female Sexuality* by Lonnie Garfield Barbach (New York, Doubleday, 1975); *Becoming Orgasmic: A Sexual and Personal Growth Program for Women* by Julia Heiman and Joseph LoPiccolo (Englewood Cliffs, NJ, Prentice-Hall, 1988); *The New Male Sexuality* by Bernie Zilbergeld (Boston, Little, Brown, 1992); *How to Overcome Premature Ejaculation* by Helen Singer Kaplan (New York, Brunner/Mazel, 1989); *The Illustrated Manual of Sex Therapy, 2nd edition*, by Helen Singer Kaplan (New York, Brunner/Mazel, 1987); and *The Joy of Sex*, edited by Alex Comfort (New York, Simon and Schuster, 1989). A visit to answer questions that come up in the context of reading is always appreciated.

Lack of knowledge regarding *safe sex practices* is a major contributor to the spread of HIV infection. Concern about HIV infection can also interfere with enjoyment of sexual activity. Detailed review of safe sex practices is essential, including benefits of using condoms and spermicides containing nonoxynol-9 (see Chapter 7 and Chapter 13). Condom use is critical for those with multiple sexual partners and for monogamous partners in whom HIV status is unknown. With prudent precautions and a little creativity (e.g., making condom application an early part of foreplay), a safe and enjoyable sexual life can still be attained.

CHAPTER 230 APPROACH TO THE SOMATIZING PATIENT

ARTHUR J. BARSKY, III

The somatizing patient presents with bodily complaints or disability out of proportion to any demonstrable organic pathology. Included in this category are anxious and depressed patients, hypochondriacs, chronic pain patients, and malingerers. These people are among the most frustrating and troublesome encountered in primary care, but they can be evaluated and managed successfully. Attention to the causative psychopathology helps to render symptoms understandable, enables the physician to distinguish them from those due to organic pathology, and facilitates management.

PSYCHOLOGICAL MECHANISMS AND CLINICAL PRESENTATIONS

Hypochondriasis. Hypochondriacal patients are people for whom illness, invalidism, and pursuit of medical care have become a way of life. Illness and medical treatment furnish them with a vocabulary for communicating with other people, a way of responding to stress, and a means for expressing their psychological needs. They are preoccupied with their bodies and their health, convinced that they have some occult serious medical disease. At the same time, they fear disease intensely. Their concern about being ill is remarkably persistent, and it is not assuaged by reassurance or a thorough medical evaluation. Although they have had extensive medical care, they have found it disappointing, failing to provide a cure or even relief of symptoms.

Clinical Presentation. Their symptoms shift and fluctuate over time, are often nonspecific and ambiguous, and are frequently similar to the transient sensations experienced by healthy individuals. When interviewed, such patients talk mainly about their illnesses and medical care and little about friends, work, or hobbies. Often, they seem as concerned with establishing the authenticity of their complaints as with obtaining relief. They adamantly deny any emotional contribution to their symptoms (in contrast to many patients with serious physical disease, who are willing to consider the possibility that anxiety and depression make their symptoms worse).

Explanatory Models. Hypochondriasis has been understood as a cognitive and perceptual process, an interpersonal communication, and an unconscious intrapsychic mechanism.

The *cognitive/perceptual* model suggests that hypochondriasis is a self-validating and self-perpetuating disorder of symptom amplification. Hypochondriacal patients are unusually sensitive to visceral and somatic sensation and are therefore bothered by normal physiologic sensations and minor discomforts that nonhypochondriacs ignore, dismiss, or are completely unaware of. Because bodily sensation seems so intense, noxious, and disturbing, they readily misattribute it to disease. Once the individual believes him/herself to be sick, it alters subsequent bodily perception, and a process of symptom amplification begins. The belief that one is sick makes preexisting symptoms more intense because they are now subject to closer scrutiny. This apparent worsening of their condition makes these patients even more firmly convinced they are sick. They become hypervigilant for other symptoms that confirm their suspicions and ignore contradictory information indicating that they are not in fact sick. For example, an individual may notice breathlessness after climbing a flight of stairs and wonder if this signifies the onset of heart or lung disease. With this suspicion in mind, the patient now notices that his face seems unusually pale in the mirror when he next shaves. This too seems to provide further evidence of disease progression. Thus, a self-validating and self-perpetuating cycle of cognitive and perceptual amplification has been set in motion.

In the *interpersonal communication model*, hypochondriasis emerges as a nonverbal way of saying something to the important people in the patient's life. The hypochondriacal patient is using a bodily pantomime to tell others that he is facing a seemingly insurmountable life problem which he cannot solve or cope with. He is asking to take "time out," saying to others (in a nonverbal language) "I am in a desperate situation and so I need special care and attention, unusual assistance and support at this time." Hypochondriacal patients have unwittingly learned that illness behaviors can be used to negotiate stressful circumstances, secure support, and solicit care. It is crucial to reemphasize that hypochondriacal patients do have the symptoms they report; they are not malingering or feigning disease. Rather, they have learned over the course of their lives that assuming the sick role can help them to postpone or avoid a crisis or challenge they face.

In the *intrapsychic model*, observers have emphasized the unconscious meaning and gratification of pain and discomfort. Bodily complaints may be amplified by a deprived and needy person who has only experienced caring and attention when sick or in pain. Suffering and illness can thus become ways to express and gratify yearnings for contact, comfort, and support. Other hypochondriacal individuals are angry and hostile, feeling rejected or wronged in some way. For them, physical symptoms offer a nonverbal way of expressing their anger, recrimination, and blame by reproaching and belaboring others with their suffering. Finally, symptoms and illness can unconsciously serve to distract some individuals from an even more painful sense of themselves as fundamentally worthless and defective as people. They can thus attribute their failures, disappointments, and rejections to a physical incapacity rather than to any personal inadequacy.

Anxiety (see Chapter 226). Individuals suffering from *chronic anxiety* focus on and become alarmed by normal bodily sensations. They report headache, gastrointestinal disturbance, or musculoskeletal pain. *Panic anxiety* has somatic manifestations that include palpitations, chest pain, tachycardia, dyspnea, choking sensations, diarrhea, cramps, sweating, and fainting.

Depression (see Chapter 227). Depression's *neurovegetative symptoms* may overshadow the characteristic affective, cognitive, and behavioral changes that are part of the depressive syndrome. As many as one half of somatizing ambulatory medical patients over age 40 are depressed. The chief complaint may be headache, constipation, weakness, fatigue, abdominal pain, insomnia, anorexia, or weight loss. Depressed patients worry about and focus attention on their bodies. A positive review of systems, chronic pain, or complaints involving multiple organ systems typify the clinical presentation, and symptoms often recur with the periodicity characteristic of depressions.

Conversion reactions are acute physical dysfunctions that suggest medical disorder but which are actually the expression of a psychological need or conflict. The emotional distress is thought of as being "converted" into, or expressed as, physical distress. The process is entirely unconscious. Symptoms are either sensory or neuromuscular (e.g., weakness, paralysis, ataxia, blindness, aphasia, deafness, anesthesia, paresthesias, or seizures) and generally of short duration. Other features include a prior history of similar reactions, major emotional stress before onset, and apparent symbolic meaning of the symptom (e.g., paralysis after losing control and striking someone or blindness after viewing a horrifying event). Other significant psychopathology is often, but invariably, present.

Somatic delusions are seen in schizophrenia, severe affective disorders, and organic brain syndromes. These are false fixed ideas that are often vivid, bizarre, or highly personalized. Unlike hypochondriacal concerns, they do not fluctuate. The individual may believe some extraordinary change has occurred in his body, for example, that his organs are shriveling up, that body parts are deformed or missing, or that foreign objects are inside an orifice or organ.

Some patients suffer from *body dysmorphic disorder*, a fixed circumscribed delusion that they are physically deformed, although their appearance is actually unremarkable. A facial feature is often the focus. The condition is extremely disabling, chronic, and can be quite difficult to treat.

Malingering differs from the abovementioned conditions in that the patient is not actually experiencing the symptoms reported and is consciously simulating or feigning disease. Malingering occurs in situations in which illness confers some obvious benefit, such as among prisoners, drug addicts, or in individuals under some legal threat. Symptoms are exaggerated, and the subject's description of them may vary with each interview. When the patient is unaware that she is being observed, she may relax the simulation and thus betray herself. Such individuals are frequently sociopaths or drug addicts. Some may have worked in a medically related field.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of somatizing includes anxiety, depression, conversion reaction, hypochondriasis, schizophrenia, and malingering. Somatizing patients, of course, have the same propensity for medical illness as their nonsomatizing counterparts. Thus, one must take care to rule out organic causes of the patient's

symptoms, just as with any other medical patient. Medical disorders that affect multiple organ systems and produce transient or recurrent nonspecific complaints (e.g., multiple sclerosis, systemic lupus, polymyalgia rheumatica, Lyme disease, myasthenia gravis, hyperparathyroidism) pose the greatest diagnostic difficulty.

WORKUP

History: Differentiating Somatization from Organic Disease. The task is not always easy (see Chapter 8, Chapter 226, and Chapter 227), but the quality, timing, and precipitants of symptoms, as well as the patient's response to illness, attitude, and choice of words, can be of considerable help.

Quality of Symptoms. A complaint whose characteristics are inconsistent with known pathophysiology is likely to be psychogenic in origin. Psychogenic sensory complaints often involve combinations of sensory modalities that are neurologically impossible (e.g., a patient reporting loss of position and vibratory sense can nonetheless walk normally; see Chapter 167). Conversion seizures do not involve incontinence or tongue biting, and the patient with conversion blindness exhibits a withdrawal or startle reflex when a hand is flashed before the face. With conversion paralysis of the upper extremity, the patient's arm avoids the face after being held above it and released. In conversion paralysis of one lower extremity, the patient's attempts to move the afflicted leg do not invoke contraction of the other leg, as is the case in neurologic disease.

Psychogenic symptoms are more likely to resemble a symptom that has afflicted someone important to the patient (a so-called *figure of identity*) or to be excessively vague or overly detailed. Diffuse inconsistent descriptions and vivid, elaborate, highly personalized, or idiosyncratic complaints are very suggestive. Psychological factors may be revealed in the choice of words (e.g., "pain in the neck" or "not having a leg to stand on").

Timing and Precipitants. Psychogenic pain is typically unaffected by activity or by the passage of time, and the patient often seems even more concerned with the physician's accepting the authenticity of the pain than with relieving it. Although both physical and psychological illness can be precipitated by stress, the onset of psychogenic complaints is often closely associated with *significant emotional stress*, such as the loss of a loved one or the onset of a major interpersonal conflict or sexual problem. Functional complaints are also prone to occur on the *anniversary* of a psychologically meaningful event, such as the death of a loved one.

Attitude Toward Symptoms. When the patient is unconcerned, inappropriately calm, or more concerned with establishing authenticity than with obtaining relief, one should suspect a strong emotional component. It must be emphasized, however, that stoical and stolid patients may remain very unemotional when afflicted with serious organic disease. As noted, patients with psychogenic complaints who unconsciously derive considerable gain from their illness are often reluctant to consider an emotional cause for their symptoms.

History: Defining the Underlying Psychopathology. Once a psychogenic etiology is suspected on the basis of the clinical presentation, evaluation should proceed to define the underlying psychopathology. Inquiry into precipitants, response to illness, and personality can be helpful.

Precipitants and Response to Illness. The history is searched for ongoing psychological stress, pending litigation or disability proceedings, prior medical complaints without a demonstrable physical cause, depression, or anxiety disorder. Details of previous medical care experiences can be revealing. A history of consulting many physicians for the same complaints or of the immediate replacement of a treated symptom with a new one help in the diagnosis of psychogenic illness.

Personality. It is important to determine if illness, discomfort, and disability have become a way of life and to what extent they are used to deal with emotional discomfort, interpersonal difficulties, and environmental stress. Does the patient see herself as a suffering and unfortunate person whose life is filled with disappointment, "bad luck," and defeat, as well as with illness? Anger and hostility may be expressed indirectly, as in cynicism, sarcasm, and uncooperativeness. The individual feels deprived and put upon and therefore reproaches, accuses, and blames others for her state. Finally, excessive dependence on others may be a feature of her personality. One senses an overpowering desire for care, attention, sympathy, and human contact, and the patient's attitude toward the physician may have a clinging and hungry quality.

Personal Significance and Secondary Gain. What personal significance does the patient attach to his symptoms or to the suspected illness? Are there possible secondary gains, such as receiving sympathy, attention, and support (including financial support) from family and friends; being excused from duties, challenges, and responsibilities; and acquiring the power to influence and manipulate others by virtue of being sick?

Physical Examination and Laboratory Studies. A thorough physical examination and a careful mental status examination are essential. Not only may unexpected evidence of organic illness turn up, but a normal examination is a prerequisite for effective reassurance and the avoidance of unnecessary laboratory testing. Unless there is evidence that is strongly suggestive of organic pathology, elaborate and, particularly, invasive studies should be avoided. Performing a test in the hope that it will reassure the patient is usually futile; patients who are highly anxious about their health often find some further source of concern when the result is negative, and the likelihood of a false-positive result is higher when the pretest probability of organic pathology is low (see Chapter 2).

PRINCIPLES OF MANAGEMENT

Support. Management must be directed at the underlying psychopathology and at the presenting bodily complaints. The first step is to put the complaint in perspective, while still recognizing that the patient has come because of physical symptoms. When the results of the workup are presented, the reality of the symptoms should not be denied, nor should it be implied that they are imaginary. The patient can be told that serious damaging organic disease has been ruled out and that stress can amplify real bodily sensations and disrupt normal function. It is important to avoid saying "there is nothing wrong," because this contradicts the patient's experience and may make him or her feel foolish or angry. The presence of symptoms is an indication of considerable distress, which the patient should be encouraged to discuss. The patient needs to know that the relationship with his or her physician will not be terminated because the medical workup is "negative."

Additional visits should be scheduled on a regular basis to provide time to further discuss personal and situational problems. By offering the patient a long-term relationship that is not contingent on organic symptoms, one may remove a major stimulus for their development. Refractory cases may benefit from referral to a psychiatrist, if the patient is willing to seek such a consultation.

Role of Drug Therapy. Nonspecific attempts to suppress somatization pharmacologically should be avoided. All too often, patients are told that their symptoms are due to their "nerves" and sent away with a prescription for a minor tranquilizer. Such an approach to therapy usually fails and often alienates the patient. However, if a pharmacologically responsive psychiatric disorder is present, treatment with the appropriate agent should be initiated. It is especially important to recognize depression because of its high prevalence, subtle manifestations, and good response to pharmacotherapy. Depression responds well to medication (see Chapter 227), panic disorder is helped by the use of antipanic medication, and generalized anxiety may respond to cognitive and behavioral interventions (see Chapter 226).

Treatment of Personality Disorders. Because the best treatment is supportive, most patients with somatization due to a personality disturbance can be managed by the primary physician. Medical intervention should be minimized when possible. Major diagnostic workups for equivocal or questionable findings should be avoided (as long as it is medically responsible to do so), as should pain medication and tranquilizers. Even though medication is often requested, these patients generally do not respond to it and tend to be especially prone to development of troublesome side effects and adverse reactions.

To avoid struggles, the patient, especially if hostile and angry, should be involved as much as possible in therapeutic and diagnostic decisions. The physician ought to make it clear that his or her role is to help the patient tolerate discomfort rather than to eliminate it. Therapeutic suggestions should be made with the caveat that although they may be of moderate palliative value, they will probably not completely eliminate the problem.

The situational or psychological need to remain distressed and symptomatic must be recognized. No surgical procedure can excise, no oral medication can cure, the need to be ill. Consequently, the physician must not expect cure. The patient's self-esteem needs to be bolstered. Acknowledging her strength to endure suffering, tolerate discomfort, and survive hardship and misfortune is particularly gratifying to her. These are qualities the patient values most in herself and are a source of what little self-esteem she has.

Treatment of Conversion Reactions. There are two aspects to the treatment of hysterical conversion reactions: symptom remission and management of the precipitating stress, internal conflict, or secondary gain to avoid recurrence or chronicity. The first is done through education, reassurance, and use of suggestion to reduce the patient's anxiety (these patients are often exceptionally suggestible). The patient should be assured that the disorder is self-limited and that the symptoms

will gradually improve and finally vanish. Conversion symptoms may recur, however, unless psychotherapy is arranged to alter the psychological forces at work.

Approach to Malingering. Malingering, once firmly established, must be dealt with by confronting the patient with the physician's conclusions. Diagnostic and therapeutic procedures should be avoided when possible because they reinforce the patient's behavior. Any abnormal laboratory tests or physical findings are suspect.

INDICATIONS FOR REFERRAL

Most somatizing patients can be managed by the primary physician. Referral is indicated when a patient has accepted a psychological explanation of his or her symptoms and wants to see a psychiatrist; when a conversion reaction, serious anxiety disorder, or psychosis is present; or when the primary physician has such a negative reaction to the patient with a personality disorder that he or she cannot serve that patient well.

TREATMENT RECOMMENDATIONS

- Explain the results of the medical workup without denying the reality of the patient's discomfort.
- Encourage discussion of psychosocial problems and set up a regular schedule of appointments for further elaboration and supportive therapy. Make it clear to the patient that physical symptoms do not need to be present to see the doctor. Avoid as-needed appointments when possible.
- Treat the underlying psychological problem specifically; do not attempt the nonspecific suppression of symptoms with tranquilizers.
- Do not try to remove or cure symptoms in the patient with a somatizing personality disorder. Acknowledge the suffering and provide support. Avoid the use of medication and the extensive workup of vague symptoms. Make adaptation to chronic discomfort the goal of care.

CHAPTER 231 APPROACH TO THE ANGRY PATIENT

ARTHUR J. BARSKY, III

Patients often become angry in response to the suffering and disability caused by disease, adverse life events, or the psychologic threats inherent in being a patient. When faced with an angry patient, the primary care physician needs to be able to recognize the source of the patient's anger, prevent it from interfering with therapeutic efforts, and help the patient to cope.

PSYCHOLOGICAL MECHANISMS

Threat from Illness. People become angry when they feel threatened or when their wishes and aims are frustrated. Disease often causes anger because it presents the threats of disfigurement, pain, lost opportunity, abandonment, and even death. Some patients are particularly enraged by the helplessness, lack of control, and enforced passivity that illness confers.

Threat of Dependency. Other patients are uncomfortable in the doctor–patient relationship because it represents the threat of dependence on the physician—of allowing someone powerful to take control of, take care of, and be responsible for them. They use anger to defend themselves against the intimacy and closeness that might develop with the doctor in the course of their relationship. Anger, then, can be an attempt to drive the physician away and allay the threat of dependency or intimacy inherent in the doctor–patient relationship.

Threats or Conflicts Elsewhere in Life. Patients commonly besiege their clinicians with anger derived from threats and stresses they are encountering elsewhere in their lives. In such instances, the animosity and hostility seem inappropriate to the situation and disproportionate to any provocation the doctor can think of. This usually occurs when patients are in conflict with important people in their lives to whom they cannot express their anger, such as an employer or a close family member.

Borderline Personality Disorder. Other patients appear to live a life permeated by a quick temper, chronic resentments, and long-standing dissatisfactions and resentments. The physician is little more than a screen onto which they project hostility garnered elsewhere. Some of these globally angry patients have a borderline personality organization. Both in their relationships with physicians and with other people, they appear explosive, stormy, and generally ungrateful. These patients relate to physicians and others in a dependent yet demanding fashion, exhibiting hostility toward and devaluation of the very people on whom they depend so desperately. Their anger expresses their expectation that people will generally be uncaring and unsympathetic. It also reflects their disappointment and feeling that they have been let down and not received the help they feel they need and deserve.

RECOGNIZING THE ANGRY PATIENT

Verbal and Nonverbal Manifestations. Anger may be expressed verbally in direct statements that convey demands, annoyance, and resentment, and in personal histories of temper outbursts and undirected violence (e.g., slamming doors). It may also be expressed more obliquely through cynicism, sarcasm, negativism, and behavior that, although superficially compliant and cooperative, is actually obstructive (i.e., passive-aggressive). Anger also finds expression in self-destructive behaviors, for example, failing to adhere to a medical regimen, keep appointments, or give up habits that are harmful to one's health.

Helpful nonverbal clues may be observed during the interview. The angry patient clenches the fists and jaws or knits their forehead in a frown. The palpebral fissures are narrowed, lips compressed, and nostrils widened. Gestures may be abrupt and gait may be jerky.

Emotional Response to Patient. Finally, the interviewer's own subjective emotional response to the patient during the interview may contain important diagnostic clues. Whenever the interviewer is aware of feeling irritated or bored with a patient, he or she should question whether these feelings are an unconscious response to anger and hostility on the part of the patient.

It is important not only to recognize that the patient is angry but also to learn what he or she is angry about. During the interview, the physician should note the subject matter that brings out irritation, annoyance, or hostility. The themes that seem to evoke anger point to the issues that are troubling the patient.

Recognizing the Boderline Patient. The globally angry patient with a borderline personality organization can be recognized by a few clinical characteristics: interpersonal relationships are either superficial or very dependent and manipulative; emotions are intense and labile, and extreme emptiness and anger predominate; social and intellectual skills may be well developed, but the patient's life is marked by lack of fulfillment and frequent failures; and impulsive, manipulative, and self-destructive behavior is present.

PRINCIPLES OF MANAGEMENT

Acknowledging the Patient's Feelings. Once the physician has recognized that the patient is angry and has defined some specific threats or frustrations that are fueling the anger, he or she can proceed to acknowledge the patient's feelings and reassure him that they will not destroy their relationship. This often helps bring about a more open give-and-take discussion between doctor and patient. The physician need not agree that the patient's feeling is justified, but he or she should acknowledge its existence by explicitly presenting the patient with observationsand the reasons for concluding that the patient is angry. Such discussion introduces a quality of openness, honesty, frankness, and sensitivity into the therapeutic relationship. The physician should convey neither fear or rejection of the patient's feelings but rather interest in trying to understand them in order to be helpful.

Setting Limits. If the patient's hostility interferes with communication, the therapeutic regimen, or coping with illness, this should be pointed out in a noncondemnatory and nonjudgmental fashion. The physician needs to indicate that although he or she recognizes and acknowledges the patient's anger, it nonetheless represents a problem because it is self-destructive, interfering with the patient's care or recovery. One need not be bullied by the globally angry patient. It is possible and necessary to set limits on the patient's behavior while making it clear that there will be no counterattack in retribution.

Exploring the Causes and Responding Appropriately. Having identified the specific frustrations and threats the patient is facing, the physician should be able to approach the patient more effectively. For the patient who is angry about being ill, detailed investigation of exact fears and sources of despair is helpful. For the patient who is angry about being thrust into the patient role, one might try to structure the relationship so as to minimize those aspects that most threaten the patient. For example, if the patient most fears dependency, the physician should assume a somewhat cool, reserved, and business-like stance, while still conveying support and sympathy. Finally, if the anger seems to be displaced on the physician from some other situation or relationship, this may be pointed out, without encouraging the patient to vent the hostility on its actual source.

Avoiding Retaliation. The physician should take care to not react with hostility and subtly retaliate against the angry and provocative patient. Maintaining a clinical distance on the situation will help the physician to see the patient's anger not as a criticism of the doctor but rather a response to the patient's own inner torment of fears, threats, and frustrated wishes. By doing so, one is in a good position to help the angry patient, preserve the therapeutic relationship, and more effectively carry out medical care.

INDICATIONS FOR REFERRAL

Caring for the patient with a suspected borderline personality disorder is often quite vexing. Psychiatric referral for confirmation of the diagnosis and management suggestions can be helpful, especially if the primary care physician finds it increasingly difficult to care for the patient. Before suggesting the referral to the patient, a

"curbside" consult with a psychiatric colleague can facilitate formulating a strategy for raising the issue of consultation with the patient and successfully arranging the referral.

CHAPTER 232 APPROACH TO THE PATIENT WITH INSOMNIA

JEFFREY B. WEILBURG

Approximately 40% of the general population experiences intermittent or chronic insomnia at least once. Epidemiologic studies find that between 10% and 17% of the population have some kind of insomnia at any given point in time and approximately 7% of the population have insomnia (persistent difficulty falling or staying asleep that compromises daytime functioning) of sufficient severity to warrant formal diagnosis and treatment. Insomnia affects patients of all ages and backgrounds but is especially prevalent in the elderly and in people of lower socioeconomic status.

The consequences of insomnia are significant, including impairment of work and social function, increased risk of motor vehicle accidents, and disturbance of mood. The cost of these problems combined with the cost of medication and other treatmentshas been estimated to exceed $100 billion/yr. The primary care physician needs to be skilled in the assessment and initial therapy of insomnia.

PATHOPHYSIOLOGY AND CLINICAL PRESENTATION

Sleep physiology is examined by using the polysomnogram, a continuous all-night recording of respiration, eye movements, electroencephalogram (EEG), muscle tone, blood oxygen saturation, and electrocardiogram.

Normal Sleep versus Insomnia. *Normal sleep* can be divided into two basic phases: *rapid eye movement sleep (REM) and non-REM (NREM)*. REM is a state of mental and physical activation. Pulse and respiration are increased but muscle tone is diminished, so little body movement occurs. The brain is active, and the EEG shows a pattern similar to that seen during waking. Most dreaming occurs during REM. In contrast, NREM is a time of deep rest. Pulse, respiration, and EEG all slow, and the patient goes from light sleep, called stages 1 and 2, to deep or delta sleep, called stages 3 and 4. REM and NREM normally cycle in a reciprocal pattern, giving a typical "architecture" to the polysomnogram. The entire cycle lasts about 90 minutes and is repeated smoothly four or five times during the night.

Insomnia is best regarded as a symptom, or complaint, which may be produced by a variety of underlying pathophysiologic processes. Therefore, insomnia has no single or pathognomonic polysomnographic pattern. Some insomniacs have slightly shorter than normal sleep times, some have less stages 3 and 4 sleep, but most have normal-appearing polysomnograms. Slight disruptions of the normal smooth cycling caused by frequent brief arousals may be related to subjectively unsatisfying sleep. Psychologic variables appear to strongly influence an insomniac's perceptions of restfulness and sleep.

Finding the underlying problem (often there are multiple problems operating simultaneously) producing the complaint is the key to effective management of insomnia.

Psychiatric Disorders appear to be the underlying cause in about half of all cases. Among patients presenting to primary care physicians, insomnia may be the initial manifestation of depression. Patients with *major depression* complain of either difficulty falling asleep or of waking in the early morning and being unable to return to sleep. Diurnal variation of mood is often noted. Severe depression with agitation may lead to markedly diminished total sleep and overall exhaustion (see Chapter 227). Patients in the manic phase of a *bipolar affective disorder* may report difficulty falling asleep or staying asleep, but they do not report feeling tired during waking times.

Patients suffering from *dysthymic disorder* (a variant of depression; see Chapter 227) typically complain of feeling tired, irritable, have difficulty falling asleep, and report that they cannot get enough sleep to feel rested. Sometimes they deny feeling sad or depressed and focus only on their physical complaints. Insomnia may be their major presenting complaint.

Patients with *anxiety and obsessive disorders* frequently have great difficulty falling asleep because they lie in bed and ruminate. *Character disorders* make up about 40% of the other psychiatrically based insomnias. Patients with narcissistic or borderline character disorders characteristically feel angry or entitled and may have difficulty falling asleep. They lie in bed, furiously trying to make themselves sleep. Such patients may use their insomnia as a justification for their inability to function or to get ahead in life. Their lack of sleep is viewed as the source of all their troubles. Some even use it as a rationale for their inability to comply with the treatment of the insomnia itself.

Active psychosis of any type (e.g., schizophrenia) produces disturbed sleep and accounts for the other 10% of psychiatric insomnia. Hallucinations, delusions, and other signs and symptoms of psychotic illness present with the insomnia, facilitating recognition.

Drugs and Substance Abuse. Drugs and alcohol account for about 10% to 15% of all cases. *Alcohol* induces sedation, but the resulting sleep is often shallow, fragmented, and not restorative. Alcoholics can have prematurely "aged" sleep (i.e., shallow and short) during and for months after cessation of drinking.

Sedatives, especially barbiturates, when used on a regular long-term basis lead to shallow fragmented sleep. *Rebound insomnia* and rebound anxiety prompt reuse, and tolerance leads to dose escalation, so patients get caught in a vicious cycle. Sedatives and alcohol depress respiratory function, which can lead to very poor quality sleep in patients with sleep apnea.

Stimulant drugs such as amphetamine, pemoline, or methylphenidate; activating antidepressants (e.g., fluoxetine, sertraline, venlafaxine, desipramine, bupropion, phenelzine, protriptyline); and the phenylpropanolamine found in many over-the-counter decongestant, cold, and diet remedies can induce significant difficulty falling asleep. The caffeine and other stimulant xanthines found in tea, coffee, cola drinks, and chocolate are well recognized and often used for their ability to keep one awake. In those who are sensitive, even small amounts will prevent sleep. Nicotine and other substances found in cigarette smoke disrupt sleep induction and continuity. Bronchodilators such as aminophylline and b-agonists can make sleep difficult when given before bed.

Medical Problems are responsible in approximately 10% of cases. *Chronic pain* is a leading, though often overlooked, factor (e.g., that experienced by elderly persons with degenerative joint disease). *Delirium* is another important cause in the elderly, resulting from unrecognized infection or medication toxicity (as from anticholinergic agents used in over-the-counter sleep remedies). *Cardiopulmonary dysfunction* may contribute by causing orthopnea, paroxysmal nocturnal dyspnea, or nocturnal angina.

Sleep apnea is a disorder characterized by repeated apneic periods due to soft tissue upper airway obstruction followed by disruption of sleep. In severe cases, behavioral changes, pulmonary hypertension, cardiac arrhythmias, and death can occur. Patients are unaware of how disrupted their sleep is, though spouses may be kept awake by loud snoring and frightened by the apneic periods. Patients complain of marked daytime sleepiness (see Chapter 46).

Urinary frequency due to infection, prostatism, diabetes, or poor timing of diuretic use are among other important disrupters of sleep. Often, it is the nocturia and disturbed sleep that causes the patient with prostatism to finally seek definitive therapy.

Primary Sleep Disorders make up another 10% of insomnia cases. In primary or idiopathic insomnia, patients have objectively verified difficulty initiating or maintaining sleep in the absence of any identifiable underlying pathology. Such patients may need more, rather than less, sensory input to fall asleep, rather like hyperactive children who require stimulants to control their activity. Others have a persistent complaint of insomnia with *no objective evidence*. Although they believe they awaken, their polysomnographic studies reveal that they are actually sleeping. There is sleep state misperception. Their polysomnographic studies are entirely normal. A final group have poorly understood *polysomnographic aberrations*, such as the intrusion of alpha EEG into delta sleep.

In *conditioned or "psychophysiologic" insomnia*, patients begin to associate bedtime with frustration, anxiety, and sleep-preventing behaviors. In this learned disorder,

they typically sleep very well while away from their usual bedroom (e.g., while on vacation or on the living room couch).

Circadian rhythm disorders may present with insomnia. In the *delayed sleep-phase syndrome*, the patient falls asleep later than the usual bedtime, sleeps well, and gets up later than is socially acceptable. This common disturbance often presents in adolescents. Other common forms are due to alternating shift work or jet travel across time zones *("jet lag")*, in which the inability to rapidly reset one's diurnal rhythm to local time leads to insomnia. For travel westward across time zones, the typical experience is awakening in the middle of night local time (morning at home) and being unable to fall back to sleep despite feeling tired. Restful sleep is not achieved. Moreover, there is marked afternoon or early evening sleepiness (bedtime at home). The inability to attain restful sleep culminates in exhaustion and the patient requests help for insomnia. Endogenous disruptions of the brain's internal circadian rhythm setter can produce a similar picture.

Nocturnal myoclonus can produce poor quality sleep and lead to the complaint of "insomnia." It is characterized by repetitive twitching of the legs, which is often unrecognized by the patient.

DIFFERENTIAL DIAGNOSIS

The most recent official version of the psychiatric diagnostic system—the Diagnostic and Statistical Manual of American Psychiatric Association, 4th edition (revised)—classifies insomnia as primary (idiopathic) and secondary (related to a primary psychiatric, medical, or substance abuse disorder). Table 232.1 provides a listing useful for primary care practice based on these categories.

Table 232.1. Causes of Insomnia

It is important to note that not all persons who sleep less than average each night have insomnia. There are *natural "short sleepers,"* persons who regularly have less than 7 hours of well-maintained sleep yet suffer no problems other than too much time on their hands at night. Those who have a brief *time-limited disturbance* of sleep related to stressful events in their lives are not regarded as having a sleep disturbance. The same pertains to normal elderly patients who experience as part of the natural *aging* process a decline in total sleep time, depth, and continuity.

WORKUP

When the complaint is persistent, when the sleep latency (the time between lights out and falling asleep) is consistently greater than 60 minutes, and when the insomnia is associated with compromised daytime functioning, a search for an underlying etiology should be undertaken.

History. A full description of the problem is essential and facilitated by having the patient keep a *sleep log* or diary, which includes time in bed, estimate of time asleep, any awakenings, time of morning arousal, estimate of sleep quality, and comments on unusual events and any associated symptoms (e.g., orthopnea, urinary frequency, pain, palpitations). Entries are recorded by the patient directly on getting up each morning. Close attention must also be given to use of sedatives, hypnotics (including over-the-counter preparations), and stimulants. Screening for abuse of alcohol and other substances is essential (see Chapter 228 and Chapter 235). It is most important to listen carefully for and inquire directly about symptoms of depression, bipolar disease, anxiety disorder, and psychosis (see Chapter 226 and Chapter 227). Occupational and travel patterns shouldbe noted. Whenever possible, interviewing the spouse, bed partner, or family member is of great value, particularly for symptoms suggestive of sleep apnea (e.g., excessive snoring, apneic episodes, disturbed sleep). Past and family medical and psychiatric histories are sometimes revealing.

Physical Examination. The pertinent physical examination is a function of the history. One checks for upper airway soft tissue obstruction in the patient with suspected sleep apnea; for jugular venous distention, rales, wheezes, heaves, and gallops when there is concern about a cardiopulmonary etiology; for moist skin, tachycardia, proptosis, goiter, and tremor when hyperthyroidism is under consideration; and for prostatic enlargement in the elderly male with sleep-disturbing nocturia. Any reported sources of pain should be evaluated and confirmed by physical examination. A careful mental status examination helps in the detection of psychiatric disease (see Chapter 226 and Chapter 227).

Laboratory Testing. Testing should be limited, selective, and based on evidence from the history and physical examination (e.g., thyroid-stimulating hormone for suspected hyperthyroidism, chest x-ray for cardiopulmonary disease, toxic screen for substance abuse). Immediate referral to the sleep laboratory is indicated only if a primary sleep disorder, such as central sleep apnea or nocturnal myoclonus, is suspected. Testing is very expensive and time consuming. Home monitoring for apnea and oxygen desaturation may prove a cost-effective screening alternative to the sleep laboratory for patients with suspected obstructive sleep apnea (see Chapter 46). Psychiatric evaluation is indicated only when character problems interfere with diagnosis or management or if the nature of a suspected mental or emotional problem is obscure.

PRINCIPLES OF MANAGEMENT

For a problem with as broad a spectrum of etiologies as insomnia, the best treatment is etiologic. Nonspecific measures are unlikely to be of much help and can be harmful. Careless use of sedative/hypnotics can be especially dangerous (e.g., giving the patient with sleep apnea or alcohol abuse a benzodiazepine). Precise diagnostic assessment allows for maximally safe and effective management. For those with substance abuse, proper withdrawal and complete abstinence from drugs and alcohol are critical (see Chapter 228 and Chapter 235).

Depression and Other Affective Disorders. All *antidepressants* are equally effective for the treatment of depression. Although the evidence is still incomplete, it has been suggested that patients with affective disorders who present with insomnia may benefit from a trial of a relatively sedating antidepressant, such as *mirtazepine, paroxetine, citalopram, nefazodone, or nortriptyline*. Full doses of antidepressants should be used if affective symptoms remain after insomnia resolves (see Chapter 227). When insomnia is due to use of an activating antidepressant, such as desipramine or a fluoxetine, adding a small amount of *trazodone* (50 mg qhs) or *clonazepam* (0.5 to 1.0 mg qhs) may be helpful. Antidepressant therapy can be started at a modest dose but should be advanced to adequately treat the underlying depression (that is the cause of the sleep disturbance).

Anxiety Disorders. Transient insomnia due to situational stress is a common nonthreatening problem, which by definition resolves on its own and often responds well to *support, reassurance,* and simple behavioral advice (see below). For anxiety disorders and character disorders complicated by insomnia, *benzodiazepines* can be used safely and effectively (see Chapter 226 and Chapter 227). *Zaleplon and zolpidem* are nonbenzodiazepines that act at the benzodiazepine receptor complex and behave clinically similar to the benzodiazepines without producing some of their undesirable side effects (see below). The use of benzodiazepines for anxiety-related depression has declined relative to the use of small doses of sedating antidepressants (e.g., nortriptyline 25 to 50 mg qhs) or *trazodone* (25 to 100 mg qhs). The efficacy and safety of this practice has yet to be fully established.

Pharmacologic Therapy: Short-term versus Chronic. There is controversy as to the proper frequency and duration of therapy when insomnia due to a long-standing anxiety disorder or characterologic disturbance is chronic. Most believe it is best to treat such insomnia with a short (1-week) course of benzodiazepine

therapy to help reestablish a more normal sleep pattern and then to stop. However, an occasional patient requires a program of benzodiazepine use two to three times per week over much longer periods. If chronic benzodiazepine therapy is contemplated, one first needs to review with the patient the importance of assiduous compliance, the risks of tolerance and withdrawal, and the possibility of physical dependence if the medication is not taken as prescribed (see Chapter 226). In addition, one must screen carefully for contraindications (e.g., sleep apnea, substance abuse). Concurrent use of alcohol and other sedatives must be prohibited because of the risk of oversedation.

For patients requiring prolonged therapy, careful monitoring is essential to ascertain efficacy, check for adverse effects, and ensure proper dosage and frequency. Drug holidays and attempts at alternative treatment are important components of any therapeutic program that involves prolonged benzodiazepine intake. The risks of tolerance and withdrawal should be reviewed with the patient before initiating such therapy. Withdrawal symptoms may develop within 3 to 20 days after cessation of chronic benzodiazepine use, especially if abrupt. It is best to taper therapy slowly over several weeks in patients with a history of prolonged intake (see Chapter 226).

Choice of Agent. Debate continues on the drug of choice for sleep. The benzodiazepines and benzodiazepine-like agents are preferred. The optimal agent would have a rapid onset yet short (48-hour) duration of action and would cause no rebound insomnia or mental problems such as hangover, motor incoordination, or memory disturbance. There are now several agents marketed for the treatment of insomnia, but none has been clearly shown to be significantly superior to any other, and all have some problems associated with their use (see Chapter 226).

The benzodiazepines used for insomnia can be divided into the short-, intermediate-, and long-acting agents. The *short-acting drugs* (e.g., *triazolam, estazololam, zaleplon*) are best prescribed for those whose primary problem is *falling asleep*. Triazolam should be used in the lowest possible doses (not to exceed 0.125 mg/d in the elderly) and should be tapered to avoid *rebound insomnia and anxiety. Zaleplon* may have some-whatlower propensity to produce rebound effects, but more experience with this new agent is required to confirm this.

The *intermediate-acting agents such as temazepam and quazepam* may be useful for those patients who complain of problems with *sleep continuity.* The possible increased receptor selectivity of quazepam has not been shown to be clearly clinically relevant. *Zolpidem* fits into the intermediate-acting group; lorazepam and diazepam may be recommended as lower cost generic alternatives. *Long-acting agents* (e.g., *flurazepam, clonazepam*) are considered when daytime anxiety compounds the discomfort.

Sedating *tricyclic antidepressants such as nortriptyline* (10 to 25 mg qhs) may help some patients with generalized anxiety and insomnia, as may *buspirone* (10 to 30 mg qhs) or *trazodone* (25 to 50 mg qhs). Antipsychotic agents can relieve insomnia and agitation in psychotic or delirious patients.

In rare instances where benzodiazepines are contraindicated (e.g., history of drug or alcohol dependence) and sedating antidepressants have not helped, antihistamines such as diphenhydramine may be used. However, the elderly and very young may experience delirium or paradoxical excitation from such drugs. Chloral hydrate should rarely be used, and there is almost never a place for treating new cases of insomnia with barbiturates, meprobamate, or over-the-counter remedies.

Psychotherapy and behavioral therapies may be used quite effectively in conjunction with medications for patients with psychiatric or stress-related problems. Cognitive and behavioral approaches, including education and support, stimulus control (attention to sleep hygiene), and sleep restriction therapy (gradual matching of time in bed to time asleep) can be combined with, and may be superior to, medication, especially in the elderly. Relaxation and biofeedback produce more modest improvements in sleep.

Jet Lag. *Melatonin* use is associated with some beneficial effects when prescribed to treat jet lag. In a placebo-controlled study of flight crews, use at bedtime on return from overseas flying and nightly thereafter for several days proved superior to placebo in minimizing the symptoms of jet lag. Proper dosage and mechanism of action (hypnotic effect versus resynchronization of circadian rhythm) remain to be established. Until there is standardization and quality control of preparations (some is derived from pineal glands of cows) and until there are reliable data on optimal dosing and side effects, it is advisable to defer melatonin use. Case reports of depression, gynecomastia, vasoconstriction, and low sperm counts argue for caution in use.

Treatment of Insomnia in the Elderly. The importance of cause-specific treatment is most poignantly experienced in caring for elderly persons with insomnia. In instances where the underlying cause is minor, emphasis on sleep hygiene (see below) and empathetic support are often the best course. Explanation on how the normal aging process affects sleep is appreciated by those wondering why they seem to sleep less. Sedatives should be used in reduced dose and with caution, if at all (see Chapter 226). Falls with catastrophic consequences (hip fracture, pulmonary embolization, disability, and death) are a major risk with sedative use in the elderly. The newer short-acting sedatives (see above) may be less likely to produce falls from motor incoordination or cognitive impairment during arousals than the older agents. When depression presents as difficulty sleeping, treatment should be etiologic and tailored to the special needs of older persons (see Chapter 227). Use of melatonin for chronic insomnia in the elderly has not been well studied, although the substance is widely used by patients because it can be obtained without prescription. The importance of adequate treatment of pain and any underlying medical problems cannot be overemphasized. Chronic pain should be addressed and effectively treated (see Chapter 236).

PATIENT EDUCATION

The overall promotion of good *"sleep hygiene'* is useful for many patients. Establishing a regular bed and wake time, avoiding any and all naps, having regular exercise (although not at night), using bed only for sleeping or lovemaking (rather than reading or watching TV), and getting in bed only when ready for sleep (leaving bed if sleep is not forthcoming) are useful suggestions. Avoidance of caffeinated foods, stimulants, cigarettes, and alcohol are necessary for some sensitive patients.

Instructing patients about these basic rules of sleep hygiene and helping them to avoid trying too hard to fall asleep are often useful. Disabusing patients of the myth that everyone must have 8 hours of sleep every night makes many people feel relieved. Also, informing patients that much of the time they spend in bed believing they are "only drowsy" is time actually spent in the lighter stages of sleep can ameliorate some patients' frustration.

THERAPEUTIC RECOMMENDATIONS

- If the insomnia is related to an underlying affective disorder, begin a sedating tricyclic antidepressant, such as nortriptyline (10 mg) or a selective serotonin reuptake inhibitor such as paroxetine 20 mg or mirtazepine 20 mg, taken an hour before bedtime every night for 2 weeks. See the patient frequently until symptoms resolve and increase the dose as needed to fully treat the depression.
- If the insomnia is related to an anxiety disorder, use triazolam, starting at 0.125 mg qhs or zolpidem 10 mg when the main problem is falling asleep, or clonazepam (0.5 mg) or flurazepam (15 mg) at bedtime if daytime anxiety is present.
- If symptoms recur after 2 weeks of treatment for anxiety-related insomnia, institute behavioral and relaxation therapies (see Chapter 226) and consider psychiatric consultation.
- If the insomnia is related to a character disorder, seek psychiatric consultation, require close adherence to good sleep hygiene, and use benzodiazepines only with caution.
- Make sure that a complete history of alcohol and substance use, including cigarettes, caffeine, nonprescription drugs, and stimulants, is obtained on every patient. Interview family members and obtain toxic screens of urine or blood when there is a doubt. Do not prescribe benzodiazepines for patients with current or past alcohol or drug use. Supervise withdrawal and abstinence, and seek psychiatric consultation when withdrawal symptoms or maintenance of abstinence is problematic.
- Treat pain and underlying medical problems aggressively; a short course of benzodiazepines may help reestablish a normal sleep pattern in some patients.
- Offer education and support to an elderly patient who has normal daytime function but who is lonely or upset as their sleep goes through the changes of normal aging.

CHAPTER 233 MANAGEMENT OF OBESITY

CAROLYN J. CRIMMINS-HINTLIAN

INTRODUCTION

Obesity is a major health problem in industrialized societies. Health risk increases when weight gain results in moderate to severe obesity. Mortality rates (all-cause, cardiovascular, and cancer-related) closely parallel increases in the body mass index once levels of obesity are reached. One third of Americans are overweight, and one fifth are on some kind of weight loss program at any given time. Weight loss is not a cure for obesity, as evidenced by patients who go from one fad diet to another, sometimes jeopardizing their health in the process (mortality appears greatest in those with the greatest fluctuations in weight). Many such patients turn to their physician with requests for pharmacotherapy. However, the majority of patients who lose weight, with or without drugs, regain lost pounds and often more within the first year.

Effective management of obesity starts with a careful workup for underlying illness that may be the cause (e.g., hypothyroidism, psychosocial or behavioral problems) or the consequence (e.g., diabetes mellitus, hypertension, osteoarthritis) of obesity (see Chapter 10). A major goal is to achieve the best weight possible in the context of overall health. Biopsychosocial and behavioral dimensions of the problem require attention. Therapy should include a customized program of patient education and physical activity (see Chapter 18). Knowledge of the rationale, safety, and effectiveness of popular diets and weight loss programs, in addition to available community resources, helps guide patients through an often confusing environment of claims and products.

PRINCIPLES OF MANAGEMENT

When a treatable etiologic factor is identified, it should be addressed directly. Weight loss should not be the only attainable goal for patients embarking on a weight reduction program. The correction of a poor image of oneself and one's body, distorted eating patterns, and the physical, social, and life-style consequences of obesity is also important. Recent appreciation of the molecular mechanisms that underlie obesity has altered the approach to therapy. Although new optimism has arisen concerning the eventual development of specific drugs for specific metabolic defects, the current best approaches to treatment still require a lifelong commitment to a *change* in *life-style*, *behavior*, and *dietary practices.* As noted, the effort begins with identifying the major precipitants of the patient's weight problem (see Chapter 10). The decision to lose weight may be part of a complex decision to improve the conduct of one's life. Consequently, the physician should be aware that patients coming for treatment are likely to be highly motivated and asking for permission to also make interpersonal, environmental, or life-style changes. Once the patient's agenda and preferences are clarified, the physician can help select the most appropriate method of weight management.

No single approach is effective for all persons. Knowledge of the strengths and weaknesses of individual weight loss modalities is essential to the design of an intelligent program. Treatment modalities can be divided into dietary, behavioral, psychosocial, pharmacologic, exercise, and surgical categories.

Dietary Approaches

"Going on a diet" is the typical first step in weight reduction, but the word "diet" implies that one is making only a temporary change in one's eating habits and patterns. Quite the contrary! The most effective diet is not a diet at all but rather a weight management program that focuses on the implementation of gradual, permanent changes in eating habits and exercise that can be followed for a lifetime.

Determining Daily Caloric Intake. The desired daily caloric intake needs to be determined. One starts by estimating the number of calories necessary to maintain an obese person's weight:

- Obese female patient: 8 to 10 calories times present weight in pounds
- Obese male patient: 10 to 12 calories times present weight in pounds (the lower number in the range is for the sedentary person)

From this figure, one subtracts 500 kcal/d for every pound per week that should be lost (a deficit of 3,500 calories equals a weight loss of 1 lb). All weight reduction programs should be nutritionally adequate except for calories and should include a variety of foods. Most fad diets are neither nutritionally sound nor based on proven scientific evidence (Table 233-1). Extravagant claims that a particular food or class of foods dramatically alters weight, appetite, or calorigenesis are unfounded. The cornerstones of efficacy and safety are a reduction in calories and nutritional balance. Nutrient content and the timing and number of meals and snacks are important determinants for short-term and long-term appetite control. Limiting fat calories is critical to decreasing body fat and maintaining weight loss.

Table 233-1. Noncommercial, Commercial, and Clinical Weight Loss Programs

When following a prescribed dietary regimen, the patient must realize that initial rapid weight loss may occur because of a negative fluid balance. After 2 to 3 weeks, the rate of weight loss slows down. Most subsequent loss reflects the catabolism of fat. Loss of fat is directly proportional to the size and duration of the energy deficit. Patients often become discouraged when they enter the slower phase. Some adjust to caloric restriction by unknowingly diminishing their expenditure of energy, one reason why an exercise program is such an important adjunct (see below).

Dietary Counseling. Dietary counseling is an essential step in the educational process. It begins with the physician's endorsement (an essential component that is often overlooked). Patients need to achieve a basic understanding of the caloric and nutritional contents of foods to be able to choose intelligently. The patient also must be presented with an approach that focuses on the connections between the body, brain, and appetite. Some of the factors that control appetite include food that is emotionally satisfying, management of stress, and exercise that suppresses hunger. The services of a registered dietitian can be helpful in this regard because such persons are specifically trained in assessing nutritional requirements and counseling food selection and preparation. In addition, the registered dietitian attempts to help people assess and change their attitudes and behaviors toward food and eating. An assessment is made that integrates medical concerns with the patient's individual and family life-style, economic status, learning ability, and psychological needs. A weight control plan must be individualized to each patient's needs and food preferences. Dietary changes must be gradually implemented to ensure lifelong positive eating habits. Nutrition counseling is likely to increase patient adherence

to a dietary regimen and improve outcome.

Weight Loss Programs. Many commercial and self-help programs are available (Table 233-1). Some provide menus and a line of foods to buy; others include individual or group support. Those that just sell products are of little long-term benefit. Integrated approaches that include moderate diet modification, an exercise program, and a behavioral approach are more effective, especially for mildly to moderately overweight persons. Noncommercial self-help groups offer a low-cost alternative for those who seek the benefit of group support, but often little professional guidance is provided. In the best-designed randomized trial of self-help versus a comprehensive commercial program, the commercial program proved superior in an intention-to-treat analysis over a 2-year period, with mean sustained weight loss of 2.9 kg compared to 0.2 kg for self-help. Compliance remains a key determinant of success, and attendance at group meetings is critical to compliance.

Fat Substitutes and Low-Fat Foods. Intensive research and development by food companies into substances that taste and satisfy like fat without providing any of the calories continues.

Olestra, a nonabsorbable mixture of sucrose esters, has recently been approved for use in food by the Food and Drug Administration. The first products are fat-free snack foods such as potato chips. Concerns about diarrhea and cramping with intake have not materialized when fat substitutes are used in small amounts (e.g., a 1-oz bag of potato chips), but the larger concern is the potential to induce fat malabsorption and deficiencies in lipid-soluble vitamins (A, D, E, K) when intake is on a daily basis and in larger quantities (potential for use in many foods as a fat substitute). The role of such substitutes remains to be defined, but use in a snack food as an occasional treat for the person who craves a bit of the "junk food" taste is probably harmless.

"Low-fat, low-cholesterol" processed foods are popular substitutes for foods high in fat, but often they are almost as high in caloric value as the foods they replace by virtue of having a very high sugar content. Even those food preparations that truly have fewer calories and less fat may provide just as much total fat and caloric intake if eaten in excess—a very common phenomenon, especially with low-fat ice cream, frozen yogurt, and baked goods. Persons consuming diets rich in these foods may experience an undesirable decline in high-density lipoprotein cholesterol if nonatherogenic essential fatty acids and monounsaturated fats are displaced from the diet (see Chapter 27). When patients substitute large quantities of "low-fat, low-cholesterol" snack foods for cholesterol-laden foods, they are likely to derive just as many calories from fat because animal fat is simply replaced in these products by partially hydrogenated vegetable or tropical oils (which are just as atherogenic and no lower in calories; see Chapter 27).

Low-Carbohydrate (Atkins) Diet

So-called *low-carbohydrate diets* (total daily carbohydrate intake as low as 20 g/day) have recently experienced a resurgence in popularity, although they have been around for more than 150 years. Stimulated by lay press authors such as Atkins, use of these diets is purported to reduce appetite and accelerate fat loss without serious side effects by development of ketosis (a consequence of fatty acid metabolism). Such claims are countered by concerns from the American Heart Association and the American Dietetic Association about the potential for adverse effects on lipids, insulin, renal function, and blood pressure from such dietary manipulation. The popularity of these diets derives from the rapid early weight loss they induce and the liberal amounts of fat they permit. Within the first 7 to 14 days, glycogen stores quickly deplete, releasing free water. Weight loss quickly follows. After this diuretic phase, weight loss slows markedly.

Despite widespread use of this diet, there is a dearth of substantive evidence as to efficacy and safety. Evidence that does exist is insufficient to draw firm conclusions for or against use. There are no long-term studies of important weight and metabolic outcomes in key patient populations, such as persons with diabetes, hyperlipidemia, hypertension, or coronary heart disease. Moreover, there are no isocaloric studies that are needed to address the question of dietary composition as a determinant of outcome. In the best systematic review of available data, the authors conclude that weight loss during use of a low-carbohydrate diet is principally a function of reduced caloric intake and its duration, not of degree of carbohydrate restriction.

The only two randomized controlled trials comparing a low-carbohydrate diet with a conventional low-fat diet (one in obese patients and the other in severely obese patients) suggested some advantages for the low-carbohydrate diet in terms of short-term weight loss and reductions in triglycerides. However, early weight loss was hard to sustain, and high rates of dropout and loss to follow-up compromised data analysis and researchers' ability to draw firm conclusions from these studies.

Behavior Modification

Behavior modification programs grew out of studies suggesting that obese persons overeat because they are stimulus-bound. Behavioral treatment is directed toward the mildly to moderately obese. Operant conditioning techniques appear to be somewhat more effective than aversive ones. Obese patients appear especially prone to respond to external cues for eating. The triggering stimuli may be situational, physiologic, or emotional. The aim of the behavioral approach is to substitute an alternative eating behavior that is practical and leads to a decreased caloric intake.

Behavior modification includes four components:

1. *Describing the behavior to be controlled.* Patients are instructed to keep records of all eating behaviors, including daily weight, time and place of eating, stimuli preceding eating that the patient is aware of, and a description of surroundings.
2. *Modifying and controlling stimuli.* Food shopping, food preparation, and food storage habits are changed, in addition to visual cues.
3. *Controlling the act of eating.* The patient is taught to eat more slowly, not skip meals, and not take snacks.
4. *Promptly reinforcing behaviors that delay and control eating.* Patients are advised to eat only in one room (cue elimination), have company while eating (cue supervision), develop methods of making diet food attractive (cue strengthening), arrange for deviations from the diet, and arrange for positive feedback if they comply with exercise and diet programs.

In addition, distracting activities such as watching television or reading while eating are discouraged. Eating behavior is made to be associated with highly specific stimuli.

Both individual and group behavioral programs are available. The average length of treatment is 18 weeks. The average weight loss is 20 lb, and at 52 weeks of follow-up, almost two thirds of patients maintain that weight loss, a very positive result. Behavior modification may prove to be most helpful in helping people maintain weight loss regardless of how it was achieved.

Exercise

An exercise or physical fitness component should be included in every weight loss program. Most obese persons are less active than lean people, but it is not known whether this is a cause or consequence of obesity. Energy expenditure and basal metabolic rate decrease with weight loss on calorically restricted diets. Exercise, in conjunction with a low-calorie diet, increases the metabolic rate. Increased physical activity for many obese people can promote weight loss and decrease body fat. Lean body mass is preserved when exercise and diet are combined. Obese persons use more energy and burn more body fat for the same amount of activity than persons of normal weight because the energy cost of most exercise is proportional to body weight. The amount of exercise needed to decrease body fat is related to its duration, intensity, and frequency. Exercise may also benefit the dieter by increasing feelings of self-control, reducing stress, improving appearance, and alleviating depression. Cardiovascular morbidity and mortality may be reduced.

The Exercise Prescription. A specific exercise prescription is essential. To tell a sedentary obese person to "get more exercise" is insufficient. Moreover, the dropout rate is high. Thirty percent or more of obese patients terminate physical training programs within several weeks of initiation, and as few as a third continue for up to 1 year. To ensure compliance, the program has to be physically realistic and capable of being incorporated into the patient's daily routine. The importance of physician input and encouragement is considerable. To ensure safety, obese patients with multiple cardiac risk factors and a sedentary life-style may benefit from electrocardiographic stress testing before an exercise program is initiated (see Chapter 18).

General guidelines for implementing a realistic exercise plan include the following:

1. Begin at the patient's level of current activity. Walking for 10 minutes a day may be a lot for a sedentary person. Encourage routine activity (e.g., park some distance from destination, use stairs instead of elevators).
2. Prescribe exercise at 60% to 80% of the patient's age-adjusted maximum heart rate. (The maximum heart rate is approximated by the formula of 200 beats/min minus the person's age.) Those who have been sedentary should start at the low end of this range.
3. Encourage the patient to exercise regularly at a specific time of the day (early morning, lunch hour, after work).
4. Emphasize the need to exercise regularly. Patients should work toward a 30-minute session four or five times a week.
5. Encourage the use of a diary to chart progress. Self-monitoring reinforces effort.
6. Encourage activity with a friend, co-worker, or family member. Referral to a credible group exercise facility may be indicated.
7. Walking should be the initial activity. When an activity other than walking is undertaken, it must be easily accessible and fit the patient's life-style.

For weight to be kept off once it has been lost, exercise must become a permanent component of a person's life-style (see also Chapter 18).

Pharmacologic Treatment

Drug therapy for weight loss continues to play a minor although much-hoped-for role in the management of obesity. Although often sought, especially by persons frustrated with other weight loss efforts, medical therapy has always been and continues to be problematic. Periodic flurries of interest followed by disappointment are characteristic. In the 1950s and 1960s, the prescription of amphetamines was commonplace, but it fell out of favor when the risks of tolerance and dependence became fully appreciated. In the 1990s, the combination of fenfluramine and dexfenfluramine was very popular until its use became linked to valvular cardiac injury.

Appetite suppression is the basic goal of pharmacotherapy and is targeted by catecholaminergic stimulants (e.g., amphetamines, phentermine, diethylpropion, phenylpropanolamine, sibutramine) and serotoninergic agents (e.g., fenfluramine, dexfenfluramine, and the selective serotonin reuptake inhibitors). The evolving appreciation for the role of leptin in natural appetite suppression is the focus of much current research, with the hope of providing safer, more effective drug therapy.

Fenfluramine and Phentermine ("Fen–Phen"). A burst of interest in pharmacotherapy followed publications reporting weight loss efficacy for the combination of extended-release *fenfluramine* and *phentermine*. Combination therapy provided synergy by acting on different neurotransmitters (central nervous system stimulation for phentermine and sedation for fenfluramine); this allowed lower doses to be used and minimized side effects. In addition, the dextro form of fenfluramine, *dexfenfluramine*, proved useful as monotherapy. Dexfenfluramine added to a calorie-restricted diet resulted in greater weight loss than diet plus placebo. In general, approximately 2 to 10 kg of weight loss could be attributed to drug therapy. However, the response was highly variable and difficult to predict. Moreover, reports of *heart valve injury* began to appear in persons taking fen–phen or dexfenfluramine for more than a few months. These reports prompted the Food and Drug Administration to *withdraw* both products from the market. Patients who took either of these drugs should be examined clinically for evidence of heart valve dysfunction, first by auscultation and then by cardiac ultrasonography if abnormalities are detected on physical examination. However, patients can be reassured that follow-up studies performed about 18 months after discontinuation of the drug indicate that abnormalities do not progress over that time period.

Updated: 12/7/01

Other adverse effects of these agents were also demonstrated. Diarrhea, polyuria, sleep disturbances, and sedation can occur with either fenfluramine or dexfenfluramine. Reversible short-term memory loss was reported in more than 10% of patients taking fenfluramine and phentermine in combination. The most serious adverse effect was an increased risk for reversible and irreversible *primary pulmonary hypertension* among patients taking either fenfluramine or dexfenfluramine for 3 months or more. Despite a 10- to 20-fold increase in relative risk, the absolute risk for this complication remains quite small. Contraindications included glaucoma and the use of monoamine oxidase inhibitors. Depression was a relative contraindication.

Orlistat. Orlistat, approved by the Food and Drug Administration, binds to and blocks the topical activity of pancreatic and gastric lipases and inhibits about 30% of gut dietary fat absorption. Randomized, double-blinded, placebo-controlled study lasting 2 years have demonstrated significant weight loss (up to 10%), a reduction in weight gain, and improvements in lipid profile and insulin levels. However, about 80% of patients experience some adverse gastrointestinal effects of the ensuing malabsorption/maldigestion (e.g., abdominal cramping, bloating, oily and greasy stools, diarrhea). The cost is high, at several dollars a day, when this agent is used three times daily, as recommended by the manufacturer. Lipid-soluble vitamin supplementation (especially vitamin D, but also vitamins A and E and b-carotene) may be necessary. Longer term data from very large samples of patients are not yet available to characterize the risks associated with prolonged therapy, nor are data available on outcomes of cardiovascular events and other pertinent end points.

Sibutramine (Meridia). At present, this is the only other agent approved by the Food and Drug Administration for the treatment of obesity. Structurally resembling amphetamines, it inhibits the reuptake of norepinephrine and serotonin to cause an increase in their central nervous system concentrations. The drug is rapidly absorbed and reaches its peak effect in 3 to 4 hours; the half-life is about 14 hours. A dose-related effect on weight loss has been noted; peak doses are associated with about 12 to 15 pounds of weight loss over 6 months; the effect appears to persist for up to 12 months with continued use. The most common side effects are dry mouth, insomnia, headache, and constipation. Other effects include an increase in blood pressure and heart rate. It is recommended that sibutramine not be used in conjunction with other agents that affect serotonin activity, such as the selective serotonin reuptake inhibitors used to treat depression, the serotonin agonists used for migraine (e.g., sumatriptan), lithium, and some analgesics (e.g., meperidine, fentanyl, dextromethorphan, pentazocine). The use of sibutramine within 2 weeks of use of a monoamine oxidase inhibitor is also to be avoided. The cost is high, at several dollars per day. The starting dosage is 10 mg/d. Because published data on safety and efficacy are limited, as is experience with long-term administration, most authorities do not recommend use of this agent. Moreover, concerns about the risk for valvular injury, found with the use of other agents that affect serotonin metabolism (see above), remain unanswered. Because of its similarity in structure to amphetamine, sibutramine is classified as a schedule IV drug by the Drug Enforcement Agency.

Over-The-Counter Diet Pills. Over-the-counter diet pills usually contain *phenylpro-panolamine*, *benzocaine*, or both, often in combination with vitamins or caffeine. They came into use after a few reports purported to show small degrees of weight loss associated with their intake. Phenylpropanolamine, a common decongestant sympathomimetic, is promoted as an appetite suppressant and is found in a number of over-the-counter diet pills (e.g., Dexatrim, Appedrine, Dietac, Dex-A-Diet, Prolamine). There is no compelling evidence to prove its efficacy in weight control, and it can be dangerous. Adverse reactions include hypertension, hypertensive crisis, renal failure, cardiac arrhythmias, acute psychotic episodes, and death. Although probably not as dangerous to dieters as phenylpropanolamine, benzocaine, a topical anesthetic, is also promoted as a diet aid and sold in candy and gum form. The use of such nonprescription agents should be discouraged.

Antidepressants. Antidepressants may stimulate the appetite, which can be troublesome. Many *tricyclics* are problematic in this regard. Switching to a serotonin reuptake inhibitor that does not stimulate the appetite (e.g., *sertraline*) may solve the problem (see Chapter 227).

Phenytoin. In the rare instance of abnormal food preoccupation and binge eating in association with electroencephalographic abnormalities, phenytoin may help. More commonly, binge eaters have primitive, impulsive characters that are often diagnosed as borderline states. With successful psychotherapy, these regressive episodes tend to disappear as healthier defenses and a less chaotic life-style emerge.

Herbal Therapies and Commercial Products. Although considerable claims are made for herbal therapies, there is no evidence of their efficacy, and no consistent listing of ingredients or standardization of preparations is available. Most preparations appear to contain harmless ingredients, but not always. In Europe, one preparation containing *Stephania tetrandra* was inadvertently replaced by another containing *Aristolochia fangch*, which caused renal injury and renal failure in more than 100 persons.

Garcinia cambogia, an herb found in plants native to India, is claimed to lower body weight and reduce fat in humans. It is a source of hydroxycitric acid, which inhibits a citrate cleavage enzyme believed to play a role in lipogenesis. Although extracts of this herb and preparations containing hydroxycitric acid are promoted and sold commercially for weight loss, there is no evidence they are effective. In a rigorous randomized, placebo-controlled study of a concentrated extract of the herb, it failed to produce any significant weight loss or evidence of fat mobilization.

Commercial food preparations and *dietary supplements* are heavily promoted and marketed, often as part of a comprehensive weight loss program (Table 233-1).

New Agents. The *leptins* are substances of the central nervous system believed important in neurotransmission of a sense of satiation, at least in animals. These and other central nervous system substances are the subject of intensive study for use in obesity.

Extreme Measures

Very Low-Calorie Diets. Very low-calorie diets severely limit calories to between 400 and 800 per day. They achieve the more rapid and sustained rate of weight reduction associated with complete starvation while avoiding the inherent risks of starvation. These diets should be restricted to patients who are more than 30% to 40% above their ideal weight, and an initial cardiac evaluation and close medical supervision are required because of the risk for life-threatening arrhythmias. They are not do-it-yourself regimens. Goals include an optimal nitrogen balance and sparing of muscle tissue. With a very low-calorie diet, a patient can achieve a weight loss of more than 75% fat and a concomitant decrease in waist-to-hip and waist-to-thigh ratios.

These diets consist of 1.5 g of protein per kilogram of ideal body weight per day in the form of lean meat, fish, or fowl; noncaloric beverages; a multivitamin and mineral supplement containing folic acid; 1,500 mL of fluid per day; 25 mEq of potassium; and a calcium supplement. The combination of a very low-calorie diet and behavior modification appears promising. Average weight losses on the diet are 45 lb in fasting periods that last approximately 12 weeks.

The very low-calorie diet is not recommended for persons who are moderately overweight or for children, adolescents, pregnant or lactating women, or the elderly. Also, it should be avoided by patients with cardiovascular disease, essential hypertension, insulin-dependent diabetes mellitus, severe renal or hepatic impairment, active cancer, or a severe psychological disturbance. High dropout rates and poor long-term maintenance are discouraging aspects of this form of treatment.

Surgical Treatment. Surgical treatment continues to be an option for the control of morbid obesity, defined as "100 lb overweight" or over 200% of desirable weight as defined by the Metropolitan Life Insurance Company tables (see Chapter 10). Although the prevalence of morbid obesity is only 0.5% of the obese population, physicians often encounter these people in clinical practice. Their already high rates of morbidity and mortality accelerate rapidly as overweight becomes increasingly severe. Medical treatments are often ineffective.

Surgical intervention should be considered only after a comprehensive program of nonsurgical therapy has been fully tried and proven ineffective. Selection should be limited to highly motivated, morbidly obese patients free of other serious medical and psychosocial problems. Adequate financial support should be available because of the frequent need for repeated hospitalizations.

Jejunoileal Bypass. Jejunoileal bypass was one of the first of the surgical treatments. It has been discontinued because of its high rate of serious complications, including intractable diarrhea, hypokalemia, hypocalcemia, formation of oxalate-containing kidney stones, liver failure, and protein malnutrition.

Gastric Reduction Procedures. Gastric reduction procedures involve the construction of a small, 15- to 50-mL pouch connected through a small stoma to an outflow tract. This class of operations has emerged as the surgical approach of choice for morbid obesity. In the gastric bypass type, food passes first into the pouch and then into the jejunum. In the gastroplasty type (gastric stapling), food passes into the distal stomach and duodenum. Gastric bypass appears more effective in promoting weight loss, but gastroplasty is associated with fewer complications. Surgical mortality ranges from 0 to 4%. After surgery, patients must be instructed to eat small amounts, eat slowly, chew carefully, avoid eating when not hungry, and take no liquids with meals. Results are impressive, with an average of 50% of excess weight lost in the first 12 months, although it is not clear whether the cause is early satiety or aversive conditioning, a consequence of the development of epigastric pain and vomiting when too much is eaten at one time.

Complications include outlet obstruction, vitamin deficiencies (thiamine, B$_{12}$, and folate), partial temporary hair loss believed to be a result of inadequate protein intake, and an increased incidence of gallstones and gastric ulcers. Benefits include improvement in glucose intolerance, reduction in blood pressure for hypertensive patients, reversal of cardiorespiratory impairment, and reduction of serum cholesterol. Psychosocial benefits depend on the degree of weight loss and are independent of side effects and complications. Patients who lose significant amounts of weight become more employable and more physically active, show improvement in their sex life and self-esteem, and acquire a more gregarious outlook on life.

Suction Lipectomy (Liposuction). Suction lipectomy (liposuction), the very popular cosmetic procedure for removal of localized fat accumulations, has produced variable results. It has become the most frequently performed cosmetic operation in the United States, with more than 150,000 procedures performed annually. It is initiated with an SQ infusion of normal saline solution mixed with 1,000 mg of lidocaine and 1 mg of epinephrine per liter to provide local anesthesia and control of bleeding. SQ fat is then removed by suction. Several liters of infusate may be needed to remove 1 to 2 L of fat. Cosmetic success depends on the elastic properties of the overlying skin. Temporary loss of skin sensation, a wavy contour, and blood loss are commonly experienced. Other adverse effects include infection, extensive bruising for 2 to 3 weeks, and edema for 3 to 6 weeks. Anecdotal reports of death after liposuction are common. Well documented reports of fatalities caused by lidocaine toxicity, drug–drug interactions, and venous thrombosis of the lower extremities have been published. Careful patient selection and full disclosure of the risks involved are required to help patients choose wisely.

Jaw Wiring. Jaw wiring, as the term implies, involves wiring the jaw shut for as long as 6 to 9 months to prevent the ingestion of solid food. The intake of high-calorie shakes and soft drinks will eliminate the benefits of surgery.

PATIENT EDUCATION

Motivation and patient education are key factors for successful weight control. Realistic goals and expectations are critical, as is the physician's support and encouragement. The patient must be willing to alter exercise and eating patterns permanently. A number of persons will be interested in commercial or nonprofit programs and appreciate reliable information regarding their effectiveness, safety, and appropriateness (Table 233-1). Although rapid weight loss programs are popular, patients need to be informed about their inadequacies for achieving long-term weight loss. Major obstacles to success need to be explored and addressed, including poor self-image, erratic eating patterns, inadequate exercise, loneliness, boredom, anger, and depression. If drug therapy is used, expectations should be realistic. Reduction to average body weight is not a realistic goal. As noted earlier, knowledge must be provided about the basic principles of nutrition, such as caloric value of foods and practical methods for changing eating habits.

Behavioral techniques are also very helpful and should include several types of action:

- Recording food intake
- Eating in only one place; using a smaller plate; not engaging in another activity while eating; keeping food otherwise out of sight
- Planning meals by shopping from a list; having low-calorie foods available; taking a brown-bag lunch; having a strategy before dining out; at parties, positioning oneself away from the food table
- Substituting an alternate activity for eating
- Increasing physical activity

INDICATIONS FOR REFERRAL

Although the interest, involvement, and encouragement of the primary physician are critical, the implementation of a comprehensive and personalized weight loss program is often best achieved with a multidisciplinary approach. Referral to a registered dietitian is enormously helpful in providing the patient with essential nutritional information and initiating a behavioral program for alteration of eating habits. Familiarity with community and commercial resources and their level of professional supervision is helpful when a patient requests a group approach. Before an exercise program is begun, it may be useful to refer the poorly conditioned, markedly obese patient for an electrocardiographic stress test (see Chapter 18). When emotional problems are too great for the primary physician and registered dietitian to handle, psychiatric referral should be considered. Surgical consultation should be considered only when the patient is so morbidly obese and so refractory to medical therapy that the risks associated with the surgery are less than those of remaining morbidly obese.

MANAGEMENT RECOMMENDATIONS

• Identify and treat specifically any etiologic factors (see Chapter 10).
• Prescribe a comprehensive approach to weight management that includes a low-fat diet, dietary counseling, behavior modification, and an exercise program (see Chapter 18).

- Avoid and discourage gimmicky food programs and appetite suppressants until safe and effective agents become available. Check any patients who have been prescribed fenfluramine or dexfenfluramine in the past for evidence of valvular cardiac injury by auscultation (and cardiac ultrasonography if valvular injury is suspected by examination).
- Individualize changes in eating and exercise patterns; make them gradual to maximize the potential for long-term compliance.
- Recommend a weight loss group to those who seek the benefit of group support; suggest one that is under professional supervision. Commercial programs that include a group program and professional supervision can be beneficial, but not those that offer only food products or supplements. **Updated: 05/16/2003**
- Advise a dietitian-supervised weight management program for patients who continually go from one fad diet to another. Warn against diets based on unsubstantiated medical claims, which may have popular appeal but are ineffective for long-term weight control.
- Restrict the use of very-low calorie diets to patients more than 30% to 40% above their ideal weight; require medical supervision.
- Advise patients considering or seeking information on a low-carbohydrate (Atkins) diet that available data are insufficient to draw conclusions about safety and efficacy, especially as regards sustained use. While short-term weight loss can be impressive, long-term weight loss is hard to sustain and potentially adverse effects on cardiovascular risk factors remain a concern. **Updated: 06/27/2003**
- Consider pharmacologic intervention only for persons at very high risk for cardiovascular, metabolic, or orthopedic morbidity.
- Consider referral for surgical therapy for only those patients with life-threatening obesity who have failed all other measures.

CHAPTER 234 APPROACH TO EATING DISORDERS

NANCY A. RIGOTTI

Anorexia nervosa, bulimia nervosa (the binge–purge syndrome), and binge-eating disorder are the principal eating disturbances of adolescents and adults. Both anorexia and bulimia are considerably more common in women and usually develop during adolescence or early adulthood. About 40% of cases of binge-eating disorder occur among boys and men. The prevalence of anorexia approaches 1 in 200 among female adolescents in Western countries, whereas bulimia may affect up to 15% of college women. These disturbances of eating behavior are psychiatric disorders that can have serious medical consequences. They extend beyond racial and socioeconomic boundaries. Because patients with these conditions often hide their problem, a high index of suspicion is required for diagnosis. Primary care physicians need to be able to recognize these disorders, evaluate and treat their medical complications, arrange and coordinate a comprehensive multidisciplinary treatment program, assist in ambulatory monitoring, and determine when a patient requires hospitalization.

PATHOPHYSIOLOGY, CLINICAL PRESENTATION, AND COURSE

Anorexia Nervosa

Anorexia nervosa is a syndrome characterized by severe weight loss (*body weight <85% of expected*, or *body mass index <17.5 kg/m^2*) resulting from inadequate food intake by persons with no medical reason to lose weight. A *distorted body image* and an *intense fear of weight gain* lead to the relentless pursuit of an unreasonable and unhealthy thinness. Weight is lost in two ways. Patients with restrictive anorexia *starve* themselves. Others, with coexistent bulimia, lose weight by *purging* after eating, usually by vomiting or taking laxatives. Those with bulimic anorexia have a graver prognosis and more medical problems. Originally more prevalent among persons of high socioeconomic status, anorexia is now becoming more evenly distributed among social classes.

Pathogenesis. The precise pathogenesis of anorexia remains unknown but appears to be multifactorial. Abnormalities in central neurotransmitter activity are suggested by alterations in serotonin metabolism. Neuroendocrine abnormalities are well documented (see below), but these appear to be the consequence, not the cause, of the starvation. Psychological and psychosocial factors are important. Onset frequently coincides with a time of separation from home or the loss of a loved one. The clinical features of the condition and its association with loss cause some to view it as a variant of depression. Others attribute anorexia to problems in emotional development and disturbed family interactions. Psychological studies find these patients to be bright, compulsive perfectionists who perform well at school and work. The prevalence of obsessive–compulsive disorder is increased among patients with anorexia. Societal pressure to be thin, communicated in the media, is also believed to contribute to the problem.

Pathophysiology. Restrictive anorexia nervosa is similar to *starvation* and can be fatal. Diets are deficient in carbohydrates and total calories, but protein and vitamin intake is relatively preserved. Consequently, vitamin deficiencies are unusual. However, inadequate nutrient intake results in a profound loss of weight, fat, and muscle mass, followed by cardiac, metabolic and endocrine, hematologic, and gastrointestinal disturbances.

Cardiac Consequences. Cardiac muscle atrophy is associated with a reduction in left ventricular wall thickness and cardiac output, but congestive failure does not occur. *Arrhythmias* and electrocardiographic changes, primarily low-voltage ST-segment depression and T-wave flattening, have been documented, as have prolonged QT intervals. Autopsies of some patients performed after sudden death have shown a degeneration of myocardial cells, which may predispose to arrhythmias.

Endocrine and Metabolic Consequences. Extreme weight loss produces a number of adverse endocrine and metabolic changes. Thyroid hormone metabolism is altered, with thyroxine preferentially converted to the *inactive reverse T$_3$ instead of active T$_3$*. A compensatory rise in thyrotropin (TSH) does not occur because the hypothalamic–pituitary response is blunted ("*sick thyroid*" syndrome). Clinical features of *hypothyroidism* (see Chapter 104) may ensue. Starvation also produces reversible hypothalamic–pituitary dysfunction that can lead to *hypothalamic amenorrhea* and *estrogen deficiency* (see Chapter 112). Besides weight loss, other factors (perhaps leptin), yet to be identified, may contribute to hypothalamic dysfunction because menstruation ceases in up to 25% of female patients with anorexia before weight loss becomes significant, and amenorrhea may persist after weight is regained. In those with long-standing estrogen deficiency, very poor nutrition, and vitamin deficiencies, significant degrees of *osteoporosis* and vertebral compression fractures may develop.

Posterior pituitary function is also disrupted; a decline in vasopressin secretion leads to *central diabetes insipidus* and polyuria (see Chapter 102). In anorexia, the hypothalamus defends core temperature poorly in the face of changes in environmental temperature, so that *hypothermia* results. Many people with anorexia have *elevated plasma cortisol* levels that do not respond to an overnight dexamethasone suppression test. However, cortisol excess is not manifested clinically, perhaps because fatty or carbohydrate substrates are lacking.

Acquired defects in lipoprotein metabolism may increase serum *cholesterol* and *carotene* levels. Blood levels of glucose, protein, amino acids, and insulin are normal or mildly reduced. Severe hypoglycemia and coma have been reported when starvation is very advanced.

Gastrointestinal Consequences. Refeeding may be followed by gastric dilatation, ileus, and transient elevations of serum liver enzymes caused by *fatty liver*. *Delayed gastric emptying* explains some of the symptoms of abdominal bloating. The combination of slowed peristalsis and the meager dietary intake results in constipation.

Volume Changes. Refeeding frequently leads to *fluid retention*, especially in the bulimic anorectic patient, who purges and is volume-depleted. Fluid retention complicates the interpretation of weight changes and frightens the patient. If fluid retention is severe, congestive heart failure may develop as the increase in intravascular volume exceeds the capacity of the weakened heart.

Hematologic Consequences. Reversible bone marrow depression is noted. Although *mild anemia* is common, it is rarely a consequence of iron, folate, or B$_{12}$ deficiency. The anemia may be masked in the setting of concurrent volume depletion and may not appear until rehydration is implemented. Despite *leukopenia*, the patient's susceptibility to infection is not increased. Thrombocytopenia is unusual.

Clinical Presentation. Characteristically, the patient denies she is ill, but her emaciation attracts attention. The presentation is remarkable for the lack of complaints. The patient typically claims to feel well and appears *unconcerned* about her emaciation. Hunger is not a complaint, but patients may report difficulty sleeping, abdominal discomfort and bloating after eating, constipation, cold intolerance, and polyuria. Amenorrhea is almost uniformly present in female patients. Unlike other persons who are starving, those with anorexia are not fatigued until malnutrition becomes very severe. Most are restless and physically active, and some exercise to excess. Listlessness is an ominous sign. The patient may present bundled in clothing because of cold intolerance.

On examination, the patient typically appears extremely thin, if not emaciated, but animated. Vital signs may reveal bradycardia, postural hypotension, and hypothermia. The skin may appear dry, pale or yellow-tinged (a consequence of carotenemia), and covered by fine downy hair (lanugo) over the face and arms. Often, the extremities are cold and cyanotic. In women, the female pattern of fat distribution disappears, but axillary and pubic hair is preserved.

Natural History. About 5% of patients with anorexia nervosa die. Most deaths are sudden, apparently caused by cardiac arrhythmias. Fatal hypoglycemic coma has also been reported. The risk for death appears to be higher in patients whose weight loss exceeds 40% of premorbid weight (or 30% if it has occurred within 3 months). Bulimic anorectic patients with metabolic abnormalities are probably at higher risk. The risk for suicide is also increased. The mortality rate is 12 times that of

age-matched normal persons.

More than 75% of patients with anorexia regain weight to near-normal levels, and menstruation resumes in the majority, but abnormal eating habits and psychosocial problems often persist. Some become bulimic. A chronic syndrome develops in about 15%, and 5% become obese. Bulimic symptoms, lower weight, and older age at presentation are associated with poor outcome.

Bulimia (Bulimia Nervosa)

This eating disorder is driven by excessive *concern* about *body weight* or *shape* and characterized by *repeated episodes* of *binge eating* (at least two times per week for 3 months), during which large amounts of high-calorie foods are consumed, usually in secrecy. The binge is followed by self-deprecating thoughts and *purging, excessive exercise*, or *fasting* (at least two times per week for 3 months) to prevent weight gain. Most bulimic patients purge by inducing vomiting or using laxatives, but some use diuretics or exercise excessively. They fear losing control of their eating behavior and are ashamed when it happens. Binges may be repeated several times daily. At other times, people with bulimia may diet rigorously or take diet pills. In severe cases, the patient may have no regular eating pattern. The result of this behavior is frequent weight fluctuations but not severe weight loss.

In contrast to persons with anorexia, those with bulimia are aware that their behavior is abnormal but often conceal the illness because of embarrassment. The bulimic patient's near-normal weight permits the illness to be hidden. Detection of surreptitious vomiting or laxative abuse can be a challenge (see below).

Pathogenesis. The high prevalence of alcohol and drug abuse among patients with bulimia has led some to postulate that bulimia is part of an impulse control disorder. Depression has also been proposed as a precipitant. Changes in neurotransmitter metabolism and a response to antidepressant medication suggest a biochemical component to the condition. Cultural pressure to be thin probably contributes. People with bulimia commonly report that a diet preceded their disease. The bingeing sometimes observed when experimentally starved normal persons resume eating has led to speculation that strict dieting contributes to the onset of bulimia.

Complications. The medical consequences of bulimia depend on the specific behaviors present.

Of Bingeing. Bingeing has few complications, although *abdominal pain* from distention is common. Acute gastric dilation and rupture are rare.

Of Chronic Induced Emesis. Repeated regurgitation of stomach contents produces *volume depletion* and a *hypochloremic metabolic alkalosis.* Dizziness, syncope, thirst, orthostatic changes in vital signs, and an elevated blood urea nitrogen occur in the volume-depleted patient. Renal compensation for the alkalosis and volume depletion causes *potassium depletion* and *hypokalemia*, which may predispose to cardiac arrhythmias, muscle cramps and weakness, paresthesias, polyuria, and constipation. T-wave flattening and U waves are seen on the electrocardiogram. Serum and urine chloride levels are low.

Reversible, painless *parotid swelling* can develop with chronic vomiting and is often accompanied by *hyperamylasemia*. Irreversible dental problems also occur. Repeated exposure of the teeth to stomach acid causes *enamel decalcification* and *erosion*. Teeth diminish in size and become discolored and sensitive to temperature changes. Many vomiters have symptoms of *reflux esophagitis.* Sore throat caused by mucosal trauma sustained during induced vomiting is common, but hematemesis is unusual. Some patients use *emetine* (ipecac) to induce vomiting. Prolonged use may cause a reversible proximal *myopathy* and a potentially fatal cardiomyopathy.

Of Laxative Abuse. Laxative abuse is a common and potentially dangerous form of purging. It may begin as a response to constipation and continue because of the temporary weight loss induced through *volume depletion*. Stimulant laxatives are used most often. The resultant increase in colonic motility produces *abdominal cramps*, and electrolytes are lost in a *watery diarrhea*. Volume depletion, *hyponatremia, hypokalemia*, and either *metabolic acidosis* or *alkalosis* may result. Calcium and magnesium depletion have also been reported. The irritation of intestinal mucosa or development of hemorrhoids as a result of rapid fecal transit may cause *rectal bleeding*, and rectal *prolapse* can occur. When laxative abuse stops, transient fluid retention, edema, and constipation are common.

Of Diuretic Abuse. Patients use diuretics more often to prevent fluid retention than to induce weight loss. Use contributes to a *hypochloremic metabolic alkalosis, hypokalemia*, and *volume depletion*. Dilutional *hyponatremia* may also occur. In contrast to vomiters and laxative abusers, patients who use diuretics do not have low urinary levels of sodium and chloride. Fluid retention transiently develops when diuretics are stopped.

Natural History and Clinical Course. Little is known about the mortality and natural history of bulimia, but the behaviors can persist for decades. About half of patients achieve full recovery, another 30% experience partial recovery, and 20% show no improvement.

Binge-eating Disorder

This condition, an important cause of obesity, is characterized by recurrent binge eating (at least 2 days weekly for 6 months) and marked distress associated with eating alone, too rapidly, when not hungry, or until uncomfortably full. The patient has feelings of guilt or disgust after a binge, but does not purge, exercise excessively, or fast. Of the several eating disorders, this is the most common among male patients and is prevalent among the obese.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis spans the array of conditions that may cause unexplained weight loss (see Chapter 9), secondary amenorrhea (see Chapter 112), electrolyte disturbances with volume depletion (see Chapter 59 and Chapter 64), and osteoporosis (see Chapter 164). Among them are malignancy, chronic infection, intestinal disorders (malabsorption, inflammatory bowel disease, or hepatitis), and endocrinopathies (e.g., hyperthyroidism, panhypopituitarism, adrenal insufficiency, diabetes mellitus). Tumors of the central nervous system mimic anorexia nervosa in rare cases. Psychiatric illnesses that can be confused with anorexia include depression, schizophrenia, and obsessive–compulsive neurosis (see Chapter 226, Chapter 227, and Chapter 230). Binge eating may be a manifestation of depression and, rarely, of an organic brain syndrome.

WORKUP

The diagnoses of anorexia nervosa and bulimia are based exclusively on clinical findings (Table 234.1). Laboratory studies help in the detection of complications (see below) and in ruling out other causes of weight loss (see Chapter 9).

Anorexia Nervosa
Low body weight (<85% of expected or BMI < 17.5 kg/m²)
Inaccurate perception of own body size, weight, or shape
Intense fear of weight gain
Amenorrhea (if female)

Bulimia Nervosa
Excessive concern about body weight or shape
Recurrent binge eating (at least twice weekly for 3 months)
Recurrent purging, excessive exercise, or fasting (at least twice
weekly for 3 months)
Absence of anorexia nervosa

Binge Eating Disorder
Recurrent binge eating (at least twice weekly for 6 months)
Marked distress with at least three of the following:
Eating very rapidly
Eating until uncomfortably full
Eating when not hungry
Eating alone
No recurrent purging, excessive exercise, or fasting
Absence of anorexia nervosa

BMI, body mass index.
Adapted from Becker AE, Grinspoon SK, Klibanski A, et al. Eating disorders.
N Engl J Med 1999;340:1092, with permission, and based on the criteria spec-
ified in the Diagnostic and Statistical Manual of Mental Disorders, 4th ed.
Washington, DC: American Psychiatric Association, 1994:539,729.

Table 234.1. American Psychiatric Association Diagnostic Criteria for Eating Disorders

Anorexia Nervosa

History. The history should explore the patient's attitudes toward weight loss, desired weight, and eating habits. A 24-hour dietary recall is more revealing than the answers to general questions about diet. Detailed weight and menstrual histories should be obtained, including the date and circumstances at the onset of weight loss, minimum and maximum weights, recent weight changes, and last normal menstrual period. One needs to ask all patients about bingeing, vomiting, and the use of laxatives, diuretics, diet pills, and emetics, and to quantify daily exercise (excessive exercise may be a variant of anorexia). Also important is inquiry into symptoms of malnutrition (fatigue, skin or hair changes), dehydration (light-headedness, syncope, thirst), hypokalemia (cramps, weakness, paresthesias, polyuria, palpitations), and other problems common to purgers (e.g., heartburn, abdominal pain, rectal bleeding). Because the riskfor suicide is increased in patients with an eating disorder, one must *screen for suicidality* during the initial visit (see Chapter 227). Likewise, because of the increased prevalence of depression, anxiety, and personality disorders among these patients, the history should be reviewed for suggestive symptoms (see Chapter 226, Chapter 227, and Chapter 230). Exploring the psychosocial history can provide information important not only to diagnosis but also to planning initial management.

Physical Examination. Important objectives are to assess the severity of malnutrition and dehydration and check for the development of complications. One should specifically take note of the general state of nutrition and hydration and follow with measurement of the height and weight (without street clothing). The blood pressure and pulse are checked for significant postural changes and the temperature noted for hypothermia. The skin is examined for pallor and the hair changes of lanugo, the chest for rales, and the extremities for edema and signs of peripheral vasoconstriction. Auscultation of the apical pulse may help detect an arrhythmia, rectal examination may reveal blood from laxative abuse, and eliciting the deep tendon reflexes for delayed relaxation can help detect secondary hypothyroidism.

In addition to these measures, a detailed physical examination is essential to rule out other causes of weight loss (see Chapter 9).

Laboratory Studies. Because serious volume, electrolyte, and cardiac rhythm disturbances may complicate anorexia nervosa, especially if the patient is bulimic, one needs to obtain a full set of serum *electrolytes*, plus *blood urea nitrogen, creatinine*, and *electrocardiogram* with rhythm strip. The finding of hyponatremia suggests excess water intake or inappropriate antidiuretic hormone secretion. Determination of the serum calcium (plus albumin) and magnesium is needed if a dysrhythmia is noted or laxative abuse is suspected. A *complete blood cell count* and measurement of *TSH, glucose, alkaline phosphatase, gonadotropins*, and serum *estrogens* (see Chapter 112) may be helpful in the initial testing for complications of starvation, such as anemia, leukopenia, secondary hypothyroidism, hypoglycemia, fatty liver, and hypothalamic amenorrhea. If amenorrhea is persistent, weight loss marked, and nutrition poor, then one should obtain a *bone mineral density* measurement to check for resultant osteoporosis (see Chapter 144 and Chapter 164). Unexplained weight loss may necessitate additional laboratory and imaging studies (see Chapter 9).

Bulimia

History. The diagnosis of bulimia requires a high index of suspicion because bingeing and purging may be concealed and no physical signs are characteristic. Clues include a preoccupation with weight and food, a history of frequent weight fluctuations, and problems common to patients who purge and become dehydrated (dizziness, thirst, syncope) or hypokalemic (muscle cramps or weakness, paresthesias, polyuria). In addition, vomiters may describe hematemesis or heartburn, and laxative abusers may complain of constipation, rectal bleeding, and fluid retention. When the diagnosis is suspected, the physician should ask directly about bingeing and purging and should order a determination of serum electrolytes. A direct inquiry may elicit the history from a patient seeking help but ashamed to volunteer the information.

Physical Examination should include a check of postural signs for evidence of volume depletion, and any salivary gland enlargement or scars on the dorsum of the hand, suggestive of chronic self-induced vomiting, should be noted. The teeth are examined for erosion and discoloration. A careful neurologic examination is also indicated to rule out any focal abnormalities indicative of a central nervous system tumor or seizure disorder, which, in rare instances, can mimic bulimia.

Laboratory Studies. Most useful are the *serum* and *urine electrolytes, blood urea nitrogen*, and *creatinine*, and the *electrocardiogram. Calcium* and *magnesium* should be measured in laxative abusers. The pattern of serum and urine electrolytes helps to determine the mode of purging. *Hypokalemic alkalosis* suggests frequent vomiting or diuretic use. A *non–anion gap acidosis* suggests laxative abuse. Some patients who vomit deny that it is voluntary. Organic causes of chronic vomiting should be excluded in these cases (see Chapter 59).

Binge-Eating Disorder

The workup focuses on the history because physical examination and laboratory findings are almost always normal, except for obese patients (see Chapter 10). Most important is to explore the patient's experiences with eating because distress characterizes the syndrome, as do feelings of disgust and guilt after a binge.

PRINCIPLES OF MANAGEMENT AND PATIENT EDUCATION

Once it has been determined that hospitalization is not required (no suicidality, no major electrolyte or cardiac disturbances; see below), then design of the outpatient management program can proceed. The multidimensional nature of eating disorders necessitates a *multidisciplinary approach* that combines medical, nutritional, psychological, and pharmacologic measures. A *team approach* is often helpful. It can be coordinated by either the primary physician or a medical specialist experienced in treating eating disorders. Close coordination and communication are essential. A set of overall treatment goals should be collectively developed, agreed upon, and consistently communicated to the patient. Teamwork also helps ease the burden of treating these patients, who can be difficult when they deny the seriousness of their illness or exhibit deceptive, manipulative, angry, or distrusting behavior. There is *no single treatment of choice* for anorexia, bulimia, or binge eating. Several therapies produce short-term weight gain in patients with anorexia, but relapse is common, so that a comprehensive, multidimensional approach is necessary.

The immediate management tasks for the primary care physician are to identify and correct any potentially dangerous metabolic disturbances, set a few basic agreed-upon goals, initiate a few simple behavioral measures, and arrange timely referral to persons expert in the management of eating disorders. Given the potentially life-threatening nature of some eating disorders, one should proceed with referral as quickly as possible.

Outpatient Monitoring and Treatment of Metabolic Disturbances. One monitors the *weight* and *vital signs* regularly. In bulimic patients or anorectic patients who purge, it is especially important to check *postural signs, cardiac rhythm*, and *serum electrolytes* at each visit. If the QT interval was prolonged on the electrocardiogram at the time of the first visit, then a *repeated electrocardiogram* is warranted, especially before any tricyclic antidepressant therapy is instituted.

The hypokalemic patient who is judged safe to manage on an outpatient basis (see below) is instructed to eat potassium-rich foods (see Chapter 32). Maintaining normal electrolyte levels should be a condition of continued outpatient treatment. If the potassium level falls below normal despite dietary measures, supplemental potassium is indicated. This must be given as *potassium chloride* to correct the metabolic alkalosis that maintains the hypokalemia. Patients should be instructed to take the supplement at a time when purging will not occur; often, this is at bedtime. Patients not able to maintain a normal potassium level with supplements require hospitalization.

Setting Goals and Implementing a Dietary Plan. Setting goals is an important component of care for patients with eating disorders. Several goals are optimally specified by the primary physician. The first goal is to halt the use of diuretics and laxatives immediately. Sometimes, gradual tapering of laxatives is necessary because of the onset of severe constipation. For patients with anorexia, a *weight goal* and a *minimum acceptable weight* below which hospitalization will be required should be specified. The minimum weight is usually set at 40% below the premorbid or ideal body weight.

The weight goal is more difficult to determine and is often a point of disagreement between physician and patient. An estimate of desirable weight for height can be derived from standard tables (see Chapter 10). The weight goal should be at least 85% of the chart weight and, for female patients, a weight at which the patient has menstruated. Unless the patient was originally obese, it is usually close to the patient's premorbid weight. The patient and all caregivers should know of and agree to these weight guidelines. A *dietitian* can be very helpful in formulating and implementing an eating plan. Weight should be regained slowly, at a rate of 1 to 2 lb weekly, to avoid precipitating congestive heart failure. *Nutritional supplements* should be added if the patient is unable to gain weight at an acceptable rate.

Treating the Complications of Refeeding and Rehydration. During a reequilibration period of several weeks, temporary constipation, fluid retention, and weight gain may occur. Patients with pedal edema can be aided by *support stockings, leg elevation*, mild *salt restriction*, and reassurance that the condition is temporary.

Diuretics in the setting of volume depletion should be avoided even if edema is present because they may exacerbate the underlying metabolic and volume disturbances. However, congestive heart failure resulting from volume overload is treated in the conventional way (see Chapter 32). To prevent constipation, patients should increase *dietary fiber* and may benefit from fiber supplements or *stool softeners*. Irritant laxative preparations are to be avoided at all costs. In cases of severe postprandial *bloating* caused by poor gastric emptying, one may be tempted to consider a prokinetic agent (e.g., metoclopramide or cisapride), but the frequency of central nervous system side effects, drug–drug interactions, and QT prolongations associated with these agents (see Chapter 61) makes their use problematic in this setting.

Amenorrhea usually responds to an *increase in weight*. Periods return within 12 months in about 70% of those who reach 90% of their ideal weight. In those who remain amenorrheic and have low serum estrogen levels leading to documented *osteoporosis*, it may be reasonable to consider *estrogen replacement therapy*, although its effects are often disappointing. No experience has been had with bisphosphonates, but they might not be very effective if the basic problem is one of too little new bone formation (see Chapter 164). Priority should be given to restoring normal weight and good nutrition, including an adequate intake of *calcium* (1.5 g/d) and *vitamin D* (400 IU/d).

Psychological and Psychopharmacologic Treatments. Because of the complex nature of eating disorders and the increased probability of serious underlying psychopathology (not to mention suicide risk), psychiatric referral for specialized multimodality care is best. Individual or group psychotherapy, behavior modification, cognitive–behavioral therapy, and family therapy are all used. Patients with early-onset anorexia appear to respond well to family therapy. Those with bulimia respond well to cognitive–behavioral measures in conjunction with interpersonal psychotherapy; so do patients with pure binge-eating disorder.

Psychopharmacologic intervention can be helpful in carefully selected instances, such as binge eating. Medication works best as a complement to psychotherapeutic and behavioral measures. *Antidepressants* have been studied the most, on the theory that eating disorders are caused by disturbances in serotonin regulation. Results have been variable. The symptoms of anorexia nervosa do not respond to antidepressant medication, but a *selective serotonin reuptake inhibitor* (SSRI) such as *fluoxetine* (up to 60 mg/d) helps sustain recovery once weight is within 15% of normal. In contrast, fluoxetine is more effective in treating the symptoms of bulimia; it is the only drug approved by the Food and Drug Administration for use in this condition. It decreases the frequency of binge eating, even in patients without coexistent depression. *Tricyclics* have also proved useful in bulimia (e.g., desipramine and imipramine, both in dosages of up to 300 mg/d). The combination of antidepressant therapy plus cognitive–behavioral therapy or psychotherapy has been found beneficial and provides the best outcomes. In binge-eating disorder, desipramine has shown promise. Unlike mild to moderate depression, in which treatment with antidepressants by primary physicians is relatively straightforward, the eating disorders should be treated with psychopharmacologic therapy only by physicians skilled and experienced in their management. One reason is the increased risk for concurrent drug and alcohol abuse, particularly among patients with bulimia.

PATIENT EDUCATION

The physician needs to inform the patient of the seriousness of her illness and its complications. The connection between the eating disorder, symptoms, and laboratory abnormalities should be explained in detail. For anorectic patients, the consequences of starvation and the necessity of weight gain must be emphasized. Patients who purge need to understand the potentialconsequences of their behavior (e.g., irreversible erosion of tooth enamel, cardiac arrhythmias) and the ineffectiveness of laxative or diuretic use for achieving real weight loss. Patients who have been starving themselves or abusing laxatives or diuretics should be instructed in the likelihood of transient discomfort (e.g., edema, constipation, bloating) as they stop purging and begin to eat.

INDICATIONS FOR ADMISSION AND REFERRAL

As noted earlier, anorexia is a potentially life-threatening condition. Medical criteria for hospitalization include the following: (a) loss of more than 40% of premorbid or ideal weight (or 30% if within 3 months); (b) rapid progression of weight loss; (c) presence of cardiac arrhythmias; (d) persistent hypokalemia unresponsive to outpatient treatment; and (c) symptoms of inadequate cerebral perfusion or mentation (syncope, severe dizziness, listlessness). The patient should understand that anorexia is a life-threatening illness and that the first priority is to protect life. Psychiatric hospitalization may be required for behavior beyond the patient's control or for incapacitating depression.

When outpatient management is deemed appropriate for a patient, referrals for psychiatric care and nutritional counseling are essential. It is best to select persons with expertise in the care of patients with eating disorders because treatment can be difficult. For patients with tooth enamel erosion caused by chronic emesis, a dental consultation should be obtained.

TREATMENT RECOMMENDATIONS

Effective treatment is a multidisciplinary effort, likely to require a coordinated team approach that includes care by mental health and nutritional professionals. The guidelines that follow pertain to the role of the primary physician:

- At the time of the first visit, assess the degree of malnutrition, dehydration, and electrolyte disturbance and decide whether care should proceed on an inpatient or outpatient basis.
- Be sure other causes of weight loss and its complications have been ruled out (see Chapter 9, Chapter 25, Chapter 59, Chapter 103, and Chapter 112).
- Obtain expert psychiatric and nutritional consultations; organize and coordinate a multidisciplinary team approach to management.
- Educate the patient about the medical complications of the illness.
- Set medical guidelines for outpatient management:
  - Minimum acceptable weight
  - Weight goal
  - Weight gain of 1 to 2 lb a week for underweight patients
  - Maintenance of normal electrolytes
- Monitor weight, postural signs, cardiac rhythm, and electrolytes.
- Treat any hypokalemia with potassium chloride.
- Address and treat any endocrinologic complications (see Chapter 104 and Chapter 112).
- Hospitalize the patient in the following circumstances:
  - Weight loss is in excess of 40% (or 30% if within 3 months).
  - Weight loss is rapidly progressive.
  - Cardiac arrhythmias develop (urgent).
  - Persistent hypokalemia is present and unresponsive to outpatient treatment.
  - Syncope, severe dizziness, or listlessness develops (urgent).
  - Severe depression develops (urgent if patient becomes suicidal).

CHAPTER 235 APPROACH TO THE SUBSTANCE-ABUSING PATIENT

PATRICK L. LILLARD

Abuse of and addiction to alcohol, tobacco, and illegal drugs is one of the foremost public health problems in the United States. The direct effects of these drugs produce serious morbidity and increased mortality. By their effects on behavior, however, they produce consequences even more serious. Abuse of and dependence on alcohol and other drugs disrupt interpersonal relationships and destroy lives. They contribute to accidents, crime, family violence, and lost productivity. IV drug use contributes strongly to the spread of AIDS and other infectious diseases.

Despite the pervasive penetration of substance use problems into all aspects of our culture, the ability of health care providers to assess and intervene has lagged behind the current state of knowledge. As few as 5% of substance-abusing patients presenting for medical attention have their substance abuse problem recognized. Unfortunately, physicians frequently treat the sequelae of drug abuse without directly addressing the underlying problem. To a significant extent, this is a reflection of the belief that substance abuse and dependence represent a character flaw or moral weakness rather than a disease. "The reality," in the words of Alan I. Leshner, "based on 25 years of research, is that drug addiction is a brain disease—a disease that disrupts the mechanisms responsible for generating, modulating, and controlling our cognitive, emotional, and social behavior."

DEFINITIONS

Addiction. The term *addiction* has gained many imprecise and pejorative meanings and has come to symbolize the stigma placed on patients with these disorders. The word *addict* is commonly used in the same biased manner as the words *drunk* and *junkie*. The American Psychiatric Association therefore does not use the term *addiction* and subclassifies *substance use disorders* as *substance dependence* and *substance abuse* in its current 4th edition of the *Diagnostic and Statistical Manual* (Table 235.1). It is important to note that these diagnoses are based on the presence of behavioral abnormalities; they do not indicate just physical dependence. *Substance dependence* or *abuse* is not an appropriate diagnosis for patients who are physically dependent on appropriately prescribed psychotropic or analgesic drugs, but who exhibit no addictive behaviors whatsoever (i.e., no compulsive, out-of-control use). The confusion of dependence with *addiction* may contribute to the underprescription of narcotic analgesics by physicians, even when they are indicated for cancer pain, and the undertreatment of anxiety disorders with benzodiazepines.

Table 235.1. Criteria for Substance Abuse and Dependence

Substance Abuse. As noted in Table 235.1, *abuse* does not indicate dependence. It most accurately refers to the illegal, maladaptive, or dangerous use of a substance. It must be recognized that alcohol- and drug-related harm is not only the result of dependence. For example, nondependent alcohol abusers may be responsible for nearly half of alcohol-related problems, such as drunken driving, alcohol-related violence, or drunkenness on the job. Adolescent experimentation with various substances becomes abusive when it is recurrent; it does not necessary indicate dependence. The descriptive term *addict* does not apply.

Substance Dependence. In its narrowest sense, *dependence* means that a person will experience pathologic symptoms and signs when abstaining from a substance. Until recently, it was thought that the most significant indicator of "*drug addiction*" was physical dependence, manifested by symptoms of *physical withdrawal* occurring during drug abstinence, such as tremor or elevated blood pressure. Although physical dependence may certainly be a key symptom of *substance dependence* to certain drugs (e.g., alcohol or opiates), it is neither necessary nor sufficient. Some highly addictive drugs, such as cocaine and amphetamine, do not produce physical dependence or withdrawal symptoms. Moreover, many drugs with no abuse potential, such as clonidine and propranolol, may produce physical dependence (e.g., severe rebound hypertension or angina with discontinuation).Indeed, because cocaine does not produce physical dependence, it was widely held until the 1980s that cocaine was not addictive—a misconception that has contributed to the recent epidemic of cocaine abuse in the United States.

PATHOPHYSIOLOGY AND CLINICAL PRESENTATION

Substance Use Disorders

Data continue to accumulate supporting the concept that substance use disorders are an acquired brain disease caused by prolonged drug exposure in a vulnerable person. Neurons in the *locus coeruleus* appear to adapt to prolonged opiate exposure and fire at abnormally high rates when opiates are abruptly withdrawn, thereby triggering much of the physical withdrawal syndrome. The *mesolimbic dopamine system* provides powerful reinforcement behaviors with important survival value (e.g., sexual activity) by producing a sense of euphoria on stimulation. The most addictive of drugs (e.g., cocaine, amphetamines, opiates, alcohol, and nicotine) are thought to tap into this "brain reward" system by mimicking or enhancing the action of endogenous neurotransmitters, such as dopamine or endorphins.

With prolonged drug exposure, the neurons in this circuit undergo molecular adaptations. It has been hypothesized that the drugs that produce these adaptive responses in the mesolimbic dopamine system cause the core symptoms of substance use disorders; a subset also produces adaptive changes in other neurons that lead to physical dependence. When the drug is stopped, the person feels that the world is intolerable without it.

In this model, the denial and manipulativeness of the person with a substance use disorder become more understandable. The key motivational system in the person's brain has been usurped by drugs. Without the drug, the person experiences strong negative emotions, an inability to feel pleasure, and an intense craving for the drug.

Why some people become addicted during the course of drug use and others do not, and why some recover and some do not, are not well understood. Factors contributing to individual vulnerability likely include genetic components, developmental experiences, intercurrent psychiatric disorders or chronic pain, current levels of distress, and complex social factors, including family and peer relationships and the availability of valued behavioral alternatives.

The debate over the origins of substance use disorders is not simply one of semantics; the inability of people to stop using alcohol, tobacco, or other drugs baffles or angers many physicians.

Cocaine, Amphetamines, and Other Central Nervous System Stimulants

Cocaine, amphetamine, and related drugs act by increasing synaptic dopamine in mesolimbic dopamine projections. Cocaine blocks the reuptake transporter that terminates the action of dopamine in the synapse. Amphetamine acts predominantly by causing dopamine release. Enhancement of the effects of serotonin and norepinephrine likely contributes to the sympathomimetic effects of these drugs. Other psychostimulants with abuse potential include methylphenidate (Ritalin) and phenmetrazine.

Pharmacokinetics. *Cocaine hydrochloride* is rapidly absorbed when taken intranasally, but it is absorbed even more rapidly during IV administration. Free-based cocaine is generally smoked, most commonly in the form of "*crack*." Because higher brain levels are achieved more rapidly, IV administration and smoking are far more addictive than intranasal "snorting."

Amphetamines include racemic amphetamine sulfate (e.g., Benzedrine and others), dextroamphetamine (e.g., Dexedrine), and methamphetamine (Methedrine). Methamphetamine is the most potent and potentially toxic form of amphetamine. Amphetamine can be taken orally or IV. Methamphetamine is also smoked (a recent name for smoked methamphetamine is "ice"). High levels of tolerance develop in persons who use amphetamine on a regular basis, so that increasing doses of the drug become necessary. These people are at high risk for the development of a paranoid psychosis.

Perhaps the most important difference between cocaine and amphetamine derivatives is in half-life; the effects of amphetamine last longer than those of cocaine. These differences in half-life lead to different use patterns (see below).

Clinical Effects and Patterns of Abuse. Cocaine and amphetamine produce many of the same clinical effects, most importantly euphoria, which is a sense of increased energy and confidence, and sympathomimetic actions. They may also produce restlessness, anxiety, hostility, and paranoia, especially with cumulative or higher doses. Other effects include tachycardia, hypertension, fever, and tremor. With dependence, patients may exhibit jitteriness, weight loss, depression, and a lack of energy.

Because the effects of cocaine are short-lived, it is often taken in binges to maintain drug-induced euphoria. At the termination of a binge, a withdrawal syndrome is often evident, characterized by severe dysphoria, anhedonia, fatigue, and a craving for cocaine.

Amphetamine may also be used in binges, but many people take the drug orally on a daily basis. They may start amphetamine to control weight or decrease fatigue. As dosages accelerate because of tolerance, many such people become irritable and paranoid. Overdosing with cocaine or amphetamine produces tachyarrhythmias, hypertension, high fever, seizures, delirium, paranoia, psychosis, coma, and cardiovascular collapse. Stroke and myocardial infarction have been reported with crack use.

Despite their similarities, cocaine and amphetamine do not parallel each other in popularity. The United States is in the waning phase of a cocaine epidemic that has lasted for nearly two decades. The use of cocaine among the middle class has declined markedly; however, use among "hard core" cocaine-dependent persons has not decreased. In this population, crack cocaine is the most frequently used form. Amphetamine, including IV methamphetamine, was popular before the start of the recent cocaine epidemic, and in the late 1990s it seems to have made a comeback.

Opiates

The opiates produce their effects by binding to endogenous opiate receptors. The major therapeutic use of opiates is for analgesia. Less potent opiates are also used as antitussives and antidiarrheal agents. The most highly abused opiates are those that interact predominantly with μ-type opiate receptors. These include heroin; less commonly morphine or meperidine, which are generally injected IV; and oxycodone and hydromorphone, which are most often taken orally. Heroin may also be smoked.

Clinical Effects and Patterns of Abuse. Opiates produce an initial sense of euphoria (a "rush"), especially after IV injection or smoking, which is followed by a sense of tranquillity and then sleepiness. Tolerance and dependence develop, so that increasing doses are required to achieve the desired euphoria. Tolerance to the respiratory depressant effects of opiates develops approximately in parallel. Tolerance to opiate-induced pupillary constriction does not develop.

Unlike alcohol, for example, opiates do not directly produce serious organ pathology. Constipation is the major side effect of opiate use and may represent a significant problem (e.g., in patients being treated for cancer pain). However, opiates produce high levels of psychological dependence, and the widely used method of administering them (IV injection, often with shared needles) may result in hepatitis B, HIV infection, endocarditis, infection of the local injection site, and other complications of nonsterile self-injection.

Overdoses of opiates may be lethal because of respiratory depression. Overdosing is most frequent when the heroin dose is purer than what the addicted person is accustomed to, when tolerance levels are miscalculated after detoxification, and when the user is inexperienced.

Withdrawal from opiates may be uncomfortable but is not lethal. Withdrawal from heroin may begin 6 to 12 hours after the last dose in dependent persons and is manifested by agitation, drug craving, tachycardia, hypertension, fever, muscle cramps, nausea, and rhinorrhea.

Sedative-Hypnotics

The sedative-hypnotics include the *benzodiazepines, barbiturates*, and the *barbiturate-like drugs* (e.g., glutethimide, ethchlorvynol). These agents enhance the inhibitory effects of g-aminobutyric acid (GABA$_A$) receptors in the brain. Because *ethyl alcohol* similarly affects these receptors, marked sedation is associated with concurrent use. In comparison with the benzodiazepines, the barbiturates and similarly acting compounds have a greater potential for abuse, overdose, and drug–drug interactions (by inducing hepatic microsomal enzymes). They have no place in general practice except as anticonvulsants (phenobarbital).

Benzodiazepines are most commonly prescribed for the short-term treatment of insomnia and for anxiety disorders (see Chapter 226 and Chapter 232). They can cause dependence with long-term use, so that the drugs must be slowly tapered after a course of treatment. The likelihood of dependence is greater with high-potency, short-acting compounds (e.g., alprazolam, triazolam) than with low-potency, long-acting compounds (e.g., diazepam, chlordiazepoxide). Although abuse and addiction may occur, it is relatively uncommon for the benzodiazepines to produce addictive behaviors (compulsive nonmedical use) except in patients with a prior history of drug abuse. Prolonged benzodiazepine use, carefully monitored, may be necessary for patients with disabling anxiety disorders (see Chapter 226).

Clinical Effects and Patterns of Abuse. When abused, the sedative-hypnotics produce disinhibition, which appears very similar to drunkenness; disinhibition is often followed by drowsiness. *Overdosing* with barbiturates produces respiratory depression and coma and may cause death. Benzodiazepines are not likely to be lethal when taken alone in overdose, but when combined with alcohol, they can cause death from respiratory depression.

Withdrawal from sedative-hypnotic drugs produces tachycardia, hypertension, fever, tremulousness, hyperreflexia, anxiety, restlessness, insomnia, and anorexia. Seizures and delirium may occur and may be severe. Unlike opiate withdrawal, sedative-hypnotic withdrawal may be fatal.

Marijuana

Marijuana is produced from the dried leaves and flowers of the hemp plant, *Cannabis sativa*. The active ingredient, D-9-tetrahydrocannabinol (THC), acts by binding to an endogenous THC receptor in the brain, the normal function of which is unknown. During the past decade, the clonal selection of hemp plants for high THC content has markedly increased the potency of marijuana sold on the street.

Marijuana is generally smoked, although occasionally it is taken orally. It produces a feeling of relaxation, mild euphoria, and increased sociability. Physical symptoms and signs include mild tachycardia, dry mouth, and conjunctival injection. The most common short-term adverse consequence is an acute panic reaction, which may occur in inexperienced users, especially after they have smoked high-potency marijuana. Rarely, large doses of high-potency marijuana can produce hallucinations, paranoia, and delirium. Marijuana is far less addictive than cocaine, amphetamine, opiates, alcohol, nicotine, or barbiturates. Nonetheless, some habitual users

appear to be dependent. Prolonged use may impair testosterone secretion and lead to gynecomastia.

Hallucinogens

The hallucinogens, or psychedelic compounds, are a group of structurally diverse compounds that appear to act by mimicking the actions of serotonin at certain of its receptor subtypes. The most widely used hallucinogens are the indolalkylamine compounds, including D-*lysergic acid diethylamide* (LSD), *dimethyltryptamine* (DMT), and *psilocybin* (which is the active ingredient in "*magic" mushrooms*), and the phenylethylamine compounds, such as the "designer" drug *MDMA* ("*ecstasy*") and *mescaline* (derived from the peyote cactus). Compounds such as MDMA, which are structurally related to amphetamine, may also have mild agonist effects on dopamine systems and produce modest euphoric effects.

Clinical Effects and Patterns of Abuse. LSD produces both *sympathomimetic* and *perceptual* effects. The sympathomimetic effects, such as increased pulse rate, blood pressure, and mydriasis, generally precede the perceptual changes, which include visual illusions, hallucinations, confusion among sensory modalities (synesthesias), depersonalization, and altered time perception. Most LSD "trips" last 8 to 12 hours. The predominant effects of psilocybin and mescaline are similar to those of LSD. MDMA produces disinhibition and increased sociability; illusions are not prominent. MDMA also produces muscle twitching and bruxism. MDMA has recently become popular at large dancing parties called "raves"; rare deaths have been reported in such circumstances from hyperthermia caused by the combination of MDMA, many hours of intense exertion, and lack of hydration.

The most common immediate adverse effect of hallucinogen use is a *panic reaction* or "bad trip." Extreme agitation or *delirium* occurs rarely, but often as a result of exposure to additional drugs or adulterants, particularly *phencyclidine*. In such circumstances, a toxic screen should be obtained.

Patients in whom *psychotic episodes* develop after hallucinogen use are difficult to sort out. Generally, the history of psychiatric disturbance precedes the use of the hallucinogen. *Flashbacks*, which consist of brief, recurrent visual illusions or hallucinations, may occur for months or, rarely, for several years after hallucinogen use.

Hallucinogens do not appear to be physically addictive. Their major dangers relate to the state of intoxication they produce, in which judgment is markedly impaired and panic reactions possible. These predispose to accidents, violence, and suicide (which may be inadvertent). In addition, animal data demonstrate that MDMA is highly toxic to serotonin neurons in the brain. Whether MDMA produces lesions of the serotonin system in humans is not known but is a concern.

Phencyclidine

Phencyclidine, like marijuana and other hallucinogens, does not produce a physiologic withdrawal pattern in humans, but a psychological abstinence syndrome is observed that includes depression, craving, and fatigue. Most important is the variable presentation of intoxication and overdose with diverse behavioral and psychological manifestations (delirium, psychosis, catatonia, mania, depression, extreme agitation and violence) or with physiologic manifestations (nystagmus, hypertension, tachycardia, hyperreflexia that may lead to rhabdomyolysis, renal failure). The behavioral and physiologic effects can occur together or in stages that complicate the diagnosis and treatment, and they can progress to life-threatening stupor and coma in which the patient is unresponsive to pain. A careful history is mandatory, as is constant awareness in the acute setting of the possibility of phencyclidine intoxication.

Alcohol and Tobacco

(See Chapter 54 and Chapter 228.)

WORKUP: SCREENING FOR SUBSTANCE ABUSE

A principal objective of the evaluation in the office setting is to screen for substance abuse. This is important in both asymptomatic persons who come in for a checkup and those who present with suggestive historical or physical findings (Table 235.2).

SUBSTANCE	HISTORY	PHYSICAL FINDINGS
Opiates	Fever HIV infection Hepatitis D Pneumonia, tuberculosis	Needle tracks, petechiae, murmur Lymphadenopathy, rash Jaundice, hepatomegaly/tenderness Pulmonary consolidation
Sedatives	Depression Seizures Lethargy, amnesia	Psychomotor retardation, sadness Observed convulsion Cognitive impairment
Stimulants	Agitation Nasal congestion Stroke, focal deficits Chest pain, infarction Syncope, palpitations	Delirium Perforated septum; mucosal edema New neurologic deficits New S₄ gallop, single S₂ Arrhythmia, enlarged heart, S₃
Hallucinogens	Psychosis, hallucinations Enlarged breasts in male patient	Disordered thinking Gynecomastia
Alcohol	[see Chapter 228]	
Any substance	Withdrawal syndrome	Tremor, tachycardia, agitation, fever

Adapted from Shine RD. The diagnosis of drug dependence by primary care providers. J Gen Intern Med 1991;6(Supp):S32, with permission.

Table 235.2. Historical and Physical Findings Suggestive of Substance Abuse

History. The best means of screening is by history. Because drug use may be an emotionally charged issue, it should be addressed after some rapport with the patient has been established. It is important that the physician feel comfortable in obtaining the history, neither apologizing for asking nor suggesting blame. Apologizing ("I have to ask these questions" or "I'm sure this doesn't apply to you, but...") may actually make it more difficult for the substance-abusing patient to respond honestly. The clinician with a judgmental approach will not diagnose this disease (see below).

Physical Examination should include a check for fever, tachycardia, hypertension, skin manifestations of HIV infection (see Chapter 13) and endocarditis, icterus, needle tracks, nasal septal perforation, mucosal congestion, gynecomastia, adenopathy, heart murmur, liver enlargement, tremor, and cognitive impairment.

Laboratory. When substance abuse is strongly suspected but cannot be confirmed by history, a toxic screen with urine and blood testing may be necessary. The febrile patient requires extensive evaluation, beginning with blood cultures (see Chapter 11).

PRINCIPLES OF MANAGEMENT

Substance abuse treatment may be divided into two phases, *initiation* of abstinence in the short term and *maintenance* of abstinence in the long term. For the physician, it is useful to view drug addiction, including alcoholism, as a chronic, relapsing, progressive disease. Even after successful treatment, patients remain at high risk for relapse. Relapses should be seen not as failures of treatment but as occasions to reinstate abstinence and subsequently to redouble efforts to maintain abstinence.

Getting the Patient into Care. The best chance of successful intervention, even with severe dependence and high levels of denial, is to match the patient's Stage of Change with a treatment strategy. In the *precontemplative stage* the patient does not recognize a problem and a labeling, coercive approach will fail. The best strategy is to be empathetic in demonstrating to the patient the problems (such as liver disease, or loss of employment) that results from substance abuse. In the *contemplation stage* the patient recognizes a problem but is ambivalent about stopping, and the treatment strategy is to use the ambivalence to demonstrate the downside of the substance use. Similarly, with the *planning stage*, the treatment should be designed to help the patient and family plan concrete steps to implement to change. Then in the *action stage* with support (AA is a good example) the patient carries out behavioral changes that result in abstinence. Finally in the *maintenance stage* the strategy is relapse prevention: high risk behavior is examined and changed before a return to precontemplation. It is important to honor confidentiality, but it useful to include the family in matching the treatment with stage of change.

It is valuable to keep referral numbers close at hand to take advantage of the patient's motivation. And remember, though an intoxicated patient has impaired

judgment and insight, they often remember an empathic clinician and seek help later.

Once the patient acknowledges having a problem, a decision can be made with the patient regarding a treatment plan. The physician should have referral numbers close at hand so that the patient's moment of motivation is not lost.

Unfortunately, the judgment and insight of an intoxicated patient are impaired, and the patient may not be able to understand the initial efforts to provide help. However, patients often remember an empathic, nonjudgmental clinician and return for help later.

Comprehensive Substance Abuse Treatment is best left to specialists and specialized organizations. Treatment programs vary according to the patient and the substance, but successful programs have several characteristics in common:

1. *Evaluation* for comorbid psychiatric or medical disorders (presence of a comorbid psychiatric disorder worsens prognosis)
2. *Education* about the effects of the drug and the nature of addiction
3. Use of *mutual support groups* such as Alcoholics Anonymous or the similarly organized Narcotics Anonymous
4. *Individual psychotherapy*
5. *Family involvement* and promotion of a sense of belonging, and use of other supportive measures such as exercise, meditation, and discussion of spirituality that may include organized religion
6. Emphasis on *abstinence* and *rehabilitation*

Importance of Abstinence. Most treatment programs stress a combination of abstinence and rehabilitation. Although there have been reports of alcoholic patients returning safely to controlled drinking, it is impossible to identify such persons ahead of time. It appears that for most people who have been drug-dependent, a single use reawakens the strong positive feelings that helped produce the dependence to begin with, and also loosens restraint. Thus, complete abstinence is the best way to avoid relapse.

Medication. Drugs that produce aversive reactions (*disulfiram* for alcohol) or block pleasure (*naltrexone* for opiates) can be of value in the short term but require a very motivated patient and intensive support. Specific pharmacologic treatment to diminish craving is not available for cocaine (despite limited success with desipramine). Clear evidence now suggests that naltrexone and acamprosate (soon to be available) do decrease alcohol use by decreasing craving and interfering with the pleasure of use. For opiate addicts not ready to be detoxified, *methadone* maintenance may be very helpful in permitting them to stabilize their lives and avoid the dangers of IV drug abuse. Methadone maintenance can be administered only at specially licensed treatment centers. LAMM, a longer-acting opiate agonist,and buprenorphine, a mixed agonist/antagonist, show promise as maintenance agents. *Nicotine patches* and *bupropion* may be useful in decreasing craving in some smokers and may play a useful role in smoking cessation programs when supplemented by psychosocial measures (see Chapter 54).

Treatment of Acute Overdoses and Toxic Reactions. An overdose or toxic reaction should be treated in the emergency department setting. The details of such treatment are beyond the scope of this book, but a few highlights are included here to aid in decision making and triage:

- Cocaine: no specific cocaine antagonist. Treatment is aimed at relieving symptoms and providing cardiovascular support.
- Opiates: cardiovascular and airway supportive care. Naloxone (Narcan), an opiate antagonist, is administered IV; usual dose is 0.01 mg/kg; average person will take approximately two ampules (0.8 mg). Half-life of naloxone is shorter than half-life of heroin, so that continuous observation and possibly repeated dosing are necessary.
- Sedative-hypnotics: airway and cardiovascular support. Benzodiazepine antagonist, flumazenil, is available, but clinical experience is limited.
- Marijuana: for panic reaction, reassurance that the feeling will pass, and ensuring that the patient is in a safe environment.
- Hallucinogens: for a "bad trip," reassurance and maintenance of a safe environment; rarely, 1 to 2 mg of lorazepam PO (or its equivalent) for agitation; for extreme agitation or delirium, physical restraint and 2 mg of lorazepam every 2 hours (or the equivalent) as needed. Obtain toxic screen to search for adulterants and additional drugs. For flashbacks, reassurance is best.

INDICATIONS FOR ADMISSION AND REFERRAL

Patients who are physically dependent on sedative-hypnotics, alcoholic patients with a history of severe withdrawal symptoms, persons with serious complicating medical or psychiatric conditions, and those who have previously failed to improve with outpatient treatment should be referred for inpatient treatment. Detoxification can be safely performed on an outpatient basis in appropriate cases, but a comprehensive specialized program is required.

Opiate detoxification protocols are based on the following:

1. Substitution of a long-acting oral opiate, methadone, for short-acting injected opiates, such as heroin, with a taper during 4 days to 2 weeks depending on the setting; or
2. Use of opiate agonist/antagonist buprenorphine, which can be given IM or sublingually during a course of 4 to 5 days.

All detoxification programs must be accompanied by strong psychological and social support, education, and planning for long-term treatment that should include, whenever possible, the continued support and involvement of the primary care physician.

CHAPTER 236 APPROACH TO THE PATIENT WITH CHRONIC NONMALIGNANT PAIN

TODD E. GORMAN

Chronic pain is a highly prevalent problem, affecting up to 17% of Americans and costing society an estimated 70 billion dollars each year. Many clinicians find chronic pain an emotional and intellectual challenge. Part of this stems from the fact that there are many myths amongst clinicians surrounding chronic pain (Table 236.1).

- Patients' complaints stem from secondary gains; they do not really suffer "pain."
- Patients with chronic pain are inherently noncompliant and manipulative.
- Patients given opiates will refer manipulative friends.
- Opiates in therapeutic doses will cause respiratory depression.
- Patients given opiates will become "addicted."
- Giving patients opiates for chronic nonmalignant pain will result in investigations by state and federal review boards.
- Chronic pain can be fixed.

Table 236.1. Myths Surrounding Chronic Pain

Unlike acute pain, chronic pain tends to be more multifactorial, less amenable to "cure," and more influenced by psychological and social factors. It typically requires continuous long-term management. These characteristics necessitate an appropriate adjustment of expectations and approach by both clinician and patient to achieve a satisfactory outcome. The principal goal is improvement in quality of life and function, rather than complete elimination of the pain.

PATHOPHYSIOLOGY AND CLINICAL PRESENTATIONS

Definition and the Biopsychosocial Model of Pain

Pain is defined by the International Association for the Study of Pain as "an unpleasant sensory and emotional experience arising from actual or potential tissue damage." Pain is an inherently subjective phenomenon, originating from a biologic source and modified by psychological and social factors. Perceptions and reports of pain and its severity rely heavily on a person's psychosocial context. For this reason, the *biopsychosocial model* proves useful in the conceptualization of pain.

Biologic Components. Pain derives from afferent signals of nociceptive fibers in the periphery, triggered by tissue damage or the threat of damage (*nociceptive pain*), or by direct neuronal activation (*neuropathic pain*). These afferent nociceptive fibers course back to the central nervous system via the spinothalamic tracts to both somatosensory and frontal cortices. *Modulation networks* from the frontal cortex and hypothalamus create a final conscious perception. These networks are the medium by which psychological factors and the psychosocial context alter the sensation of pain.

The biologic component of chronic pain is less well understood than that of acute pain. It appears that many patients suffering from chronic pain do so with a minor biologic stimulus or occasionally even without one once the process has begun. Psychological and social factors clearly play a larger role in modulating the perception and perpetuating it. Perpetuation likely occurs via *neuronal sensitization* and the above-mentioned modulation networks.

In neuronal sensitization, the threshold for activating nociceptors is lowered by repetitive stimuli. Continuous triggering of nociceptive fibers generates pain even when the stimulus is minimal. Modulatory factors include *expectation*, whereby the sensation of pain is heightened by the anticipation of its arrival. This is related to the effects of norepinephrine on sympathetic input to nociceptive fibers; it lowers their threshold for activation and even activates them directly. A well-known corollary to the modulation of pain through expectation is the *placebo effect*, which is still poorly understood but clearly decreases an individual's perception of pain via neuronal modulation.

Psychological Components. Besides modulating pain, psychological components may actually be considered as a cause (i.e., *primary*) or effect (i.e., *secondary*) of chronic pain. Primary psychological considerations include whether the patient has a major *depression* (see Chapter 227), *anxiety* disorder (see Chapter 226), *somatoform disorder* or *personality disorder* (see Chapter 227 and Chapter 230), or *substance abuse* problem (see Chapter 235), or whether the patient is malingering (Table 236.2).

Psychological factors	Social factors
Major depression (1° or 2°)	Domestic violence
Anxiety disorders (1° or 2°)	Daily activities causing pain
Somatoform disorders	Activities hindered by pain
Personality disorders	Work hindered by pain
Substance abuse (1° or 2°)	Work contributing to pain
Malingering	Secondary gain

Table 236.2. Psychological and Social Factors Contributing to Chronic Pain

Most of these disorders cause a heightened awareness of somatic sensations, a charged emotional state, and a sense of expectation. Heightened awareness results in an inability to suppress stimuli that the individual might otherwise be capable of suppressing. A charged emotional state sensitizes nociceptive fibers to stimuli, also creating an enhanced conscious perception of pain.

Secondary psychological processes like depression and anxiety are common among patients with chronic pain, as is secondary substance abuse if the patient

self-medicates with alcohol or narcotics. These secondary processes may also contribute to modulating and perpetuating a sensation of pain.

Social Contributors encompass elements in the home, in the work environment, and at leisure (Table 236.2). Although the home environment may serve as a potential source of relief and support for the patient with chronic pain, more often it contributes to the presentation, as with *domestic violence*. Pain may even serve as a cause for escape from a troubled home situation to the doctor. Likewise, a person's leisure and work environments may contribute to or be hindered by pain. Social factors can drive the sensation of pain into a chronic state if secondary gain is a possibility (e.g., ongoing litigation, worker's compensation).

Categorizations of Pain

Pain can be categorized by either clinical presentation (acute vs. chronic; diffuse vs. localized) or by underlying mechanism (neuropathic vs. nociceptive; biologic vs. psychosocial).

Acute versus Chronic Pain. In general, *acute pain* emanates from an identifiable biologic stimulus, is self-limited, does not have much of a psychological component, and is more amenable to pure pharmacologic intervention. *Chronic pain* is that which lasts longer than a typically expected time for healing, or 3 to 6 months. It can be further subclassified as chronic nonmalignant pain or chronic malignant pain (see Chapter 90). Chronic nonmalignant pain, on the other hand, may or may not have an identifiable biologic stimulus, is by definition *not* self-limited, has greater psychosocial underpinnings, and is less amenable to pure pharmacologic intervention.

Diffuse versus Localized Pain. Some patients present with total body pain or pain that migrates from one site to another. These cases tend to have dominant psychosocial components. Most patients present with pain localized to a certain anatomic region, which remains consistent over time. The most common presentations include pain localized to one of five regions: head and face, nonaxial musculoskeletal structures, low back, abdomen and pelvis, and peripheral nerves.

Nociceptive versus Neuropathic Pain. *Nociceptive pain* develops from actual or potential tissue or organ damage. *Somatic* nociceptive pain is typically attributable to specific anatomic areas or structures. Patients present with pain that is well localized and stabbing, throbbing, or achy. *Visceral* nociceptive pain, being organ-based, is less well localized and typically more dull and cramping.

Neuropathic pain, on the other hand, derives from direct nerve stimulation. This may occur with or without a nociceptive component. The pain is typically characterized as burning, tingling, and lancinating, often occurring in a dermatomal distribution. A sensory deficit may accompany the pain. Sensitization can lead to the nerves firing in the absence of any peripheral stimulus. Examples of neuropathic pain include post-herpetic neuralgia, diabetic neuropathy, sciatica, trigeminal neuralgia, reflex sympathetic dystrophy, and phantom limb pain.

Predominantly Biologic versus Predominantly Psychosocial. The balance of biologic and psychosocial components may vary tremendously. Some cases have a primarily *biologic* cause with no evidence of psychiatric pathology (e.g., a functional, well-adjusted octogenarian with severe osteoarthritis). Others present with the subjective report of pain but no objective findings and go on to meet formal criteria for a primary *psychiatric* disorder (e.g., a young professional suffering from hypochondriasis).

The majority of patients presenting with chronic pain are somewhere in between these two extremes, with a *combination* of both biologic and psychosocial components. Quantification of overlap has not been performed extensively in patients presenting with chronic pain, although some data exist. For example, *comorbid major depression* is found in 8% to 50% of patients presenting with chronic pain, with *dysthymia* seen in more than 75%. Likewise, *anxiety disorders* (both panic attack and generalized anxiety disorder) are seen in more than 50%.

DIFFERENTIAL DIAGNOSIS

Any differential diagnosis for chronic pain must include both biologic and psychosocial factors. The biologic causes are best considered in terms of pain location (Table 236.3). The psychosocial determinants are essential considerations in assessing factors that may trigger, sustain, or aggravate pain (Table 236.2).

Table 236.3. Differential Diagnoses of Chronic Pain Based on Location

WORKUP

The heterogeneity of chronic pain complaints and the variety of mechanisms and presentations necessitate exploration of both biologic and psychosocial dimensions of the problem. The workup should define the patient's psychosocial context, classify the pain process precisely, and determine the likelihood of serious underlying biologic pathology.

Defining the Psychosocial Context. All patients presenting with chronic pain must be screened carefully for depression, anxiety, evidence of a somatoform disorder or personality disorder, substance use/abuse, and possible secondary gain. Clues suggesting a primary psychological or social cause include depressed or anxious affect, history of substance abuse, multiple unrelated sites of pain, onset in adolescence, history of difficult social interactions, and absence of a clear pathophysiologic mechanism (Table 236.4). Home, work, and leisure activities should be reviewed in depth for possible precipitating and aggravating social factors (see the Appendix for a more detailed discussion of screening for domestic violence).

- The patient admits depression or anxiety that predates the pain.
- The pain began in adolescence or at time of trauma (suggests pain disorder or PTSD).
- The patient has a history of substance abuse.
- There are multiple, unrelated sites of pain over time (suggests somatization disorder).
- There is no demonstrable pathophysiologic mechanism to explain the physical symptoms.
- There is a history of difficult social interactions to suggest a personality disorder.
- There is evidence of physical, sexual, or emotional abuse.
- There is potential for or history of the patient pursuing secondary gains, such as litigation reward or worker's compensation (suggests malingering).

PTSD, posttraumatic stress disorder.

Table 236.4. Signs That Psychosocial Factors Are Predominant in a Patient's Chronic Pain

Classifying the Process. The classic cardinal features of pain should always be documented: onset/duration, quality/severity, location/spread, alleviating/aggravating factors, and associated symptoms. Circumstances surrounding the onset of the pain, in addition to the location of pain and associated symptoms, are all particularly helpful in determining whether or not a patient's presentation might relate to a biologically plausible process or is predominantly psychological or psychosocial in origin. These features will also help determine if the pain is acute or chronic, localized or diffuse, somatic or visceral, and nociceptive or neuropathic. Correct classification helps guide further workup and management.

Patients of different cultural backgrounds will describe pain *quality* in distinctively different terms, so that some basic cultural understanding is necessary to interpret the complaint of pain properly. For example, patients of Caribbean descent often describe abdominal pain as *grippée*, whereas Southeast Asians may use temperature to describe abdominal pain, and Latinos refer to many sensations as *nervios*. Pain severity can be assessed by standard severity scales, most of which are cross-culturally reproducible. Examples include the visual analogue pain scale or 1-to-10 rating scales. These scales may also be useful when applied to stepwise pharmacologic management, so it is worth documenting severity during the workup.

Determining the Likelihood of Serious Underlying Biologic Pathology. If the pain complaint is relatively new, has little in the way of associated psychiatric symptoms, and is accompanied by constitutional or other objective findings, then the likelihood of a primary biologic process increases markedly and the workup can focus on the appropriate physical examination and laboratory testing.

PRINCIPLES OF MANAGEMENT

Basic Approach

A systematic, multidimensional approach is crucial to achieving a successful outcome for the patient with chronic pain (Fig. 236.1). Simultaneously addressing the biologic and psychosocial components helps assure the patient that the validity of the complaint is not in question; as a result, compliance with psychiatric referral is improved, should it be needed.

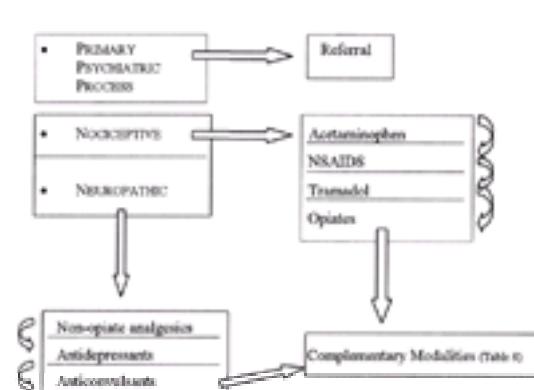

FIG. 236.1. Sample approach to the management of patients with chronic pain.

Early Psychiatric Referral. Early referral is essential if the initial evaluation reveals evidence for a primary psychiatric or psychosocial problem (e.g., anxiety, depression, personality disorder, domestic violence). Effective management may require formal psychiatric input, including psychopharmacologic intervention, psychotherapy, and social interventions. Patients with what appears to be a psychiatric process secondary to the chronic pain are better managed by first addressing the biologic cause of the pain rather than by psychiatric referral, as attention to biologic factors is likely to improve both processes at once.

Symptomatic Relief. Early symptom relief is a priority, especially in persons with a suspected primary biologic mechanism. The intervention is usually pharmacologic, tailored to whether the pain is primarily nociceptive or neuropathic in origin. A stepwise approach is recommended, beginning with pain medications that have the greatest benefit-to-risk ratio (Table 236.5). The goal is to provide enough analgesia that daily activity can be sustained. Complementary approaches to pain control may be needed when medications do not suffice.

Table 236.5. Overview of Medications Used to Treat Pain

Nociceptive (Non-neuropathic) Pain

Treatment begins with non-narcotic analgesics and advances to narcotic agents as required. Non-narcotic analgesics are first-line treatment for nociceptive pain, with acetaminophen being the first step for most situations.

Acetaminophen. Its mechanism of action remains unknown, but it continues to be the drug of choice of the American College of Rheumatology and the National Kidney Foundation for the treatment of chronic pain. Acetaminophen in adosage of 1,000 mg four times per day is as effective as NSAIDs. This dose of acetaminophen is safe in those patients who drink fewer than five alcoholic beverages per day and have no known hepatic dysfunction. The most common side effect is mild gastrointestinal upset.

Nonsteroidal Antiinflammatory Drugs. Diseases with a prominent inflammatory component are candidates for trials of NSAIDs if acetaminophen proves insufficient. NSAIDs are the next-most-frequently used class of agents for nociceptive pain, after non-narcotic analgesics. However, they are associated with many side effects, particularly gastrointestinal and renal. *Aspirin* is the prototypic NSAID. It also is directly analgesic, being the milligram-for-milligram equivalent of acetaminophen. However, it is not indicated for the treatment of chronic pain because of its association with gastrointestinal toxicity, which makes the long-term use of most NSAIDs problematic. The concomitant use of omeprazole or misoprostol can partly prevent gastrointestinal toxicity, but with the disadvantage of incurring the expense and side effects of another drug (see Chapter 68).

NSAIDs may differ from one another in their selectivity as inhibitors of cyclooxygenase-1 (Cox-1) or cyclooxygenase-2 (Cox-2). *Cox-2 inhibitors* (e.g., celecoxib) seem to generate fewer gastrointestinal complications in endoscopic studies, but they have been studied *in vivo* only for osteoarthritis and rheumatoid arthritis for short periods of time. The literature regarding their use as long-term therapy should be followed.

Tramadol is a centrally acting analgesic with dual effects; it acts primarily as a monoamine (norepinephrine and serotonin) reuptake inhibitor that blocks pain transmission in the spinal cord, and secondarily as a blocker of central nervous system μ-opioid receptors. It has a very low potential for abuse. Comparative studies in patients with osteoarthritis have shown it to be equivalent in analgesic effect to naproxen and propoxyphene. It is rapidly absorbed, with a peak effect at 2 hours and a half-life of 6 hours. It is metabolized by the liver, then excreted by the kidneys. Its benefits include a relative lack of potential for abuse and respiratory depression in comparison with opiates, but it still causes many side effects, including nausea, drowsiness, sweating, and constipation. Slowly titrating the dose upward can minimize the transient nausea. Tramadol might be considered as an opiate alternative once acetaminophen has failed in disease states without much objective inflammation, such as osteoarthritis.

Opiates. Opiates are the most potent class of analgesics for the treatment of chronic pain and have no ceiling for therapeutic effect. Many clinicians agonize over whether to prescribe opiates for chronic nonmalignant pain, a difficulty usually stemming from misconceptions (Table 236.1). Perhaps the most pervasive misconception is the idea that patients placed on long-term therapy with opiates will become "addicts."

Addiction, Substance Abuse, and Tolerance. Distinctions must be made between the terms *substance abuse, addiction*, and *tolerance*, as many clinicians erroneously equate them. *Substance abuse* implies the problem of dangerous use of an agent, with or without physical dependence. The term *addiction* implies compulsive substance use and an inability to control intake despite negative consequences. *Tolerance* to narcotics has nothing to do with abuse or addiction; it merely implies a physical dependence in which a higher dose of an agent is required over time to achieve the same effect. It is a well-recognized phenomenon associated with long-term narcotic use.

Contracting. Patients receiving narcotics and enrolled in a chronic pain program with contracting for routine follow-up have a less than 3% chance of becoming addicts or abusers if they have not been addicts or abusers previously. A current or prior history of abuse or addiction is a relative but not an absolute contraindication to long-term narcotic use, as many such patients will adhere to the terms of a contract (Fig. 236.2). Such a contract allows for the tapering and discontinuation of a narcotic whenever a clinician fears that an abusive or addictive situation is developing. Narcotics can be prescribed for any patient who meets a few criteria for their use (Table 236.6). Opioid analgesics all affect the μ-receptor but differ in their potency, onset, duration of action, and route of administration.

FIG. 236.2. Patient–Provider Contract for the Long-term Use of Opioids

Table 236.6. Criteria for Giving a Patient Opiates for Chronic Nonmalignant Pain

Dose-related Side Effects and Dosing. Dose-related side effects tend to be similar for all opiates and include nausea, vomiting, constipation, urinary retention, pruritus, sedation, and respiratory depression (when given in toxic doses). One starts with low doses and titrates upward. The most common mistake is underdosing. In the absence of sedation, one should not hesitate to increase the dose to achieve adequate pain relief. Tolerance can develop to all opioids, and to all the various side effects. The only effect of opiates to which a patient will not develop tolerance is constipation, which should be treated preemptively.

Choice of Agent. Several narcotic preparations are best avoided. *Butorphanol* is probably best avoided because it is a combination agonist–antagonist. *Meperidine* likewise should be avoided because its metabolites tend to cause seizures. Narcotics in a *fixed combination* with cyclooxygenase inhibitors or acetaminophen should probably be avoided because of their high street value and the danger of acetaminophen overdose with dose escalations. Patients, however, should be encouraged to take maximal doses of acetaminophen simultaneously for synergy. *Oxycodone* is the long-acting agent of choice. It is formulated for oral administration and does not have the same profile of side effects as long-acting morphine—namely, there are fewer active metabolites to cause histamine release. Likewise, it is less frequently associated in the mind of the public with substance abuse and terminal illness.

Neuropathic Pain

Neuropathic pain is characteristically more resistant to pharmacologic interventions than is nociceptive pain. The agents generally used for neuropathic pain are *antidepressants* (tricyclics, selective serotonin reuptake inhibitors), *anticonvulsants* (gabapentin, baclofen, carbamazepine, phenytoin), and topical *capsaicin* cream.

Table 236.7. General Principles to Follow When Prescribing Narcotics for Chronic Pain

Antidepressants. Tricyclic antidepressants are useful in neuropathic pain. They have a rapid onset of action and vary in their side effect profiles (Table 236.5). Tricyclics have been shown in controlled trials to provide analgesia in post-herpetic neuralgia, diabetic neuropathy, tension and migraine headache, rheumatoid arthritis, and low back pain. They have also been shown to potentiate opioid analgesics and so should be used selectively in situations of nociceptive pain. The doses required for analgesia can be much lower than those needed to treat affective disorders.

Selective serotonin reuptake inhibitors have not yet been fully evaluated for most chronic pain syndromes. For tension headaches, paroxetine and fluoxetine have both been shown to provide some benefit, although citalopram did not. For migraine headaches and fibromyalgia, fluoxetine has shown conflicting results so far. For diabetic neuropathy, paroxetine and citalopram both showed some benefit but were not as effective as imipramine.

Anticonvulsants. *Phenytoin* and *carbamazepine* were first shown to relieve the pain associated with trigeminal neuralgia. Antiarrhythmic drugs followed. All these agents help by blocking the conduction of nociceptive fibers. *Gabapentin* is now the agent of choice for most neuropathic pain, especially the lancinating types (e.g., sciatica). It is well tolerated, and dosing is limited primarily by the sedating effects. Beginning with a low dose and titrating upward very gradually minimizes the side effect of sedation, so that gabapentin is useful even in the elderly. *Baclofen* is a gabapentin agonist and is also generally well tolerated. It is used primarily for painful spasticity (e.g., in patients with spinal cord injury).

Capsaicin Cream impedes afferent pain impulses by depleting substance P from sensory nerve fibers. It has been used in post-herpetic neuralgia with some success, but it must be applied several times a day to provide sufficient pain relief. It often causes severe burning at the site of application for the first 1 to 2 weeks of treatment, so that concurrent use of topical lidocaine is necessary during this period.

Complementary Modalities

When therapeutic goals are not achieved with initial pharmacologic and psychosocial interventions, complementary modalities can be explored. Some of the many complementary modalities available have more data behind them than do others (Table 236.8).

	HEADACHE	MUSCULOSKELETAL	LOW BACK	ABDOMINAL/PELVIC	PERIPHERAL NERVE

Radiculopathy.

Table 236.8. Overview of Complementary Approaches to the Treatment of Chronic Pain

Acupuncture. Acupuncture has been increasing in popularity among patients and physicians during the past three decades. In the United States in 1997, more than 1 million patients made more than 5 million visits for treatment with acupuncture. Acupuncture has been applied to many conditions besides pain (e.g., asthma, depression), but its principal contribution is in pain management, the focus of a National Institutes of Health (NIH) Consensus Statement in 1998.

Mode of Action. Acupuncture stems from traditional Chinese medicine, which holds that body energy (*Qi*, pronounced "chee") becomes imbalanced to cause disease. This imbalance is thought to be corrected by manipulating specific channels, called meridians, through which energy flows. This view predates the Western approach of mind–body dualism, which emphasizes disease as a purely biologic phenomenon. The biologic mechanism of acupuncture is becoming better understood. The procedure appears to trigger serotonin release in the central nervous system and to increase circulating levels of endogenous opioids. Naloxone can block the therapeutic effects of acupuncture.

Clinical Studies of acupuncture for pain have been flawed; most are case series or case reports. The few randomized, controlled trials that have been performed lack a rigorous study design and adequate sample size and have problems with control groups. Comparisons between studies are difficult because there are many different ways of applying the needles with regard to location and manipulation. Manipulation is performed either manually, electrically, or through moxibustion (the combustion of a specific herb at the needle insertion site). Furthermore, control arms are controversial. Even "sham" acupuncture, in which needles are placed randomly, has been shown to provide pain relief, possibly through "nonspecific" opioid-releasing effects.

Evidence of Efficacy. The NIH Consensus Statement focused on studies that included either a sham or placebo control, but case series were used when necessary. The strongest evidence for the efficacy of acupuncture has been demonstrated in cases of postoperative pain and nausea related to chemotherapy or pregnancy. Ample evidence supports the efficacy of acupuncture as a therapeutic option for *myofascial pain* and nonspecific *low back pain*. Approximately half of patients in laboratory and clinical studies showed a favorable response after 10 treatments during approximately 1 month. For low back pain specifically, responses lasting to 3 months were seen; the rate of overall pain reduction was nearly 60%, with a corresponding reduction in consumption of analgesic tablets. Less convincing evidence but some positive studies support the efficacy of acupuncture in treating *headaches, osteoarthritis, fibromyalgia, carpal tunnel syndrome*, and *menstrual cramps*.

Adverse Effects. The incidence of adverse effects appears to be exceedingly low, certainly lower than that of commonly accepted pharmacologic interventions for chronic pain. Of the nearly 200 reported complications of acupuncture, *viral hepatitis* was by far the most common, stemming from a time when needles were not sterilized properly. All needles currently used by regulated providers conform to Food and Drug Administration safety regulations. Other, very rare complications include *pneumothorax* (with emphysema), *ecchymoses* (with anticoagulation), preterm induction of labor (in pregnant women), and *conduction problems* (with pacemakers when electrical stimulation of needles is used).

In the absence of clinical data, clinical judgment is critical in deciding whether or not an individual patient might benefit from a trial of acupuncture. The use of acupuncture for chronic pain will likely become more commonplace for various indications as more trials emerge and shed light on the risk–benefit ratio for specific situations. Better data will drive improved standardization of training, licensing, supervision, and reimbursement, and will help define the role of acupuncture in our treatment algorithms.

If referral of a patient to a physician acupuncturist is being considered, information can be obtained through the American Academy of Medical Acupuncture (http://www.medicalacupuncture.org). If referral to a nonphysician acupuncturist is being considered, information is available through the American Association of Oriental Medicine (http://www.aaom.org).

Behavioral Approaches. Busy primary care providers classically overlook behavioral interventions. A recent review of complementary medicine in the United States showed that millionsof Americans are already using these techniques, although most of their providers remain unaware of this and are unfamiliar with the techniques. The importance of behavioral approaches in the treatment of chronic pain, however, cannot be overemphasized, as the risk is negligible and benefit has been demonstrated.

In 1996, the NIH released a Consensus Statement with regard to these modalities. Like the statement for acupuncture, this statement was prepared by a non-Federal, 12-member expert panel that reviewed the literature, presented findings to an open conference, and ultimately drafted the statement based on scientific data rather than anecdote whenever possible. The panel members focused on the four modalities most widely used and reported in the literature: *relaxation, hypnosis, cognitive behavioral therapy*, and *biofeedback* (see also Chapter 226).

Relaxation. The goal is to train patients to control their focus of conscious attention. The two components are (a) *repetitive focus* on a word, phrase, sound, prayer,

body sensation, or muscular activity; and (b) adoption of a *passive attitude* toward intruding thoughts. Techniques include paced respiration, progressive muscle relaxation, concentration meditation, and movement meditation. Once patients master these techniques, they are capable of decreasing their perception of pain and level of arousal. There is strong evidence for the effectiveness of this approach in reducing chronic pain in a variety of medical conditions.

Hypnosis likewise aims at selective focus of attention but adds a suggestive phase to reinforce new responses to pain. The *presuggestion phase* involves pure focus of attention (e.g., with relaxation techniques). The *suggestive phase* is geared toward specific goals, such as analgesia. The *postsuggestive phase* involves imprinting for continued use of a new behavior. Suggestive evidence of the efficacy of hypnosis has been noted in tension headache, temporomandibular joint pain, and irritable bowel syndrome.

Cognitive Behavioral Therapy attempts to transform patterns of negative attitudes into more productive thoughts, emotions, and actions. This is accomplished by training the patient to recognize current responses and to develop healthier responses and the skills to execute them. Evidence of the efficacy of this approach has been moderate in low back pain, rheumatoid arthritis, and osteoarthritis; evidence suggests it is mildly useful for tension headache.

Biofeedback involves education about physiologic responses to painful stimuli and ways to exercise voluntary control over these responses. Measurements are made with electromyography, electroencephalography, thermometers, and cardiac monitors. These tools allow patients to see their physiologic response to pain, and they are coached on techniques to affect these responses. This leaves patients feeling more in control of their pain. Moderate evidence for the efficacy of biofeedback has been noted in the treatment of tension and migraine headaches.

Data on these behavioral techniques are currently insufficient to suggest that one technique be used over another for a particular condition. However, several metaanalyses have shown consistently positive effects of multimodal behavioral approaches, particularly for headache, joint pain, and back pain. For now, physicians should probably be capable of describing *relaxation techniques* to patients for use in the management of almost any type of chronic pain. Further instruction in any of the techniques might be pursued through psychiatric/psychologic referral.

Spinal Manipulation. Although the purported applications of spinal manipulation by chiropractors are many, low back pain accounts for the vast majority of visits. Although some evidence of its efficacy has been found in the treatment of acute back pain (see Chapter 147), little has been noted in the treatment of chronic low back pain (i.e., lasting longer than 3 months). Available data are incomparable and conflicting. The consensus expert view after review of all published studies is that it is inappropriate to refer patients with chronic low back pain for manipulation. Nonetheless, more than half of patients being treated with manipulation by chiropractors have chronic low back pain. Therefore, patients with chronic low back pain should be dissuaded from undergoing spinal manipulation, as there is currently no evidence in favor of it, the current recommendations addressing chronic low back pain weigh against it, and chiropractors do not appear to adhere to the criteria for appropriateness reliably.

Invasive Techniques

Invasive techniques gained popularity in the 1980s, after extensive studies showed them to be effective in patients with terminal cancer. Their use has now been extended to patients with nonmalignant chronic pain, based on the results of limited studies. These interventions are never used as monotherapy. They are added only when more conservative measures have been ineffective and clinical evidence is available to suggest a possible benefit, especially in the setting of neuropathic pain. Invasive techniques are performed primarily by anesthesiologists in pain centers.

Local Anesthetics (e.g., *bupivacaine*) may be given in the form of epidural or plexus blocks, and *sympathetic blocks* are performed with opioids. These techniques are primarily used for acute pain states and are rarely employed for acute flares of chronic states (e.g., reflex sympathetic dystrophy). *Neurolytic blocks* with alcohol have primarily been used in patients with chronic abdominal cancer pain, but one retrospective study has shown efficacy for lumbar sympathetic neurolytics in reducing the pain of patients with inoperable claudication.

Spinal Injection of Opioids (usually given as an intrathecal or epidural injection of morphine) has been quite effective in end-stage cancer patients who are unable to take oral opiates to therapeutic levels because of side effects. These techniques have been extended to some patients with chronic nonmalignant pain; significant reduction of pain was achieved in 60 of 80 patients under study conditions. The patients included had chronic low back pain that surgery failed to alleviate, post-herpetic neuralgia, and peripheral nerve injury. More than half of the patients had mild systemic side effects (constipation, urinary hesitancy, nausea, impotence, nightmares, pruritus); approximately 20% also had system malfunctions, and a few experienced epidural hematoma, infection (epidural abscess, pocket infection, meningitis), or cerebrospinal fluid leaks. The current recommendations are that this should remain a method of last resort, to be used only after a patient has passed a psychological evaluation and responded favorably to a 3-day test of intrathecal opiates before the pump is implanted.

Pain Centers

"Pain centers" have become increasingly numerous during the past decade as pain management has become recognized as a discipline in its own right. Centers range from small clinics offering only one type of intervention to large entities offering a multidisciplinary approach. They are directed by physicians (anesthesiologists, internists, psychiatrists) and may be staffed by nurses, physical therapists, psychologists, and social workers.

Pain specialists may be located through the American Pain Society (847-375-4715) or the American Academy of Pain Medicine (www.painmed.org). Information on more than 200 multidisciplinary centers may be found via the Rehabilitation Accreditation Commission (520-325-1044).

PATIENT EDUCATION AND INDICATIONS FOR REFERRAL

The principal objective is to redirect the patient's expectations toward a gradual improvement in *functioning* and *quality of life* rather than complete elimination of pain. Patients benefit from understanding that chronic pain has biologic and psychosocial components, which necessitates a multidisciplinary approach to therapy.

General internists should be able to manage their patients' pain medications and treat secondary psychiatric comorbidities. They must also determine the need for and coordinate appropriate referrals as follows:

- To *psychiatry* if a primary psychiatric disorder is suspected
- To a *substance abuse counseling* program if an abuse problem is uncovered
- To a *social service program* if overwhelming social factors are a factor (e.g., domestic violence)
- To *practitioners of complementary methods* (e.g., psychologists, behavioral therapists) when pharmacologic and psychotherapeutic measures prove insufficient
- To a *pain center*, primarily if complex neuropathic pain is a factor or if invasive techniques are required, which most pain centers manage (although some pain centers offer a broader range of techniques than do others)

THERAPEUTIC RECOMMMENDATIONS

- View chronic pain as a chronic disease. Treatment goals must *focus on improvement in functioning and quality of life* rather than on elimination of pain.
- Consider the *psychosocial aspects* of pain as much as the biologic aspects. Identify and address primary psychiatric processes, and treat secondary processes along with the pain.
- Classify the biologic aspect of a patient's pain as primarily *nociceptive* or *neuropathic*, localize it, and consider reversible causes of pain for the various sites.
- *Nociceptive pain* is treated stepwise with non-opiate analgesics, NSAIDs, and opiates. Tylenol remains the non-opiate of choice over tramadol. Long-term NSAID use predisposes to gastrointestinal toxicity, which is partly avoidable with concomitant omeprazole or misoprostol. The role of Cox-2 inhibitors is not yet firmly established. Do not hesitate to prescribe opiates on a long-term basis to patients who meet the criteria. Long-acting opiates should be used, with short-acting agents administered for breakthrough pain. Attempt to treat pain more proactively than reactively. Have the patient sign an opiate contract.
- *Neuropathic pain* is treated variably with antidepressants, anticonvulsants, and topical capsaicin cream where appropriate.
- A *multidisciplinary approach* to treatment is critical. This involves directed referrals to psychiatry (primary psychiatric disorders, behavioral training), pain centers (invasive techniques), and elsewhere for acupuncture when appropriate.

PART 16 ALLIED FIELDS

CHAPTER 237 ALTERNATIVE/COMPLEMENTARY THERAPIES: EVIDENCE-BASED GUIDES

ERNIE-PAUL BARRETTE

INTRODUCTION

Editors' note: Given the widespread use of alternative/complementary therapies by patients and the concerns of their physicians regarding efficacy and safety, we thought a new section of this book would be helpful to readers and their patients. The goal is to provide detailed review of the available evidence pertaining to specific alternative/complementary therapies. These therapies and the sum of supporting evidence have already been considered in many of the chapters, but this section provides an opportunity for background, more in-depth analysis of the data, and recommendations. References are formally cited in the text. The section will be updated regularly in the web-based version of Primary Care Medicine. *We begin by examining some of the commonly used herbal therapies and the evidence supporting their use. We hope you find the effort useful.*

HERBAL THERAPIES: AN EVIDENCE-BASED GUIDE TO USE

Before 1993, herbal therapy was relatively obscure, although used by a significant number of patients. In 1993, the Food and Drug Administration proposed removing herbal therapies from the over-the-counter market, but a vigorous letter-writing campaign resulted instead in passage of the Dietary Supplement Health and Education Act (DSHEA) in 1994. DSHEA allowed the marketing of all supplements (defined broadly to include herbs, vitamins, minerals, and amino acids) to be expanded with information regarding uses based on "structure and function." Manufacturers would not be allowed to claim to treat, cure, or prevent a disease, but they could still attempt to provide the public with a considerable amount of information on when to use herbal therapies. The use of alternative medicines has dramatically increased since the passage of DSHEA. Unfortunately, DSHEA does not require any evidence of efficacy or safety, nor does it define any standards of quality. If concerns regarding the safety of a supplement are raised, it is up to the Food and Drug Administration to gather and present evidence to justify removing it from the market or limiting its availability.

STATE OF THE ART REGARDING ASSESSMENT OF HERBAL THERAPIES

The number of published clinical trials of herbal medicines is surprisingly great to those who have not reviewed this field. Unfortunately, many of the trials are in journals that are inaccessible or not published in English. Most of these studies lack adequate controls, have poorly defined inclusion criteria, and measure outcomes that are not validated or clinically relevant. Many are simply too short in duration or enroll too few subjects to provide substantive clinical information. This chapter reviews the best evidence supporting the use of several herbal therapies for specific indications. In addition, pertinent safety concerns are discussed.

In Germany, a commission was formed to evaluate the many herbs claimed to have therapeutic value. Members of the "Commission E" included physicians, pharmacists, naturopathic physicians, and scientists. They have published several hundred monographs in the German Federal Register. These monographs have been recently translated and are readily available (1). This resource represents extensive experience in Europe regarding botanical medicines. Monographs with both positive and negative recommendations are included, along with discussions of adverse effects, drug interactions, use during pregnancy and nursing, specific indications, and dosages. Unfortunately, no references are provided. Also, only a positive or negative recommendation is provided. Thus, neither the strength of the evidence nor the vigor of the recommendation can be determined.

COMMONLY USED HERBAL PREPARATIONS

Echinacea for Upper Respiratory Infections

Extracts of three species, *E. purpurea*, *E. angustifolia*, and *E. pallida*, are promoted for both treatment and prevention of upper respiratory infections. *Echinacea* was used by native Americans as an antiseptic and analgesic and was listed in the National Formulary until the introduction of synthetic antibiotics. The Commission E has recommended *Echinacea* for "supportive therapy for colds and chronic infections of the respiratory tract." Unfortunately, no standardized extract exists. Multiple species, various methods of extraction, and different parts of the plant are used, and additional herbal and homeopathic agents are frequently included with preparations of *Echinacea*. All these factors make a comparison of the literature and products very difficult.

Evidence for Efficacy. A systematic review in the Cochrane collaboration collected all the trials of *Echinacea* in the prevention or treatment of upper respiratory viral infections (2). A total of 40 controlled trials were found; 24 studies were excluded, primarily because of a lack of randomization or because a condition other than the common cold was studied. Eight trials involving 985 subjects addressed the treatment of an acute upper respiratory infection. Three different combination products and two different mono-preparations were given for 6 to 10 days in a double-blinded fashion in seven trials (single-blinded in one). Six of eight trials showed a significant benefit with *Echinacea*. However, because of the various outcome measurements and methods of presenting data, no pooling of outcomes was possible.

Five trials including 1,272 subjects tested *Echinacea* in the prevention of upper respiratory infections. Two combination products and three mono-preparations (*E. purpurea* herb, *E. purpurea* roots, and *E. angustifolia* root) were studied for 8 to 12 weeks. The incidence of upper respiratory infections was lower in the treated arms in all five studies (rate ratios of 0.51, 0.67, 0.84, 0.86, and 0.88). However, only in the first two listed trials was the result statistically significant. In the first trial listed, a large number of subjects dropped out after enrollment and were not included in the analysis. In all the studies, questions regarding the case definition of an upper respiratory infection were raised. The duration of illness was significantly shorter in one trial but unchanged in two other trials.

A recent study not included in the Cochrane review compared the fluid extract of *E. purpurea* with a placebo in 109 subjects who had a history of more than three colds in the prior year (3). The lower incidence of respiratory infections with *Echinacea* was not statistically significant (rate ratio, 0.88; 95% CI, 0.60 to 1.22). This result is similar to those of the three more rigorous trials mentioned above. It is unknown whether a much larger trial would confirm this modest benefit with a confidence interval not including one.

Safety. No serious adverse effects have been reported. Because of its immune-stimulating properties, *Echinacea* is not recommended for persons with autoimmune disorders.

Summary. Although many trials have been published, they involve many different species of *Echinacea* along with many other herbs and additives. The Cochrane reviewers felt that the quality of reporting was "insufficient" in two thirds of the trials. Because of the distinctive taste of *Echinacea*, blinding in the placebo arm in all trials is difficult. The best trials have consistently showed a nonsignificant decrease of 12% to 16% in the relative risk for respiratory infections. The substance appears well tolerated, but it should not be used by persons with autoimmune disease.

Ginkgo Biloba for Dementia and Memory Enhancement in Normal Older Persons

Ginkgo biloba extracts have been used in Chinese herbal medicine for many centuries. The use of ginkgo biloba has increased in Europe during the last 30 years, and it is now the most prescribed herbal medicine in Germany. It is among the top three herbal products consumed in the United States. Most products are based on a standardized extract, EGb 761, which contains 22% to 27% flavone glycosides (quercetin, kaempferol, isorhamnetin) and 5% to 7% terpene lactones (2.8% to 3.4% ginkgolides A, B, and C; 2.6% to 3.2% bilobalide). EGb 761 is now off patent and may be used by any manufacturer. Unfortunately, another standardized extract

process is also used, LI 1370. Although LI 1370 specifies 25% flavone glycosides and 6% terpenoids, the different process may result in different concentrations of individual ingredients. It is not known whether the active ingredient is a specific component or a combination. The Commission E approved ginkgo biloba for use in dementia syndromes, specifically primary degenerative dementia, vascular dementia, and mixed forms. They also approved it for intermittent claudication, vertigo, and tinnitus.

Evidence for Efficacy. The body of research regarding potential mechanisms of action is extensive; these include scavenging free radicals, blocking platelet-activating factor, increasing blood flow, stabilizing membranes, and decreasing capillary fragility, among others.

For use in Alzheimer's Disease. A rigorous metaanalysis has been conducted of published studies regarding the use of ginkgo biloba in Alzheimer's disease ([4]). Inclusion criteria for studies in the analysis were as follows: (a) well-defined patient groups with Alzheimer's disease (e.g., Diagnostic and Statistical Manual III-R definition); (b) explicit exclusion of patients with depression or other neurologic diseases or taking medications with central nervous system activity; (c) use of standardized extracts of ginkgo biloba; (d) randomized, placebo-controlled, double-blinded design; (e) objective outcome measurement of cognitive function. Remarkably, 57 articles addressing ginkgo biloba and dementia were found, mostly in German and French. However, the majority of trials used "cerebral insufficiency" as the entry criterion, which is an old imprecise term encompassing a diverse range of symptoms. After the exclusion of studies based on a criterion of "cerebral insufficiency," inadequately blinded, or lacking a placebo control, only four studies remained. An earlier metaanalysis, in which the criteria for inclusion were much less restrictive, included only 8 of the 40 trials it found ([5]), thus confirming the poor quality of most of the clinical studies of ginkgo biloba.

From the four good trials, a total of 424 subjects were included in the metaanalysis. Studies ranged in length from 12 to 26 weeks. All four trials used EGb 761. The analysis reported a significant effect size of 0.40 (p <.0001). The result was described as a modest benefit on cognitive function in Alzheimer's disease and was felt to be similar to the benefit of donepezil. The four studies reported inconsistent results in regard to noncognitive outcomes. In the only U.S. trial, which was included in the metaanalysis, improvement was noted on a functional scale, the Geriatric Evaluation by Relative's Rating Instrument (GERRI), but not on the Clinical Global Impression of Change (CGIC) Scale ([6]).

For use in normal older persons. Extrapolating from the modest benefit in Alzheimer's patients, promoters of ginkgo biloba claim the substance improves memory and cognitive performance in normal older persons. Many seniors take Ginko-containing products in hopes of improving their mental functioning, making Ginko one of the top-selling herbal remedies in the United States. However, there is little evidence that ginkgo can improve memory or concentration in nondemented older persons. In the best randomized trial to date, 230 patients, age 60 or older, without significant neurologic or psychiatric illness, were randomized to either Ginkoba 40 mg three times daily or matching placebo. Participants completed 14 standardized tests of memory, language, and concentration before the trial and at the end of 6 weeks. All 14 tests of cognitive function, as well as ratings by participants' family members, showed no difference between the groups ([6a]).	**Updated: 9/03/02**

Safety. Because one of the known effects of gingko biloba is antagonism of platelet-activating factor, it is not surprising that several cases of severe *bleeding* during its use have been reported. These include spontaneous bilateral subdural hematomas ([7]), subarachnoid hemorrhage ([8]), subdural hematoma ([9]), intracerebral hemorrhage ([10]), and spontaneous hyphema ([11]). The first three patients were not taking any other medications that would have increased their risk for bleeding. The first two cases note a prolonged bleeding time. Because of these antiplatelet effects and the reports of associated bleeding complications, ginkgo should be avoided in patients with bleeding disorders and in those taking warfarin or drugs with antiplatelet effects.

Summary. Several adequate trials report a modest improvement in cognitive function in patients with Alzheimer's disease, similar to that seen with donepezil (see [Chapter 173]), but results of well-designed randomized study find no support for the claim that ginkgo improves memory or cognitive performance in healthy older persons. Standardized extracts contain 24% flavone glycosides and 6% terpene lactones. The usual dose is 40 mg three times daily. Adverse effects are mild and rare, but because of case reports of severe bleeding with Ginkgo biloba, the substance should be avoided in persons at risk for bleeding, such as those with a known bleeding disorder or with need for warfarin or an antiplatelet agent. Case reports of severe bleeding with Ginkgo biloba suggest that it be administered with caution in all patients at risk for bleeding, especially those taking warfarin or aspirin.

Kava-Kava for Anxiety

The botanical name of kava-kava is *Piper methysticum* ("intoxicating pepper"). Kava-kava has been used in Pacific Island communities for centuries for its relaxing and tranquilizing effects ([12]) and was even consumed as part of a ceremony. The root was chewed (causing numbness of the tongue) and spit into a communal bowl. Later, it was ground. This macerate was mixed with water and coconut milk. After straining, the mixture was shared. Kava continues to be used in Micronesia, Melanesia, and Polynesia. Captain James Cook first reported its use to the West. The Commission E has given kava a positive rating for the "condition of nervous anxiety, stress, and restlessness."

Evidence for Efficacy. Kava was first studied by German scientists in the 19th century. Little research was performed in the early 20th century, but pharmacologic studies were restarted in Germany in the 1950s. Animal studies showed a sedative, analgesic, anticonvulsant, and muscle-relaxant effect. The active agents are felt to be the kavalactones (pyrones), primarily kawain, dihydrokawain, methysticin, and dihydromethysticin. Although the results of early studies with D,L-kawain suggested a benefit in treating anxiety, all recent trials have used an extract standardized to the content of kavalactones.

Five double-blinded, placebo-controlled trials of kava have been published. Three trials are of questionable relevance. One trial lasted for 2 days. Two trials examined kava in 40 menopausal women with poorly defined psychovegetative symptoms. The fourth trial compared kava (100 mg three times daily, the equivalent of 210 mg of kavalactones daily) with placebo for 4 weeks in 58 subjects exhibiting anxiety, tension, and agitation syndromes of nonpsychotic origin ([13]). Significant improvement on the Hamilton Anxiety Scale (HAMA) was noted at 1 week with kava (p = .0039). This benefit (compared to placebo) continued during the 4-week trial. The minimal improvement with placebo at both 1 and 4 weeks casts doubt on the validity of the blinding in this study. Another trial compared kava (210 mg of kavalactones daily) with oxazepam (15 mg daily) and bromazepam (9 mg daily) for 42 days in 172 subjects in double-blinded fashion. Similar improvements in HAMA scores were seen in all three arms ([14]).

The best evidence supporting the use of kava is a double-blinded, randomized, controlled multicenter trial comparing kava (100 mg three times daily, 70% kavalactones) with placebo ([15]). A standardized extract, WS 1490, was used that provided 210 mg of kavalactones daily. One hundred one subjects with generalized anxiety disorder, adjustment disorder with anxiety, agoraphobia, and specific phobia as defined in the Diagnostic and Statistical Manual III-R were enrolled. The trial lasted 24 weeks and used HAMA scores with an intent-to-treat analysis as the primary outcome. The HAMA score improved in both arms, but the improvement was significantly greater with kava (30.7 to 17.1) than with placebo (31.4 to 20.3; p = .02) by 8 weeks. Both arms showed continued improvement for 16 weeks and then plateaued. The benefit of kava persisted from 8 weeks to the end of the trial. At 24 weeks, the HAMA scores remained improved with kava (kava, 30.7 to 9.7; placebo 31.4 to 15.2; p <.001). Adverse effects were minimal. Three subjects in the kava arm dropped out, two because of improvement of symptoms. Seven subjects in the placebo arm dropped out. Overall, the trial addressed concerns regarding poorly defined entry criteria and inadequate duration of follow-up.

Safety. In large, observational trials, adverse effects have been rare. In several small trials, worsening of cognitive function and coordination were seen, as expected with benzodiazepines but not with kava. Heavy, prolonged use of kava results in a well-described skin disorder characterized by dry, yellow scaling ([16]). Of greatest concern are the case reports of dystonic reactions in five patients, including torticollis, generalized choreoathetosis, and oral–lingual dyskinesia ([17],[18]). A single controversial report describes a semicomatose state in a man who combined kava with alprazolam ([19]). Necrotizing hepatitis was seen in one woman ([20]).

Summary. One adequate trial suggests a benefit of kava in generalized anxiety. Sedating medications and alcohol may augment the effect of kava. Kava is contraindicated in pregnancy and nursing. Most trials used 100 mg of kava (70% kavalactones) three times daily, which provided 210 mg of kavalactones daily. However, the Commission E recommends 60 to 120 mg kavalactones daily.

Milk Thistle for Hepatitis and Cirrhosis

Milk thistle (*Silybum marianum*) has a 2,000-year history of use by herbalists. Although it was reported to relieve many conditions, it is currently promoted for liver and biliary disorders. The active ingredients are called *silymarin*, which is composed of three isomeric compounds (silibinin, silidianin, and silichristin). Twenty to forty percent of silymarin is concentrated in the bile. Milk thistle has been used in Europe for 30 years. The Commission E recommended its use as supportive treatment for chronic inflammatory liver conditions.

Evidence for Efficacy. For acute *viral hepatitis*, the evidence is inconsistent. In one double-blinded, randomized, controlled trial of 57 subjects with acute hepatitis A

or B, treatment with 140 mg of silymarin three times daily for 3 to 4 weeks normalized bilirubin and AST (aspartate aminotransferase) levels more frequently did placebo (*p* <.05) (21). However, silymarin had no effect on the clearance of hepatitis B surface antigen, a more important clinical marker. In another study, of 52 nonalcoholic male patients with acute hepatitis B randomly assigned to silymarin (70 mg three times daily) or no treatment, no effect was seen on ALT (alanine aminotransferase), AST, and bilirubin levels or on clearance of hepatitis B surface antigen (22). Although milk thistle is recommended by naturopathic physicians for acute hepatitis, little evidence is available to support its use.

Many studies on milk thistle for alcoholic hepatitis have been published. Unfortunately, most trials either include very few subjects, are short in duration, or are poorly controlled. In a large randomized, double-blinded, controlled trial for alcoholic hepatitis, 106 men received either milk thistle (420 mg/d) or placebo (23). Subjects were enrolled after admission to a military hospital because of elevations in AST or ALT for longer than 1 month. Although alcoholism was the presumed underlying condition, 20% of the men denied alcohol use. After 4 weeks, treatment with silymarin resulted in a significant decrease in ALT and AST levels; no improvement was noted with placebo (*p* <.001). Liver biopsy also showed an improvement with treatment in comparison with placebo (*p* = .022). However, although 90 biopsies were performed at the start of the trial, only 29 were performed at 4 weeks, which may have influenced the result.

Another randomized, double-blinded, controlled trial of 116 subjects, all with histologically confirmed alcoholic hepatitis, compared silymarin (420 mg/d) with placebo (24). After 3 months, significant improvements, noted in both arms in laboratory test results and histologic findings, suggested no benefit from the addition of milk thistle to adequate supportive care. Not surprisingly, in the information prepared by supplement manufacturers, these negative trial findings are rarely discussed.

Two trials addressed the use of milk thistle in cirrhosis. In an oft-quoted European multicenter study, 170 subjects were entered in a randomized, double-blinded, controlled trial comparing silymarin (140 mg three times daily) with placebo for 2 to 6 years (mean follow-up of 41 months) (25). Cirrhosis was confirmed by biopsy in 70%. Fifty-four percent of the subjects in each arm were alcoholic. Exclusion criteria included end-stage liver disease, primary biliary cirrhosis, malignancies, and immunosuppressive therapy. Noncompliant subjects were withdrawn from the analysis. At 2 years, overall survival was trending better with silymarin (n = 105, 77% vs. 67%; *p* =.07), and at 4 years, cumulative survival was improved with silymarin (n = 29, 58% vs. 38%; *p* =.036). Survival benefit was limited to alcoholics (*p* =.01) and to those rated Child's class A on entry (*p* =.03). Unfortunately, more of the alcoholic patients receiving placebo continued to drink (73% vs. 55%), and more of the subjects rated Child's class C on entry were assigned to placebo (11% vs. 3%). Both of these factors, which favor milk thistle, may have influenced the analysis. This study represents the best evidence supporting milk thistle.

A similar European randomized, double-blinded, controlled multicenter trial compared milk thistle (150 mg three times daily) with placebo (26). Two hundred subjects with biopsy-confirmed alcoholic cirrhosis were enrolled. Exclusion criteria included other causes of cirrhosis and use of colchicine, penicillamine, or corticosteroids. One hundred twenty-five subjects completed the 2-year follow-up. Survival was not improved at 2 years or at 5 years (odds ratio, 1.01; 95% CI, 0.46 to 2.22). Retrospective testing of stored sera, which was available for 75 of the 200 entrants, showed 29 to be positive for hepatitis C. Among these 29, treatment may have been protective (silymarin deaths, 0 in 13; placebo deaths, 4 in 16; *p* =.059).

Safety. No serious adverse effects have been reported.

Summary. Results are inconclusive. The best evidence suggests a benefit in cirrhosis. Any benefit is probably limited to alcoholic persons and those rated Child's class A. The usual dosage studied is 140 mg, standardized to contain 70% to 80% silymarin, three times daily.

St. John's Wort for Depression

The history of St. John's wort (*Hypericum perforatum*) as an herbal agent dates back 2,000 years. The use of *Hypericum* for mood problems continued into the 19th century but was forgotten early in this century. During the last 30 years, Europe has produced an extensive literature. In 1984, the Commission E gave St. John's wort a positive rating for use in psychovegetative disturbances, depressive moods, and anxiety or nervous unrest. St. John's wort is the most commonly prescribed antidepressant in Germany. After press and television coverage of a metaanalysis with positive findings in 1996 (27), the sales of St. John's wort in the United States rose from $20 million to $200 million during the next 2 years. It remains one of the top three herbal remedies consumed in the United States.

Evidence for Efficacy. Evidence suggests that the active ingredients are naphthodianthrones, primarily hypericin, pseudohypericin, and protohypericin. Although monoamine oxidase inhibitor activity is seen *in vitro*, this does not appear to be clinically important. The exact mechanism of St. John's wort is not known, but the best evidence supports effects on g-aminobutyric acid (GABA), serotonin, and norepinephrine receptors. The hypericin content of St. John's wort varies from 0.06% to 0.75%, depending on the time of harvest and quality of the plants. A standardized extract, LI 160, based on the content of hypericin has been used in most studies. However, recent studies have suggested that another component of St. John's wort, hyperforin, may be the active agent. The content of hyperforin ranges from 2% in the flowers to 4.5% in the fruit. If hyperforin is the active agent and the most commonly used standardized extract, LI 160, is titrated to hypericin, then the clinical efficacy may vary from batch to batch. Despite the extensive knowledge of the components of St. John's wort and their actions in model systems, lingering uncertainties regarding which component or components are the most clinically relevant will continue to confound efforts to standardize preparations and treatment trials.

An update of the original 1996 metaanalysis included 27 trials (28). All randomized trials comparing St. John's wort (alone or in combination with other herbal agents) with placebo or antidepressant medications in depressed patients were included. A total of 2,291 patients were included in the 27 studies. Seven trials used Diagnostic and Statistical Manual III and two trials used International Classification of Diseases 10 definitions of depression as entry criteria. In the remaining 18 studies, entry criteria were usually "neurotic depression" or "mild to moderate depressive disorders." LI 160 was tested in 11 trials. Two trials used St. John's wort with valerian. Of the 27 trials, 24 were double-blinded. However, six studies used a liquid preparation of *Hypericum*, which has a distinctive taste and is difficult to conceal. In 26 of the trials, the duration was 4 to 8 weeks. One study lasted 12 weeks but was less rigorous in design. Standard definitions of treatment responder were used. Many trials used more than one measurement, such as a Hamilton Depression Scale (HAMD) score of less than 10 or less than 50% of the baseline score (17 trials), or "much improved" on the Clinical Global Impression (CGI) Scale (12 trials).

The results from 14 of the 17 trials comparing St. John's wort with placebo were combined. The St. John's wort response rate was 56%, whereas the response rate for placebo was 25%. The pooled rate ratio confirmed a significant effect (2.47; 95% CI, 1.69 to 3.61). Ten trials compared St. John's wort with another active agent, either a tricyclic antidepressant (eight trials) or a benzodiazepine (two trials). A pooling of responder rates from these trials suggested equivalence (mono-preparations rate ratio, 1.01; 95% CI, 0.87 to 1.16; combination preparations rate ratio, 1.52; 95% CI, 0.78 to 2.94). When the analysis was limited to the four trials comparing mono-preparations of St. John's wort versus tricyclic antidepressants in patients with major depression defined according to the Diagnostic and Statistical Manual III, the results were similar. Dropouts and adverse effects were seen less with St. John's wort than with standard antidepressants (dropouts, 8.9% vs. 13.6%; any adverse effect, 26.3% vs. 44.7%).

Only one trial looked at severely depressed patients (29). In this 6-week trial comparing twice the usual dose of St. John's wort (600 mg three times daily) with imipramine (50 mg three times daily), the decrease in HAMD scores was significantly greater with imipramine (26.1 to 13.4) than with St. John's wort (25.3 to 14.4; *p* <.02).

The major criticisms of these trials relate to duration and subjects. All the trials ran from 4 to 8 weeks with the one exception of a poorly designed trial lasting 12 weeks. Consequently, no data were provided regarding the duration of response. The subjects entered had a baseline HAMD score in the range of 16 to 20, which is less than the usual values of 20 to 24 required in most trials of antidepressants. The bulk of evidence addresses milder depression, and few subjects were more severely depressed. The comparative trials with tricyclic antidepressants used doses lower than those considered standard, and there were few studies involving the SSRI antidepressants. Finally, the variety of commercially produced products makes comparisons difficult.

In an effort to overcome these important methodologic limitations, a major multi-center trial (30) was conducted of 340 adults with moderate to severe major depression (HAM-D score >20) randomized to H. perforatum, placebo, or sertraline and followed for 4 months. There was no significant mean difference in Hamilton Depression Scale (HAM-D) score or rates of full response at 8 weeks among the three groups, but there was a significant improvement at 8 weeks in Clinical Global Impression (CGI) score for patients treated with sertraline. Although overall clinical response rates were not significantly different, there were more partial responders among the sertraline patients and more full responders among the placebo patients.

Updated: 4/29/02

Safety. Adverse effects, which are generally mild, include gastrointestinal upset, dizziness, sedation, restlessness, and fatigue. St. John's wort may cause photosensitivity in fair-skinned patients, which can be severe at high doses. It should not be used during pregnancy and should not be combined with other

antidepressants.

Summary. At best, available evidence suggests St. John's wort may provide some short-term benefit to persons with mild depressive symptoms, but it should not be prescribed in lieu of standard antidepressant therapy (see Chapter 227) to persons with moderate or severe major depression.

Saw Palmetto for Benign Prostatic Hyperplasia

Saw palmetto (*Serenoa repens*) is a plant native to the southeastern United States. Native American Indians used the extract of the dried fruit from this dwarf palm for urinary difficulties, among other conditions. It was adopted by Naturopathic and Eclectic physicians in the 19th century and is primarily promoted as a treatment for benign prostatic hyperplasia (BPH). In Germany, 90% of prescriptions for BPH are herbal medicines. Almost all these prescriptions are for saw palmetto alone or with additional herbal agents. Saw palmetto has received a positive rating for BPH by the Commission E.

Evidence for Efficacy. One systematic review of the literature from 1966 to 1997 was able to identify 18 trials, 16 of which were double-blinded (31). Randomized, controlled trials of symptomatic BPH were included that lasted for at least 30 days. Ten trials compared saw palmetto with placebo, two trials compared saw palmetto with finasteride, and the remaining trials used products containing saw palmetto and other phytotherapeutic agents. The mean study duration was 9 weeks (range, 4 to 48 weeks), and 9.6% of subjects were lost to follow-up (range, 4% to 15%).

The results of this metaanalysis showed a modest benefit. An improvement in self-rated symptoms (risk ratio, 1.72; 95% CI, 1.21 to 2.44, favoring saw palmetto) was seen in six studies. Nocturia improved in 10 trials (weighted mean difference, -0.76 episodes per night; 95% CI, -1.22 to -0.32). Saw palmetto increased peak urine flow rates in eight trials (WMD, 1.93 mL/s; 95% CI, 0.72 to 3.14 mL/s). Because the natural history of BPH involves slow changes and some improvement in a subset of patients, the results of trials of less than 6 months' duration represent weak evidence. Also, in the large trials of pharmaceutical agents for BPH, a robust placebo response was seen. In some of the trials with saw palmetto, little change occurred with placebo. The authors of this review felt that blinding was adequate in only 9 of the 18 studies.

Two specific trials address these concerns and provide stronger evidence. A European double-blinded, randomized, controlled multicenter trial compared b-sitosterol with placebo in men who had symptomatic BPH (32). Although it is not certain, the bulk of the evidence suggests that b-sitosterol is the active ingredient in saw palmetto extract. This trial enrolled 200 men, who received 20 mg of b-sitosterol three times daily or placebo for 6 months. The self-reported symptoms measured with the International Prostate Symptom Score, a validated instrument, improved (IPSS mean change, -7.4 with treatment versus -2.1 with placebo; *p* <.01). Peak urine flow rates were significantly better with b-sitosterol (baseline 9.9 mL/s to 15.2 ml/s at 6 months) than with placebo (baseline 10.2 mL/s to 11.4 mL/s at 6 months; *p* <.01).

Another European multicenter trial compared saw palmetto with finasteride without a placebo arm (33). In this 6-month, double-blinded study, 1,098 men with symptomatic BPH were randomized either to 160 mg of saw palmetto twice daily and finasteride placebo or to 5 mg of finasteride and saw palmetto placebo. Quality-of-life scores and the IPSS improved equally with the two treatments (-37% for saw palmetto vs. -39% for finasteride), while the peak urine flow rates improved slightly more with finasteride (from 10.6 ± 2.8 to 13.3 ± 6.7 mL/s with saw palmetto, and from 10.8 ± 3.1 to 14.0 ± 7.4 mL/s with finasteride; *p* = .035). Values for prostate-specific antigen (PSA) decreased 41% with finasteride but did not change with saw palmetto. Sexual dysfunction was seen somewhat more often with finasteride.

Safety. Minimal adverse effects have been reported.

Summary. Evidence suggests a modest improvement in BPH symptoms, similar to that achieved with finasteride (little information available comparing saw palmetto with a-adrenergic blockers). The substance does not affect the PSA level. The usual dosage studied is 160 mg twice a day.

Valerian for Insomnia

Valerian (*Valeriana officinalis*) has been used for more than 100 years as a hypnotic and mild tranquilizer. With the advent of barbiturates, it was dropped from the U.S. National Formulary and U.S. Pharmacopoeia. It remains popular as a hypnotic in Europe, where it is usually combined with hops, passionflower, lemon balm, and lavender. The Commission E has given valerian a positive rating for "nervous sleep disturbances." The active components are not known, and its mechanism is poorly understood. Proposed mechanisms involve binding to GABA or serotonin receptors, and inhibiting the breakdown of GABA. The Food and Drug Administration lists valerian as GRAS (generally recognized as safe), and it is approved as a flavoring agent.

Evidence for Efficacy. Several studies suggest a benefit with valerian. However, most of the trials have serious deficiencies, such as small enrollment (*n* = 8, 10, 14, 12), enrollment of normal subjects rather than subjects with sleep disturbances, and use of nonvalidated symptom scores. In the largest trial, 166 volunteers received nine samples (three each of placebo, 400 mg of aqueous valerian extract, and a commercial herbal sedative containing 120 mg of valerian with 60 mg of hops) to be taken on nonconsecutive nights (34). One hundred twenty-eight subjects completed the trial (23% dropout rate). Sleep latency and sleep quality were better on the nights when valerian was taken than on placebo nights. Subset analysis showed the benefit to be limited to self-described poor sleepers. Interestingly, the commercial preparation of valerian with hops was no different from placebo.

In the most rigorous study, 121 patients with insomnia (International Classification of Diseases 10) were enrolled in a double-blinded, randomized, controlled multicenter trial comparing valerian (600 mg, 70% alcohol extract standardized to 0.4% to 0.6% valeric acid) with placebo for 28 days (35). Those who had major depression and were taking medications were excluded. A marked placebo response suggested adequate blinding. At 14 days, a significant improvement was noted on the CGI Scale with treatment. By 28 days, valerian significantly improved sleep in comparison with placebo on three standardized scales. This study suggests that the benefit of valerian occurs slowly, during 4 weeks. If this is true, the results of earlier studies lasting 1 to 7 days are difficult to accept.

Valerian is usually standardized to the content of valerenic acid (usually 0.8%). However in the absence of a standardized extract procedure and because of uncertainty regarding the active component, different commercial products may vary in efficacy. Relative proportions of the components vary with season of harvest and species harvested. This adds further uncertainty to any comparison.

Safety. Adverse effects are rare and generally mild. A possible withdrawal reaction was reported after general anesthesia for biopsy in a patient who had taken valerian (530 mg to 2 g) five times a day for "many years" (36). Tachycardia, high-output cardiac failure, delirium, and oliguria were noted and responded to benzodiazepine. In general, valerian should not be used with other sedating medications.

Summary. Despite its historical use as a sedative, only one adequate trial supports the use of valerian. Without a standardized extract, products likely will have very different ratios of ingredients. Valerian should not be combined with other sedatives.

Ephedra for Weight Loss and Performance Enhancement. Extract of the Asian ephedra species *Ephedra sinica* is a traditional Chinese herbal preparation (Ma huang) rich in sympathomimetics and used for millennia for difficulty breathing. It was also once popular in the United States before the advent of safer symphathomimetic decongestants and bronchodilators. Its unregulated sale as an ingredient in many weight-loss preparations and so-called "energy-boosters" or performance enhancers (popular with body builders and athletes) has soared in the United States with its classification as an herbal preparation and nutritional supplement exempt from U.S. Food and Drug Administration (FDA) approval for safety and efficacy (37).

Updated: 5/16/03

Efficacy. Ephedra's actions relate to its strong symphathomimetic content, particularly from ephedrine, but also from pseudoephedrine, phenylpropanolamine, and norpseudoephedrine (38). These constituents provide a potent combination of alpha- and beta-adrenergic stimulation. Cardiovascular effects include vasoconstriction and increases in blood pressure, heart rate, myocardial contractility, and automaticity; appetite is suppressed, and metabolic rate is increased; bronchodilation results from beta-adrenergic stimulation.

Updated: 5/16/03

Safety. Being a potent symphathomimetic extract, ephedra has long been recognized as a potentially hazardous substance, but its recent classification as an herbal preparation/dietary supplement and consequent exemption from FDA approval has enabled makers of nonprescription weight-loss and performance enhancing products to incorporate it into many of their offerings. Tragically, but not surprisingly, a flurry of reports have appeared of serious and often fatal cardiac and neurologic events associated with its use, the most notable being the death of a major league baseball pitcher who was using an ephedra-containing weight-loss product during spring training. In the most comprehensive analysis to date of reports of ephedra-related adverse events, investigators found ephedra use to be nearly 100- to 700-times more dangerous than that of other popular herbal preparations, such as kava and ginko (39). | **Updated: 5/16/03**

Summary. Nonprescription ephedra-containing preparations can have potent, sometimes fatal symphathomimetic effects and are dangerous to use, even by healthy young persons. Until the loop-hole in the law governing their sale is closed, physicians should warn potential users of ephedra-containing products (e.g., persons interested in weight loss, body building, or physical performance enhancement) of the serious risks associated with their use and urge that they not be purchased. | **Updated: 5/16/03**

CHAPTER 238 CARING FOR THE ADOLESCENT PATIENT

LAWRENCE J. RONAN

Most experts on adolescence recommend annual visits to a physician between the ages of 11 and 21 years, with a complete physical examination at least once in early adolescence (ages 11 to 14), middle adolescence (ages 15 to 17), and late adolescence (ages 18 to 21). The emphasis during the annual visits is on prevention and health promotion. Adolescent deaths are caused predominantly by accidents, homicides, and suicides. The major causes of adolescent morbidity include pregnancy, sexually transmitted diseases, substance abuse, smoking, physical violence, and depression. Because the leading causes of mortality and morbidity are unintended injury or are largely preventable, the focus of care for adolescents is on primary as well as secondary prevention. During visits, both biomedical and psychosocial issues are addressed. Adolescent care emphasizes the cultivation of healthful life-long habits to prevent heart disease and cancer. The primary care physician whose practice involves primarily adults needs to know the basics of adolescent preventive care because many adolescents present to the offices of these physicians for care.

CONSENT

In general, parents are responsible for giving consent for their children's care until the child reaches the age of 18. Adolescents, however, have a greater right than do younger children to participate in their own health care decisions. Practitioners should review their state laws regarding the specific services that minors may obtain without the consent of their parents. These services usually are related to pregnancy, birth control, abortion, the evaluation and treatment of sexually transmitted diseases (including HIV infection), substance abuse, and sexual assault. Some states also include outpatient mental health services. "Emancipated" minors have the legal right to give consent for their own care. These adolescents are married, have children, serve in the military, live apart from their parents, or are homeless. "Mature minors," adolescents who understand the risks and benefits of treatment and its alternatives, also have the legal right to give consent.

HISTORY TAKING

Adolescence is a dynamic time in the life cycle associated with rapid and dramatic changes in physical, social, and emotional development. The adolescent health history focuses on five contextual and developmental domains:

1. Social and emotional development
2. Physical development and health habits
3. Sexual development
4. Family functioning
5. School performance

The unique aspects of the five developmental domains should be explored in each stage of adolescence—early, middle, and late.

Early Adolescence: Ages 11 to 14 Years. Early adolescence heralds the start of dramatic physical changes. Girls undergo rapid spurts of growth, the development of pubic hair and breasts, and changes in the distribution of body fat. Generally, puberty begins in girls 2 to 3 years earlier than in boys. Boys acquire deeper voices, larger testicles, and pubic hair, and acne frequently develops. Early adolescents are preoccupied with looks and anxious about physical changes. Also, early teen-agers move from elementary to middle school, where academic demands are higher, autonomy is greater, and socialization is increased. Their thinking, although increasingly abstract, is for the most part still concrete and oriented to the present. Early teens are focused on self, family, and peers. Sexual exploration and recreational drug experimentation begin. The profound biologic, emotional, and psychological changes experienced by early teens stress the family as they challenge limits and rules and also explore new and sometimes risky behaviors.

Middle Adolescence: Ages 15 to 17 Years. By middle adolescence, the physical development of girls is complete, and most boys are well on their way to the completion of puberty. Although the thinking of middle adolescents remains concrete, many of them are progressing from concrete to abstract, formal, operational thinking. Friends become hugely important. Middle teens, also, become aware of the larger world and social issues. The growing need for autonomy places teens in conflict with family rules. Middle teens are very aware of academic pressures and anxious about school and sports performance. They can obtain work permits and driver licenses.

Late Adolescence: Ages 18 to 21 Years. Pubertal development is complete. The late adolescent focuses on vocational and personal development. Older teens are legally responsible for themselves, often living separately from parents and struggling with decisions about further schooling, jobs, or the military. High-risk behaviors peek at this stage, including promiscuity, substance abuse, and eating disorders.

PHYSICAL EXAMINATION

Measure and plot on a standard growth chart the adolescent's height and weight. Determine the patient's body mass index. Document a blood pressure measurement at every annual visit. Evaluate for scoliosis. Look for evidence of physical abuse. Examine the adolescent's teeth for cavities, malocclusion, gingivitis, and congenital dental anomalies. Determine the Tanner stage or Sexual Maturity Rating (SMR). For girls, provide instruction in breast self-examination and inspect the external genitalia. Perform a pelvic examination with Papanicolaou smear annually for all girls who are sexually active or 18 years of age or older. Examine boys for gynecomastia and hernias. Check the testicles for abnormal masses or congenital anomalies (at high risk for testicular cancer are boys with a history of undescended testes or a single testicle). Check the skin for acne.

LABORATORY EVALUATION

Perform a random *cholesterol* determination on teen-agers who have a positive family history for early cardiovascular disease or hyperlipidemia. Adolescents who are unsure of their family history should also be screened. Girls with heavy menses, weight loss, or eating disorders, or who are extremely athletic, should have a *screening hematocrit* or hemoglobin determination.

Only adolescents at increased risk for exposure to tuberculosis require *tuberculin (purified protein derivative, or PPD) skin testing*. These risks include exposure to tuberculosis, homelessness, a history of incarceration, immigrant status, HIV infection or living with an HIV-infected person, and illicit drug use. It is reasonable to test once between 11 and 16 years if the teen-ager has no risk factors (see also Chapter 38).

Sexually active teen-agers should be screened for sexually transmitted diseases. The frequency of screening remains controversial. Usually, girls are screened during each annual pelvic examination, which should include a cervical culture for gonorrhea, immunologic testing of cervical fluid for *Chlamydia* infection, *serologic testing* for *syphilis*, and visual inspection of the genitalia and *Papanicolaou smear* for human papillomavirus. For boys, screening consists of *urine DNA* or *leukocyte esterase* analysis for *gonorrhea* and *Chlamydia* infection, serologic testing for syphilis, and visual inspection of the genitalia for human papillomavirus (see also Chapter 107, Chapter 117, Chapter 124, Chapter 125, and Chapter 136).

The clinician should offer *HIV testing* to adolescents at risk for HIV infection. Risks include the use of IV drugs, previous infection with a sexually transmitted disease, blood transfusion before 1985, exchange of sex for money or drugs, homelessness, a history of more than one sexual partner in the last 6 months, male

homosexuality, or a sexual partner with any of the above risk factors for HIV infection (see also Chapter 7).

IMMUNIZATIONS

(See also Chapter 6.) Ensure that the teen-ager's immunizations are up to date at every clinical encounter. Tetanus–diphtheria (Td) toxoid; measles, mumps, and rubella (MMR) vaccine; and hepatitis B vaccine should be given to the adolescent if the previously recommended doses were missed, not documented, or given before the recommended minimum age. (The recommended minimum age for completion of the second dose of MMR vaccination is 4 to 6 years; for varicella vaccination, 12 to 18 months; and for the third dose of hepatitis vaccine, 6 to 18 months.) By 11 to 12 years of age, the teen-ager is also due for the tetanus booster. For incompletely immunized or unimmunized adolescents (especially newly arrived immigrants), follow the recommendation of the Red Book regarding immunization schedules for adolescents. Schools routinely request documentation; make certain that your medical records regarding the patient's immunization status are kept up to date.

ANTICIPATORY GUIDANCE

Prevention of Injury and Violence. The use of seat belts reduces motor vehicle fatalities by 45% and the rate of serious injury by 50%. In 80% of road fatalities, the victim was not wearing a seat belt. Counsel adolescents to use seat belts. In addition, promote the use of other safety devices, such as bicycle and motorcycle helmets, protective gear for rollerblading and skate boarding, and appropriate athletic protective devices. Ask the teen-ager about access to weapons.

Mental Health. Screen for depression and suicidal ideation. Risk factors include poor school performance, family dysfunction, substance abuse, physical or sexual abuse, and previous suicide attempts or plans. Note that the vegetative signs associated with adult depression (e.g., sleep disturbance, lack of interest, decreased concentration) can be part of normal adolescent development. Moreover, adolescent depression may masquerade as vague somatic complaints, such as abdominal pain or headaches. Suicidal ideation requires immediate referral. Recurrent or serious depression necessitates consultation with a mental health professional.

Nutrition and Exercise. Counsel adolescents about a healthful diet, safe weight management, and regular exercise. Screen for faddist diets, anorexia and bulimia, and the use of anabolic steroids by athletes. Recommend dietary supplements of calcium (1000 mg/d) and folic acid (400 mg/d) for female adolescents.

Sexuality. Discuss sex frankly. Explore early adolescents' understanding of sexuality. Discuss responsible sexual behavior, including abstinence. Educate about birth control, stressing the use of latex condoms to prevent sexually transmitted diseases and especially HIV infection. Provide birth control and instructions on appropriate use.

Abuse of Tobacco, Alcohol, and Other Substances. Ask about smoking and the use of alcohol and other drugs during the past 6 months. Educate about the harmful effects of substance abuse. Explore family history, frequency and amount of use, and circumstances surrounding use. Encourage participation in community peer self-help groups. Determine social and psychological factors that prompt the use of drugs and refer to social services and mental health professionals as necessary.

Abuse. Screen all adolescents annually for a history of physical, emotional, and sexual abuse. Pursue aggressively any suspicion, asking about circumstances and people involved. Be aware of local reporting requirements to state offices. Involve mental health and social services professionals early in all suspected cases of abuse.

SPECIAL ISSUES AND NEED FOR REFERRAL

Scoliosis is a lateral curvature of the spine associated with rotation of the involved vertebrae. Although scoliosis may be associated with chronic illness (neurofibromatosis, cerebral palsy, Marfan syndrome, poliomyelitis), the most common type is idiopathic, generally beginning at age 8 or 10 years of age and progressing during growth through adolescence. It is classically asymptomatic. The clinician screens for scoliosis with the forward bend test and visual inspection for rib cage deformation and waistline asymmetry. A positive result on screening warrants imaging with a "scoliosis plain film series," radiography of the entire spine in both the posterior and lateral planes with the patient in the standing position. All curves greater than 15 degrees require referral to an orthopedic specialist if spinal growth is not completed. (Adolescent girls usually complete spinal growth 18 to 24 months after menarche).

Eating Disorders. Between 5% and 10% of adolescent girls and young women have an eating disorder. The diagnosis of anorexia nervosa and bulimia nervosa is made through the history. Ask about recurrent dieting, body image, interruption of menses, and physical activity. Assess for the use of laxatives and diuretics, self-induced vomiting, and starvation. Except in extreme cases, the physical examination findings and results of the laboratory evaluation are normal. In anorexia, weight loss greater than 10% of previous weight or a body mass index below the fifth percentile suggests the diagnosis. Use laboratory findings to exclude other causes of weight loss: hyperthyroidism, inflammatory bowel disease, diabetes, and connective tissue disorders (see Chapter 73, Chapter 102, Chapter 103, and Chapter 146). Once the diagnosis has been made, treatment should be carried out by a multidisciplinary team that includes the primary clinician, a psychologist or psychiatrist, and a nutritionist skilled in the management of eating disorder problems (see Chapter 234).

School Failure. Not uncommonly, an adolescent or more likely the adolescent's parent turns to the clinician for an explanation of poor academic performance. The differential diagnosis for academic failure in adolescence is broad, and more than one factor is often involved. A thorough history, physical examination, and appropriate laboratory studies should serve to identify psychological (depression, anxiety) and physical (hearing, visual) problems, chronic disease (asthma, neurologic dysfunction), learning disorders (attention deficit disorders), drug abuse, limited intellectual ability (developmental delay), and social difficulties (dysfunctional family life, poor peer relations, abuse). Coordinate with the patient's parent, teacher, and school counselor. Many school districts are mandated to provide neuropsychological testing to aid in both diagnosis and treatment strategies.

Hypertension. Definitions of normal, borderline, and high blood pressure in adolescence involve calculating the teen's percentile for age and height. Normal is below the 90th percentile, high normal is between the 90th and 95th percentiles, and high (hypertension) is a systolic or diastolic pressure equal to or greater than the 95th percentile on three separate occasions.

Consider secondary causes of hypertension, including renal disease, oral contraception, and use of drugs such as cocaine or steroids. The medical history focuses on growth and development, past illnesses (especially during the neonatal period and infancy), and family history. On physical examination, look for evidence of end-organ damage. Tailor the laboratory evaluation as the clinical situation warrants and obtain a urinalysis, values for blood urea nitrogen, creatinine, and electrolytes, and a complete blood cell count. Consider renal ultrasonography and echocardiography (see Chapter 14 and Chapter 19).

Obesity. Teen-agers with a body mass index between the 85th and 90th percentiles are at high risk for obesity and require diet assessment and counseling. Adolescents with a body mass index above the 95th percentile for age and sex require aggressive nutrition counseling and benefit from a multidisciplinary approach that involves diet, exercise, and counseling (see Chapter 10 and Chapter 233).

Gynecomastia. In the majority of male adolescents (60% to 70%), transient enlargement of one or both breasts develops during transition through Tanner stages II to III as a normal part of puberty. Type I idiopathic gynecomastia is usually unilateral (20% of cases are bilateral) and tender; it consists of a firm mass below the areola. Type II is the more generalized breast enlargement found in obese adolescents. Although more than 95% of cases of gynecomastia are idiopathic and resolve spontaneously, be alert to pathologic causes: drugs; Klinefelter's syndrome; adrenal, pituitary, and testicular tumors; hypothyroidism; and hepatic dysfunction. Most cases of gynecomastia resolve within a period of months to 2 years, and require only reassurance and support to the anxious teen. On occasion, because of severe psychological damage or a persistent problem, either pharmacologic treatment (e.g., danazol) or surgical intervention is required (see also Chapter 99).

APPENDIX: APPROACHES TO ENCOURAGING COMPLIANCE

That 20% to 80% of patients do not comply with medical advice is repeatedly quoted. Such dismal statistics are derived from a rigid definition of compliance as patients' all-or-nothing adherence to medical instructions, whereas their treatment behaviors are far more variable, ranging from the optimal cooperative response to the ritualistic, retreatist, and innovative. Regardless of the extent and variability of noncompliance, patients' adherence to medication regimens is critical in effectively treating medical disorders, as is their adoption and learning of appropriate behaviors (in regard to eating, exercise, smoking, drinking, relaxation, and use of drugs) for preventing disease.

Explanations and theories of noncompliance have focused on patients' beliefs, attitudes, expectations, and feelings that interfere with their "taking pills" or "changing habits." Even if such factors do interfere, they can be changed. Compliance can be improved by practitioner–patient communication that responds to patient views and develops the patient's ability to adhere to medical advice through education and the learning of new behaviors. By making the clinical decision a "shared" process, the physician empowers the patient and fosters a partnership that enhances compliance and outcomes.

Specific Strategies

The education/communication strategies and techniques helpful in facilitating compliance begin with the doctor–patient relationship. A positive, mutually respectful doctor–patient relationship is important in making the patient "ready" to receive patient education and negotiate the goals and means of treatment. Moreover, the physician's explanations and educational efforts, in turn, contribute to that relationship. Specific strategies utilize persuasion, medical advice, feedback, and monitoring.

Persuasion, or Why Do It?

1. Describe immediate and long-term treatment benefits along with health risk and cost. If possible, present treatment options and acknowledge if the rationale differs from the views of the patient.
2. Assist patients in clarifying their priorities (requests) for treatment (e.g., patients presenting with pain may request an explanation rather than medication).
3. Use your expertise, experience, and relationship to assert your own expectations for patient compliance in supporting the patient's treatment choice and capacity to carry it out.

Medical Advice, or What to Do

1. Adapt instructions to the patient's language and knowledge level, responding to any misconceptions about treatment.
2. Make directions explicit, simple, personalized, and operational (how many, what kind, and when to take "pills"; organizing "pill taking" into the routine of the patient's everyday life).
3. Use multiple modes of communication, both verbal and written instructions, and, when available, audiovisual materials that reinforce general knowledge about treatment. Enlist other members of the clinical team in providing instructions; also recruit family in the educational process.

Feedback, or What Advice Was Negotiated?

1. Have the patient repeat the medical advice given and the rationale for it.
2. Have the patient rehearse how medical advice will be carried out.
3. Jointly plan return visits, phone calls, and additional reviews with clinical team (nurse practitioners, physician assistants) if needed.

Monitoring Compliance, or What Have You Done?

1. At return visits, review the patient's compliance by direct questioning, again eliciting the rationale along with the problems the patient has experienced in treatment.
2. Use information to reexplain or redesign treatment, reinforce behaviors, and reward the patient.
3. Encourage and organize the patient's self-monitoring of treatment (e.g., blood pressure measurements).

In general, these educational strategies and tactics are not systematically carried out in practitioner–patient communication. Their use in patient education should result in greater compliance with medical advice.

APPENDIX TO SECTION 12 MINOR SURGICAL OFFICE PROCEDURES FOR SKIN PROBLEMS

ERIC KORTZ AND CHARLES J. McCABE

SIMPLE LACERATIONS

Treatment of simple lacerations is one of the most commonly performed outpatient surgical procedures. All lacerations should be evaluated for the extent of injury to surrounding structures, particularly nerves. This is most important with lacerations of the face, hand, and wrist. All injuries involving peripheral nerves should be referred to an emergency room; digital nerve branches can be approximated with excellent long-term benefit. All tendon injuries should receive the attention of a hand surgeon. Those lacerations complicated by bone fracture should be treated by an orthopedic surgeon.

In uncomplicated wounds, foreign material around and within the wound, including devitalized tissue, should be removed before definitive closure.

The following materials are used to treat simple lacerations:

Anesthetic

1. 1% or 2% Xylocaine without epinephrine
2. 5-mL to 10-mL syringes
3. 19-G to 22-G needles

Prep Solution

1. Gentle soap solution
2. Betadine
3. Normal saline

Drapes

1. Three or four sterile towels

Instruments

1. Adson forceps
2. Needle holders (plastic)
3. Hemostat
4. Irrigation bulb syringe
5. Suture scissors
6. Suture material (Table 1)
7. Six to 12 sterile gauze pads
8. Sterile gloves

LOCATION	SUTURES	REMOVAL TIME (DAYS)
Scalp	3-0	10–14
Face	5-0, 6-0	4–5
Neck	3-0, 4-0	7–10
Trunk	3-0	7–10
Extremities	3-0	8–12
Hands	4-0, 5-0	8–12
Feet	3-0, 4-0	8–12
Oral mucosa	4-0, 3-0 chromic	10–14

Table 1. Suture Selection and Removal Time

Dressings

1. Xeroform gauze
2. Two gauze pads
3. Tape or gauze roll

Anesthesia

- Infiltration of the wound edges may either precede or follow wound cleansing and debridement, depending on the patient and the wound.
- The path of the injecting needle should proceed from clean, prepped areas to deeper tissue levels. The interior of the wound should be avoided.
- Aspiration should precede infiltration of anesthetic to prevent intravascular injection.

Skin-Wound Preparation and Draping

- Copiously irrigate the wound with normal saline under moderate pressure. Foreign material and devitalized tissue are removed at this time. The wound and surrounding skin are then cleansed with a gentle detergent, followed by an antiseptic such as Betadine applied to the surrounding skin only.
- Sterile drapes are placed to isolate the wound completely, including enough surrounding skin to allow easy approach and a working surface area.

Wound Closure

- Hemostasis is obtained. Bleeding is usually minimal. Closure proceeds in one or several layers, depending on the depth of the wound. Subcutaneous sutures are of the absorbable type, either 3-0 or 4-0 Dexon or chromic. These sutures should be simple, interrupted stitches secured with minimal tension.
- Skin closure for minor lacerations is best achieved with a nonabsorbable monofilament suture. Nylon is an inexpensive and excellent choice. The suture

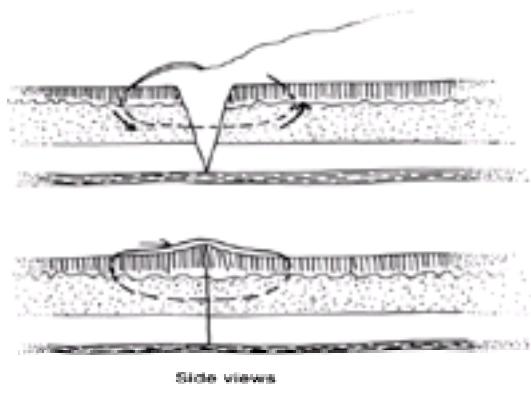
placement technique shouldbe simple, interrupted, and allow for approximation of the wound edges without inducing ischemia. As <u>Figure 1</u> demonstrates, the curved needle should enter the skin at an acute angle. Advancement is then with the natural curve of the needle and includes all layers (epidermis, dermis, and the upper subcutaneous tissue). Care should be taken to maintain equal depth and width from the wound edge with each stitch. A good technique is to sequentially divide the wound in half. The first stitch is placed directly in the center of the laceration. Subsequent sutures subdivide the remaining open surface. Corresponding parts of an irregular wound should be approximated first.


Figure 1. Simple interrupted stitch for skin closure. Notice the path of the needle; the needle enters and leaves the skin at acute angles, which allows eversion of the skin edges. (Grossman JA: Minor Injuries and Disorders: Surgical and Medical Care, p 52. Philadelphia, JB Lippincott, 1984)

Dressings

- After the entire wound is closed, normal saline or a gauze sponge can be used to clean the skin of dried blood and Betadine.
- The wound is then covered with a strip of xeroform gauze and dry sterile dressing.
- Lacerations involving the fingers, palm, or wrist should be immobilized.
- Follow-up for patients with minor lacerations can be done at the time of suture removal. A convenient schedule for suture removal is presented in <u>Table 1</u>.

SIMPLE PARONYCHIA

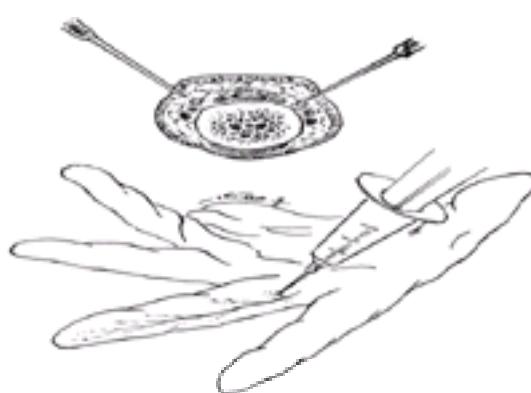
Paronychia (<u>Fig. 2</u>) represents a soft tissue infection and abscess formation along the nail border. The patient usually complains of pain, and the area surrounding the nail base is red, swollen, and tender.


Figure 2. Metacarpal block. Entrance of needle is at the palmar base of finger, medial and lateral. The needle path is then toward the palmar metacarpal head. (Van Way CW III, Buerk CA (eds): Surgical Skills in Patient Care, p 55. St Louis, CV Mosby, 1978)

The following materials are used to treat simple paronychia:

Anesthetic

1. 1% or 2% Xylocaine without epinephrine
2. 5-mL to 10-mL syringes
3. 19-G to 22-G needles

Prep Solution

1. Gentle soap solution
2. Betadine or alcohol
3. Normal saline

Drapes

1. Three or four sterile towels

Instruments

1. Adson forceps
2. Pediatric suture scissors
3. Kelly clamps
4. No. 15 scalpel blade
5. Scalpel handle
6. Sterile gloves

Dressings

1. Nu-Gauze ¼ inch
2. Two gauze pads
3. Tape or gauze roll

Anesthesia

Complete anesthesia of the finger may be accomplished with a metacarpal block (<u>Fig. 3</u>). After alcohol preparation of the skin over the metacarpophalangeal joint is

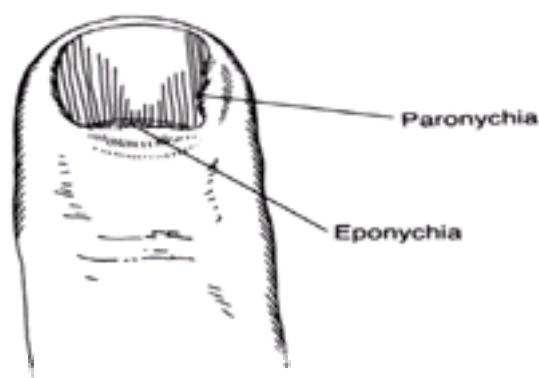
performed, points for needle entrance are selected on the medial and lateral palmar surface of the metacarpal head. Care is taken to aspirate each time before the infiltration of 1 to 2 mL of Xylocaine.


Figure 3. Simple paronychia. (Grossman JA: Minor Injuries and Disorders: Surgical and Medical Care, p 253. Philadelphia, JB Lippincott, 1984)

Preparation of Skin

The entire digit, including the metacarpal head, may be washed with a gentle soap solution, followed by application of a uniform layer of Betadine.

Draping

Placement of sterile towels must achieve isolation of the digit involved and exposure of the metacarpal area. Additional anesthesia is sometimes necessary.

Incision and Drainage

Treatment of the laterally based infection (see Figure 2) involves incising the skin along the lateral edge of the nail; a small incision is made directly over the swollen, fluctuant area. After drainage of purulent material, a wick is used to prevent premature wound closure. The wick s removed after 24 to 36 hours and soaking of the digit is begun on a twice-daily schedule.

Occasionally, a portion of the nail must be removed to establish adequate drainage, particularly if the infection has established penetration of the subungual space. A small scissors is used to separate the nail from the underlying matrix. This dissection is carried out from the tip of the nail to the base in a vertical strip involving $\frac{1}{6}$ to ¼ inch of the nail surface. The nail is then incised with a No. 15 blade or a scissors along this vertical line. A Kelly clamp is then used to grasp the portion of nail to be removed and tease the nail from beneath the eponychium.

Dressing

Xeroform or Vaseline-impregnated gauze is placed within the wound created by nail removal, taking care to place a layer between the matrix and the eponychium to ensure that nail growth can occur in the area of resection. A gauze pad covers this dressing, which is secured in place. Routine administration of antibiotics is unnecessary; however, those patients with diabetes should be placed on antistreptococcal and antistaphylococcal coverage for 7 days.

ABSCESS

A subcutaneous abscess is often seen. The patient usually complains of pain and swelling. Abscesses commonly occur in the perianal region. If fluctuance is present, incision and drainage should be preformed.

The following materials are used to treat abscesses:

Anesthetics

1. 1% to 2% Xylocaine without epinephrine
2. 5-mL to 10-mL syringes
3. 19-G to 22-G needles

Prep Solution

1. Betadine

Drapes

1. Three or four sterile towels

Instruments

1. No. 11 or 15 scalpel blade
2. Scalpel handle
3. Kelly clamps
4. Adson forceps
5. Five or six gauze pads
6. Sterile gloves

Dressing

1. ¼- to ½-inch Nu-Gauze strip

Anesthesia

After alcohol preparation of the skin, superficial skin infiltration is carried out in a linear course across the abscess. A second linear course is then traversed directly perpendicular to the first. Care is taken to remain superficial to the abscess cavity.

Skin Preparation

A single layer of Betadine is applied to the abscess and sufficient surrounding skin for adequate exposure.

Drapes

Placement of drapes ensures isolation of the abscess and the prepared surrounding skin.

Incision and Drainage

A linear incision is made through the skin, entering the abscess cavity. The cavity is opened widely across the entire abscess dimension. If more drainage is desired, a second incision is made perpendicular to the first, forming a cruciate design.

Dressing

After complete drainage of the cavity, placement of strip gauze within the wound is necessary to maintain drainage and ensure secondary healing of the wound. Although antibiotics are not necessary for most, those patients with diabetes or accompanying cellulitis may benefit from 24 to 48 hours of gram-positive coverage. Continued packing of the wound should proceed with daily changes until healthy closure of the defect occurs.

BURNS

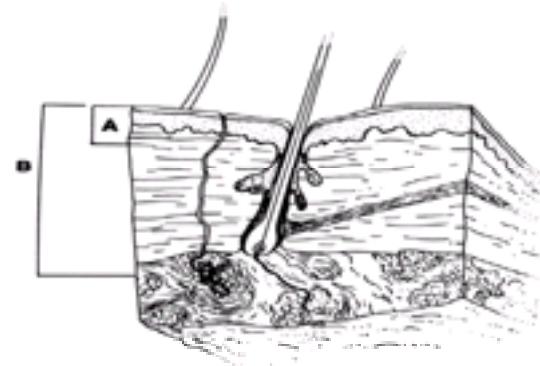
Burns of the skin can result from many sources: flame, steam, scald, electrical, and chemical. These agents cause variable cellular damage to the layers of epidermis, dermis, and subcutaneous fat, depending on the depth. Classification, and therefore treatment, of burn wounds is based on the depth and surface area of skin involved. *First-degree burns* are those that involve just the superficial layers of the epidermis (Fig. 4). *Second-degree burns* involve the epidermis and dermis; a broad distinction is made between superficial and deep burns, based on the amount of dermis involved. Deep second-degree burns involve the entire papillary dermis, with penetration to some or all of the reticular dermis. *Third-degree burns* involve all layers of the epidermis and dermis, with penetration into underlying fat and muscle.


Figure 4. Anatomy of the skin demonstrating (A) epidermis. (B) epidermis and dermis (ie, full thickness). (Grossman JA: Minor Injuries and Disorders: Surgical and Medical Care, p 71. Philadelphia, JB Lippincott, 1984)

The surface area of burns has traditionally been based on the rule of nines. Each arm is considered 9 percent of the body surface area, each leg is 18 percent, the anterior and the posterior trunk are each 18 percent, the head is 9 percent, and perineum/genitalia is 1 percent.

Using these classifications, the treatment of burns can proceed in an organized fashion. All second-degree burns covering more than 5 percent to 10 percent of the body, all third-degree burns, any burns associated with electrical current, and all burns of the ears, eyes, face, hands, feet, or perineum should be immediately referred to a major hospital familiar with burn care. The remaining first-degree burns and second-degree burns covering less than 5 percent of the body can be cared for on an outpatient basis with adequate wound care and follow-up.

The following materials are used to treat burns:

Prep Solution

1. pHisoHex, gentle soap
2. Normal saline

Drapes

1. Three or four sterile drapes

Instruments

1. Adson forceps
2. Suture scissors
3. Silvadene cream
4. Sterile gloves

Dressings

1. Sterile gauze pads
2. Roll gauze

Skin Preparation

Chemical burns should first receive generous lavage with normal saline to dilute the irritant. First- and second-degree burns should be washed with a gentle soap solution. For second-degree burns with ruptured bullae, all free skin should be debrided.

Draping

The cleansed, debrided area of a burn is isolated on a sterile field.

Dressing

Silvadene cream is applied to the surface of the burn in a thin, even layer. Application with a tongue depressor works nicely. Silvadene is subsequently covered with dry gauze pads, which are secured with rolled gauze. Complete dressing change should then be done twice daily, with complete cleansing of the wound before a new dressing is applied. Healing for first-degree burns can be expected in 3 to 4 days; second-degree burns require 10 to 20 days. Although controversial, treatment with oral penicillin at moderate dosages, 250 mg four times a day for 3 days, may help to prevent deepening of the burn wound secondary to strep infection.

SKIN BIOPSY

The following materials are used in skin biopsies:

Anesthesia

1. 1% to 2% Xylocaine without epinephrine
2. 5-mL syringe
3. 22-G needle

Prep Solutions

1. Gentle soap solution
2. Betadine

Drapes

1. Three or four drapes

Instruments

1. No. 15 scalpel blade and handle
2. Sterile skin biopsy punch
3. Adson forceps
4. Suture scissors
5. Needle holders
6. Nylon suture
7. Five or six sterile gauze pads
8. Pathology specimen container
9. Sterile gloves

Dressings

1. Xeroform gauze
2. Gauze pad
3. Tape or gauze roll

Anesthesia

After alcohol preparation of the skin is done, complete superficial skin infiltration is accomplished, including the lesion of interest.

Skin Preparation

After the area is cleansed with a gentle soap, a single layer of Betadine is applied.

Draping

The entire prepared area is isolated from surrounding skin and environment.

Biopsy

If a scalpel blade is to be used, an ellipse, surrounding the lesion in question, is created. The entire depth of the epidermis and dermis should be penetrated. Care is taken in the creation of the ellipse to ensure sufficient local skin mobility to allow edge approximation after skin excision has been done. Skin excision is accomplished by elevating one of the corners and sharply separating it from underlying subcutaneous tissue with sharp scissors. Hemostasis is easily obtained by gentle pressure for 1 to 2 minutes. Wound closure then follows, as described for lacerations.

Alternatively, skin biopsy can be performed by using a skin punch. After anesthesia and skin preparation, the circular punch is pressed against the skin, and cutting is achieved with a gentle twisting motion. Once the entire depth of skin has been traversed, it is separated from underlying subcutaneous tissue with sharp scissors. Wound closure is accomplished with several simple sutures. The specimen is then placed in the proper pathology container and solution.

Dressing

The sutured wound should be covered with a strip of Vaseline-impregnated gauze. A dry sterile gauze pad is placed and held securely with tape or gauze roll.

APPENDIX: EVALUATION OF ATRIAL FIBRILLATION IN THE OUTPATIENT SETTING

Atrial fibrillation (AF) is one of several dysrhythmias that can produce an irregularly irregular heartbeat. It is often a manifestation of underlying heart disease but sometimes is discovered in a patient with no overt cardiac pathology. Many patients tolerate the arrhythmia well and can be evaluated thoroughly and safely in the outpatient setting, although the etiology does not necessarily need to be harmless. The primary care physician needs to determine if it is safe to conduct the assessment in the office setting and how to carry out a cost-efficient evaluation.

PATHOPHYSIOLOGY

The postulated electrophysiologic mechanisms of AF include focal automaticity and a complex form of reentry. Factors that may precipitate or perpetuate AF include increased atrial size, increased atrial pressure, varying repolarization times of neighboring areas of atrial myocardium, and occurrence of atrial premature beats during the vulnerable period of an atrial cycle. Increases in circulating catecholamines may precipitate atrial premature beats and AF. Ischemia and disease of the sinoatrial nodes also predispose to atrial dysrhythmias by suppressing the SA node and allowing other atrial foci to fire. Epidemiologic data from the Framingham study reveal that heart failure and rheumatic heart disease are the most powerful predictors of AF and hypertension the most commonly associated condition, suggesting that myocardial damage and left atrial dilatation are important precursors of the condition.

CLINICAL PRESENTATIONS

The hallmarks of AF are the characteristic electrocardiographic findings of an *irregularly irregular ventricular rhythm* and *atrial fibrillatory waves*. The fibrillatory waves range in appearance from fine irregular undulations of the baseline to very coarse waves. The QRS duration is usually normal but may widen with aberrant conduction and simulate ventricular tachyarrhythmias. The ST segments and T waves may be abnormal in appearance if there is rapid ventricular response, underlying heart disease, or use of digitalis.

AF can present as a paroxysmal or chronic dysrhythmia, both with and without evidence of underlying heart disease. Its incidence in community settings is about 2% over 20 years. The overwhelming majority of AF patients have underlying heart disease at the time of onset. AF is often a sign of advanced heart disease; onset is associated with a twofold increase in mortality.

Some patients with incidentally discovered AF are asymptomatic; however, if the AF is paroxysmal or the ventricular rate is very rapid, *palpitations* may be reported. If cardiac output falls precipitously, symptoms of *heart failure* may occur. Rapid rate may also lead to myocardial *ischemia* in patients with underlying coronary artery disease. Systemic *embolization* may be the first sign of AF and present as an acute neurologic or peripheral vascular event. An increasingly common cause of transient AF is *coronary artery bypass graft* surgery. Usually, the AF is self-limited and resolves during the recovery period.

A number of acute noncardiac conditions can precipitate AF in the absence of clinically apparent heart disease; these include acute *alcohol intoxication*, decompensated *chronic obstructive lung disease, pneumonia, and pulmonary embolization*. However, AF does not always occur in the context of overt heart disease or an acute event such as sudden pulmonary decompensation. The entities associated with seemingly isolated bouts of AF deserve particular attention because detection is sometimes difficult and therapy is different from most other causes of AF.

Lone Atrial Fibrillation. "Lone" AF (LAF) is used to denote AF in patients without clinically evident heart disease. In about two thirds of cases, the condition presents as isolated or recurrent episodes of paroxysmal AF; in the remainder, the AF is chronic. Studies of military recruits found its prevalence to be about 1 in 10,000. LAF is a harmless condition in young people; they characteristically experience episodes precipitated by emotional stress, alcohol, use of stimulants, or smoking. Detailed investigations have failed to reveal underlying heart disease, chamber enlargement, or risk of embolization. The prognosis in young patients is excellent, with no increased risk of stroke. In those with LAF over the age of 60, there is a moderate increase in stroke risk, believed due to silent progression of atherosclerotic disease. Older LAF patients with hypertension have high stroke risk and should probably not be designated as having LAF but rather as having AF with underlying hypertensive heart disease.

Alcoholic Cardiomyopathy. The early stages of alcoholic cardiomyopathy may present as paroxysms of AF triggered by binge drinking. The distinction between this condition and lone fibrillation triggered by alcohol ("*holiday heart*") may be difficult but is suggested by the finding of cardiomegaly even in the absence of heart failure. Abstinence can halt or even reverse the condition, but continued drinking leads to progression and, in some, chronic AF.

Tachycardia-Bradycardia Syndrome. Also known as *sick sinus syndrome*, this is an important and sometimes subtle cause of AF. The exact cause of this condition is unknown but is believed to be related to diffuse degeneration of conducting system tissue. Patients exhibit sinus node dysfunction, often in conjunction with arterioventricular nodal disease and lack of an adequate escape mechanism. Atrial tachyarrhythmias may alternate with symptomatic bradycardia and sinus arrest. Clinical presentations include palpitations, lightheadedness, and syncope. At times, the first manifestation may be a paroxysm of AF. Identification is most important, because treatment directed only toward the AF may worsen the bradyarrhythmia (see Chapter 28). Paroxysmal AF due to sick sinus syndrome is associated with an increased risk of thromboembolism.

Wolff-Parkinson-White Syndrome. WPW is a preexcitation syndrome that produces a host of supraventricular and ventricular dysrhythmias, particularly paroxysms of AF associated with a very rapid ventricular response rate. In fact, a ventricular rate greater than 200 beats/min in the absence of another cause for AF should make one suspicious of WPW. The condition is believed to be at least partially congenital in nature and characterized by rapid atrioventricular conduction over an accessory pathway (*the Kent bundle*). This anomalous conduction pathway bypasses the arterioventricular node and produces preexcitation, manifested by the characteristic baseline ECG findings of a *shortened PR interval* (less than 0.12 seconds) and *delta waves* at the onset of the QRS. Some WPW patients have normal baseline ECGs and show anomalous conduction only during tachyarrhythmias, making electrocardiographic identification difficult. During rapid AF, there may be a widening of the QRS, mimicking ventricular fibrillation. The reported incidence of AF among patients with WPW ranges from 11% to 39%. WPW is an important cause of AF to recognize, because the AF may actually worsen with digitalis therapy (see Chapter 28) and has the potential to degenerate into ventricular tachycardia and fibrillation.

Apathetic Hyperthyroidism of the Elderly. AF that appears to occur in the absence of underlying heart disease may be due to hyperthyroidism, especially in the elderly. In the most florid form of this presentation, patients may manifest marked apathy suggesting depression or impressive weight loss that may simulate occult malignancy (see Chapter 103). Sometimes, AF is the predominant manifestation. The usual signs and symptoms of thyrotoxicosis are absent. The AF is difficult to control with standard modes of antiarrhythmic therapy but usually reverts to sinus rhythm with correction of the hyperthyroid state (see Chapter 28).

DIFFERENTIAL DIAGNOSIS

AF is only one of a number of dysrhythmias that present as an irregularly irregular pulse. Frequent atrial premature beats, MAT, SVTs with variable block, sinus arrhythmia, and frequent ventricular premature beats all may produce an irregularly irregular rhythm.

The most common cause of AF in the community setting is hypertensive heart disease; however, only those hypertensive patients with evidence of left ventricular hypertrophy are likely to develop AF. The major causes of AF are listed in Table 25.2.

Table 25.2. Important Causes of Atrial Fibrillation

WORKUP

The diagnosis of AF is based on the characteristic *ECG findings* of an irregularly irregular ventricular response and atrial fibrillatory waves. These fibrillatory waves range from barely perceptible irregular undulations of the ECG baseline to very coarse waves. The standard lead best suited for detection of atrial activity is lead V_1, followed by leads II, III, and AVF. Occasionally, the routine 12-lead ECG will show no atrial activity; in such instances, one can check lead V_3R for evidence of atrialactivity or infer the diagnosis of AF based on the characteristic ventricular response pattern and a QRS of normal duration. MAT, paroxysmal atrial tachycardia, atrial flutter with variable block, frequent atrial premature beats, and sinus arrhythmia all produce rhythms that can resemble AF, but the presence of P waves or flutter waves on ECG separate them from AF. If the ventricular response rate is too rapid to reveal atrial activity, *vagal maneuvers* and *gentle carotid sinus massage* can be attempted (provided there is no evidence of carotid artery disease) to slow the rate and uncover any hidden fibrillatory or P waves.

History. The young patient with a paroxysm of AF should be questioned about a prior history of such episodes, excess intake of stimulants and alcohol, emotional stress, fever, heart murmur, and chest pain. Older patients should be queried about preexisting heart disease, hypertension, chest pain, dyspnea, cough, calf pain, leg edema, fever, lightheadedness, near-syncope, loss of consciousness, weight loss, depression, history of heart murmur or rheumatic fever, and any prior attacks of palpitations. A careful drug history should be taken with emphasis on alcohol abuse (see Chapter 228). Any use of digitalis should be noted; however, digitalis toxicity only rarely results in AF. A long-standing history of attacks dating from young adulthood suggests WPW syndrome. The presence of marked weight loss and depression in an elderly patient with unexplained AF points to apathetic hyperthyroidism. The older patient with episodes of altered consciousness may suffer from sick sinus syndrome.

Physical Examination. In addition to noting heart rate, blood pressure, respiratory rate, jugular venous pulse, and other signs of hemodynamic status, the patient should be checked for apathetic appearance, evidence of marked weight loss, cyanosis, goiter, wheezes, friction rub, heart murmur, calf tenderness, asymmetric leg edema, and signs of alcohol intoxication. The most common cause of "silent" mitral valve disease is failure to listen specifically for the murmurs of mitral stenosis and mitral regurgitation. Placing the patient in the left lateral decubitus position may be necessary to appreciate the murmurs. Only in rare instances are the murmurs of mitral valve disease truly inaudible (see Chapter 33).

Laboratory Studies. The *ECG* often provides useful information beyond identification of the arrhythmia. A ventricular response rate greater than 200 beats/min suggests WPW syndrome, as does a widened QRS due to aberrant conduction; delta waves may be seen within some of the aberrantly conducted beats. The appearance of the fibrillatory waves on ECG provides some hints of etiology. Coarse fibrillatory waves are most typical of AF resulting from rheumatic heart disease and other causes of marked left atrial enlargement, whereas fine fibrillatory waves are more common in cases due to atherosclerotic and hypertensive heart diseases. The ST and T wave segments should be checked for evidence of ischemia, strain, digitalis effect, and pericarditis (see Chapter 20). Advanced valvular and hypertensive forms of heart disease are suggested by finding ECG evidence of left ventricular hypertrophy.

A cardiogram taken after return to sinus rhythm should be checked for a shortened PR interval and delta waves diagnostic of WPW syndrome. Occasionally, preexcitation is concealed on the resting ECG, so that the ECG of some WPW patients appears normal; in such instances, the diagnosis of WPW syndrome can be difficult. Other clues to WPW syndrome include a ventricular response rate during AF of greater than 200 beats/min and delta waves distorting the QRS complex.

A rhythm strip sometimes reveals sinus node disease, but often a 24-hour *Holter monitor* will be needed to detect the episodes of bradycardia and tachycardia that characterize the sick sinus syndrome. *Chest radiograph* is the best simple test for determining heart failure, cardiomegaly, and intrapulmonary pathology. Cardiomegaly may be the only evidence of an underlying cardiomyopathy. *Echocardiogram* provides an excellent noninvasive means of further evaluating suspected valvular, congenital, cardiomyopathic, and pericardial forms of heart disease. However, the cost effectiveness of ordering an echocardiogram routinely in the workup of AF to search for an occult high-risk cause such as mitral stenosis remains a subject of debate. The elderly apathetic patient with unexplained AF requires measurement of *thyrotropin* level to rule out hyperthyroidism (see Chapter 103). Although AF is a very uncommon manifestation of digitalis toxicity, a serum *digoxin level* is probably worth checking when no other cause is apparent and the patient is known to be taking the drug.

In summary, the evaluation can be performed on an outpatient basis if the patient is tolerating the rhythm well and there is no evidence of failure, ischemia, or embolization. A careful history and physical examination, supplemented by ECG, chest radiograph, and, in selected instances, an echocardiogram complete the evaluation in most patients. Patients with AF of unknown cause should be studied further for evidence of sick sinus syndrome, apathetic hyperthyroidism, alcoholic cardiomyopathy, and WPW syndrome.

INDICATIONS FOR ADMISSION

Once the diagnosis of AF is established, one needs to determine if workup can proceed on an outpatient basis. Prompt hospital admission is needed for the patient with evidence of acute congestive heart failure, ischemia, embolization, hypotension,or a very rapid ventricular response rate (more than 150 to 170 beats/min). If there is no hemodynamic compromise, an outpatient workup can commence.

APPENDIX: POTASSIUM SUPPLEMENTATION IN CONGESTIVE HEART FAILURE

Indications and Precautions. Patients with heart failure have considerable underlying heart disease and often take digitalis and diuretics, putting them at greatly increased risk for hypokalemia-induced arrhythmias. Prompt correction and prevention of hypokalemia are essential. However, because ACE inhibitor therapy has become a standard part of the CHF treatment regimen, the use of potassium supplements and potassium-sparing diuretics must be undertaken with caution and careful monitoring of the serum potassium. The risk of hyperkalemia is substantial, particularly in the setting of renal failure.

Individual responses to potassium-wasting diuretics and ACE inhibitors vary widely as do requirements for potassium replacement, necessitating regular monitoring of the serum potassium level, which is not an exact measure of total body potassium but rather a rough guide. Potassium supplementation should not be undertaken unless the serum potassium falls below 3.5 mg/dL.

Approaches to Supplementation. Potassium may be taken in the form of dietary additions or potassium-containing preparations. The amount needed is usually determined empirically, ranging from 0 to 60 mEq/d over and above normal dietary potassium intake.

Dietary Measures. For patients on thiazides, dietary replacement often suffices. When a loop diuretic is used, the potassium loss may be greater, necessitating a potassium preparation (unless a potassium-sparing agent is used). *Dietary measures* are the most palatable way to provide potassium. There are 15 mEq in a 10-oz glass of orange, pineapple, or grapefruit juice; a medium-sized banana; a baked potato; or two oranges. Tomato juice has almost twice the potassium content of orange juice, but most brands have added salt to enhance taste.

Salt Substitutes. *Salt substitutes* contain potassium chloride (KCl), but some are also 50% sodium chloride. Even those that are pure KCl do not provide sufficient potassium to serve effectively as a supplement.

Patients who need to maintain normokalemia but cannot do so by dietary means require a *potassium preparation*. There is a plethora of these on the market. Oral supplements combine potassium with any of a number of different anions. Only the chloride form is effective in correcting the hypokalemic alkalosis that results from diuretic use. However, any form will prevent potassium depletion unless there is concurrently severe sodium chloride depletion.

Potassium Chloride Elixir. *Potassium chloride elixir* remains the safest and least expensive. The 10% solution contains 20 mEq of potassium per tablespoon (15 mL). It is most easily taken in orange juice; some find it unpalatable, even when mixed in fruit juice. However, when faced with the high cost of alternatives, many patients who complain of its taste are willing to reconsider using it. Its safety, chloride content, and ability to deliver more potassium per dose than most other preparations strongly recommend it. Citrus-flavored *effervescent* tablets dissolved in water provide an alternative to the elixir preparation but at greater cost and without much improvement in taste.

Potassium Chloride Tablets. The earliest preparations caused a high incidence of mucosal injury, leading to gastrointestinal ulceration, bleeding, obstruction, and perforation. A second generation of tablet preparations was devised by encoating them in a *wax matrix* to slow release and reduce mucosal injury. Examples include Slow-K, Kaon-Cl, Klotrix, K-Tab, and others. Encoating decreases the risk of gastrointestinal complications but does not entirely eliminate it. Complications continue to occur, often in unpredictable fashion.

Microencapsulation. *Microencapsulation* represents another release strategy. KCl is prepared in small crystals, each coated with a polymer permeable to water, theoretically helping to disperse the potassium while minimizing locally high concentrations. Endoscopic data suggest some improved safety over other tablet forms, but cost is almost 10 times that of the elixir for an equivalent dose. Moreover, because each tablet contains only 8 mEq of potassium, multiple tablets are needed each day to provide the 15 to 45 mEq usually required.

Potassium Gluconate and Bicarbonate. *Potassium gluconate and bicarbonate preparations* are available, some in the form of liquids, others as effervescent tablets. Although they tend to be more palatable, disadvantages include high cost and absence of chloride to counter alkalosis.

Potassium-Sparing Diuretics. If all attempts at potassium supplementation fail, then a potassium-sparing diuretic is indicated. Combinations with a thiazide are now available in generic formulation and may provide a reasonable and inexpensive alternative to diuretic plus potassium supplementation in patients requiring both a thiazide and tight potassium control. As noted above, use of a potassium-sparing diuretic in persons taking an ACE inhibitor should be undertaken only with great caution and close monitoring for hyperkalemia, particularly in the setting of worsening renal function.

Refractory Hypokalemia. *Refractory hypokalemia* requires checking for hypomagnesemia (see above) and hyperaldosteronism (see Chapter 19).

APPENDIX: MANAGEMENT OF HYPERTROPHIC CARDIOMYOPATHY

Hypertrophic cardiomyopathy (HCM) with left ventricular outflow tract obstruction (also referred to as *idiopathic hypertrophic subaortic stenosis* [IHSS]) has many clinical features that resemble valvular aortic stenosis. Noteworthy differences include absence of an ejection sound in early systole and absence of poststenotic dilatation of the ascending aorta. Patients with IHSS have an increase in the intensity of their murmur with Valsalva (absent in those with HCM and no outflow tract obstruction). IHSS and other forms of HCM are generally but not always *familial*, usually transmitted as an autosomal dominant trait. Because of the potential for high frequency in family members, familial screening is essential. Transthoracic ultrasound is diagnostic; cardiac catheterization is rarely necessary.

The most serious consequence of IHSS is *sudden cardiac death*. Those at greatest risk have a history of prior syncope and ventricular tachyarrhythmias and a family history of sudden death. Such high-risk persons require warning about engaging in strenuous exercise; bacterial endocarditis prophylaxis is indicated. Those who develop atrial fibrillation are at risk for embolization and need oral anticoagulation (see Chapter 28 and Chapter 83). *Beta-blockade* is recommended for most individuals—the decrease in contractility reduces the degree of outflow tract obstruction. Treatment of hypertension has particular merit. Data from community-based study suggest that the prognosis is not quite as serious as originally suspected from referral center investigations. Most patients do quite well, but there appears to be a subset at increased risk.

APPENDIX: EVALUATION OF INTERSTITIAL LUNG DISEASE

When a chest radiograph shows a diffuse infiltrative pattern that is labeled "interstitial" in appearance, a wide variety of diagnostic possibilities emerge, ranging from sarcoidosis and rheumatoid disease to pneumoconiosis and idiopathic pulmonary fibrosis. With such a large number of diagnostic possibilities at hand, an efficient approach to workup is essential. The primary physician's role is to narrow the differential by careful attention to important elements of the history and physical examination, supplemented by a few well-chosen initial laboratory studies.

PATHOPHYSIOLOGY AND CLINICAL PRESENTATION

Most conditions that cause this diffuse parenchymal radiographic pattern are not truly "interstitial"; in addition to involving the area between the alveolar epithelium and the capillary endothelial basement membrane, they may also affect the gas-exchanging portion of the lung (including the alveolar epithelium, alveolar space, and pulmonary microvasculature).

Most of the interstitial lung diseases begin with parenchymal injury that is followed by an inflammatory response and collagen deposition. It is the widespread nature of the injury and inflammatory response—often compromising the alveolar walls—that accounts for the pathophysiology and clinical presentation. In a few instances, the process is invasive or infiltrative rather than inflammatory; in others, a filling of the alveolar space occurs with an outpouring of material.

The physiologic consequences of such alveolar compromise are the development of a *restrictive defect*; this is manifested by a reduction in forced vital capacity and a *ventilation–perfusion mismatch* that is created when inflammation and fibrosis of the gas-exchanging surfaces cause a reduction in carbon monoxide diffusing capacity and oxygen tension (Po_2). Symptoms may be minimal, although progressive dyspnea is the rule, at times accompanied by a dry cough. The lungs may be clear to auscultation, or basilar crackles may predominate.

DIFFERENTIAL DIAGNOSIS

The conditions responsible for interstitial lung disease can be grouped according to their underlying pathophysiology: drug-induced inflammatory response, connective tissue disease, pneumoconiosis, alveolar filling disease, primary lung disease, and idiopathic disease (Table 51.1).

Table 51.1. Differential Diagnosis of Interstitial Lung Disease

The most common causes are sarcoidosis and idiopathic pulmonary fibrosis, although in industrial settings the pneumoconioses may predominate.

WORKUP

History should focus on the duration of symptoms, speed of progression, and presence of fever, hemoptysis, pleuritic chest pain, and symptoms of extrathoracic disease (e.g., joint pain, lymphadenopathy, skin changes). Most conditions have a chronic, progressive course, but acute onset with *fever* and a rapidly progressive course suggest a hypersensitivity pneumonitis, usually a consequence of exposure to organic antigens (ranging from cocaine to bird droppings). Fever, bothersome dry cough, and a subacute course (2 to 10 weeks) accompanied by a patchy, bilateral air space process characterize bronchiolitis obliterans organizing pneumonia, in which a lymphocytic infiltrate and granulation tissue occupy the distal airways and alveoli. *Productive cough* is rare in interstitial lung disease, but its presence indicates fluid-filled alveoli, as can occur in diffuse alveolar cell carcinoma. *Hemoptysis* suggests conditions that cause diffuse alveolar bleeding (e.g., Goodpasture's syndrome, lupus, severe mitral stenosis, idiopathic pulmonary hemosiderosis). Bleeding that originates from or occurs in the context of upper airway disease is a hallmark of Wegener's granulomatosis. *Pleuritic pain* indicates that the inflammatory process has spread to involve the pleura, which is characteristic of the connective tissue diseases and some drug-induced conditions. Sudden, severe pleuritic pain and acute dyspnea raise the question of a spontaneous pneumothorax, which occurs with many of the primary lung diseases, such as histiocytosis X and lymphangiomyomatosis.

The presence of extrapulmonary symptoms—especially if they predate the development of lung findings—can be diagnostic. *Polyarticular symptoms* and *skin changes* characterize the connective tissue/rheumatoid diseases and sarcoidosis; the latter is often associated with *lymph gland enlargement*. Patients with idiopathic pulmonary fibrosis may have arthralgias,but symptoms of joint inflammation are absent. A history of renal disease, especially *nephritis*, can be a clue for Goodpasture's syndrome and lupus, although in the former, pulmonary disease usually predates renal involvement.

The *drug* and *occupational history* is one of the most important parts of the clinical assessment. Long-term use of such chemotherapeutic agents as methotrexate, busulfan, bleomycin, and cyclophosphamide may result in interstitial lung changes, as may prolonged use of nitrofurantoin, gold, amiodarone, or penicillamine. High-dose procainamide can lead to a lupuslike serositis syndrome. Radiation therapy may trigger a diffuse pneumonitis 6 to 12 weeks after treatment, followed by fibrosis. Occupational exposures, including distant ones, to inorganic dusts such as silicone, asbestos, talc, beryllium, and coal deserve careful review. Patients with a hypersensitivity pneumonitis should be queried about exposure to organic dusts on the job; typically, symptoms are worse at work. They should also be asked about nasal inhalation of cocaine, which has been reported as a cause of hypersensitivity pneumonitis. A *smoking* history is always pertinent. It is uncommon for lung disease to develop in nonsmoking patients with Goodpasture's syndrome.

Physical Examination is particularly useful for signs of extrathoracic disease; the pulmonary findings are usually nonspecific. The skin is checked for signs of connective tissue disease (rheumatoid nodules, malar flush, changes of scleroderma) and sarcoidosis (see above), and the lymph nodes are checked for sarcoid-related enlargement. Patients with hemoptysis should undergo a careful upper airway examination that includes a search for the signs of necrotizing changes in the nasal passages and sinuses that typify Wegener's granulomatosis. The joints are examined for evidence of inflammation (swelling, warmth, redness, effusion), which is indicative of rheumatoid disease but also occurs with sarcoidosis and Wegener's granulomatosis. Enlargement of the liver and spleen are oft-noted features of sarcoidosis and occasional findings in advanced connective tissue disease and histiocytosis X.

As noted earlier, the pulmonary findings are typically nonspecific and may even be grossly normal. Bilateral basilar rales are common in many forms of interstitial lung disease, especially the drug-related, idiopathic, connective tissue, and pneumoconiosis varieties. In those conditions associated with alveolar filling, the rales are likely to be "wet" in quality, whereas those without fluid in the alveoli produce "dry" crackles (sometimes referred to as "Velcro" rales) on end-inspiration. The heart is checked for mitral stenosis if a history of hemoptysis is present, and for signs of cor pulmonale and right-sided failure (right ventricular heave or third heart sound,

increased intensity of second heart sound, jugular venous distention, peripheral edema) resulting from chronic hypoxemia-induced pulmonary hypertension.

Chest Radiographic Findings are usually nonspecific but can be helpful. Radiologic adjectives describing the diffuse changes associated with interstitial disease include such terms as "reticular (linear)", "reticulonodular", and "nodular", and "ground glass." The lower lobes tend to be more involved than the upper ones, and a "honeycomb" or cystic appearance to the lung fields develops as fibrous tissue replaces normal alveoli. Exceptions to these generalizations are the upper lobe predilection and nodular infiltrates of silicosis, berylliosis, chronic hypersensitivity pneumonitis, and histiocytosis X.

Unfortunately, no particular radiographic pattern is diagnostic, although a few emerge as useful. The alveolar filling diseases tend to produce alveolar densities in an ill-defined or "fluffy" nodular pattern; an air bronchogram might ensue as involved alveoli become silhouetted by uninvolved airway. The development of such a pattern in a patient with previously known interstitial disease suggests a superimposed process, such as alveolar cell carcinoma or active inflammation. Frankly nodular infiltrates are seen with sarcoidosis and Wegener's granulomatosis as a result of granuloma formation; nodular infiltrates may even occur with the pneumoconioses and hypersensitivity pneumonitis.

Radiographic findings outside the lung parenchyma are important and worth noting. The concurrent appearance of pleural involvement suggests connective tissue disease, asbestosis, and occasionally sarcoidosis. Bilateral hilar adenopathy can be pathognomonic of sarcoidosis (see above). Diffuse infiltrates, hilar adenopathy, and pneumothorax point to histiocytosis X. A thin rim of calcium in the hilar nodes is characteristic of silicosis.

Pulmonary Function Tests help confirm the interstitial nature of the disease (particularly when radiographic findings are minimal) and provide a baseline with which to judge disease course, although they correlate poorly with degree of pathologic change. As noted earlier, the ratio of *forced expiratory volume* (FEV_1) to *forced vital capacity* (FVC) increases and demonstrates a restrictive pattern secondary to a steady reduction in FVC. Some interstitial conditions (e.g., lymphangiomyomatosis, histiocytosis X) can also cause airway obstruction and may reduce the FEV_1. The diffusion capacity is typically reduced, although it may be preserved until rather late in the course of illness, when mismatching of ventilation and perfusion becomes prominent. *Arterial blood gases* are initially normal, but with disease progression, hypoxemia, hypocarbia, and a respiratory alkalosis ensue. The hypocarbia is a manifestation of tachypnea, triggered predominantly by increased work of breathing as the lung stiffens during progression of the fibrotic process.

Laboratory Studies. Few routine noninvasive laboratory studies are of diagnostic value. A simple yet often overlooked test is *urinalysis*, which can provide important evidence of glomerular injury (red cells, casts, albuminuria), suggestive of connective tissue disease, Wegener's granulomatosis, and Goodpasture's syndrome. Most other tests should be ordered only when the history, physical examination, and chest radiograph indicate a reasonable pretest probability of the condition in question. Unselective testing is associated with a high rate of false-positive results (see Chapter 2). If connective tissue disease is suspected, then *rheumatoid factor, antinuclear antibody*, and *DNA binding* studies (see Chapter 146) and a *urinalysis* should be considered. Hypersensitivity pneumonitis, especially if drug-induced, may produce a finding of 10% to 20% eosinophils on the *peripheral smear* examination, but test sensitivity is low (20%). The ACE level is useful for gauging disease activity but lacks sensitivity for the diagnosis of sarcoidosis. Measurement of *precipitating antibodies* is frequently ordered when inhalation of a potentially sensitizing organicdust is suspected, but the test does not distinguish between an etiologic role and exposure. Patients suspected of having Goodpasture's syndrome are usually positive for *antiglomerular basement membrane antibody*. Patients with Wegener's granulomatosis test positive for *antineutrophil cytoplasmic autoantibodies* in only 60% of cases, but specificity is high (<95%).

Fiberoptic bronchoscopy with *bronchoalveolar lavage* provides an opportunity to sample the cellular and fluid contents of the distal airways (counts of total white cells, macrophages, lymphocytes and lymphocyte subsets, neutrophils, and eosinophils; malignant cells; antibodies). Alterations in the normal cellular profile may aid the diagnosis, as can the discovery of malignant cells. However, because of considerable overlap among causes, the findings are usually nonspecific. Lavage data sometimes help stage illness and predict response to therapy.

Except for patients with connective tissue disease, pneumoconiosis, or drug- or radiation-induced disease, most patients with interstitial lung disease usually require a tissue diagnosis. The morbidity of *transbronchial biopsy*, a means of obtaining tissue during bronchoscopy, is low. Unfortunately, however, it rarely establishes a definitive tissue diagnosis. Most forms of interstitial disease that necessitate a tissue diagnosis require more tissue than can be obtained by the transbronchial approach. However, when sarcoidosis, lymphangitic carcinomatosis, or an alveolar filling disease is suspected, a transbronchial biopsy may suffice. In most other instances, an *open lung biopsy* or, when an experienced operator is available, a *video-assisted thoracic lung biopsy* is required.

INDICATIONS FOR REFERRAL AND ADMISSION

Referral to a pulmonary medical specialist is indicated when the diagnosis remains elusive after completion of the noninvasive segment of the evaluation and the need for lavage or a tissue diagnosis is being considered. A thoughtful consultation may save the patient an unnecessary procedure and help select those patients most likely to warrant an invasive evaluation. Hospitalization is indicated when severe ventilation–perfusion mismatching leads to clinically significant hypoxemia (Po_2 <55 mm Hg).

APPENDIX: EXAMINATION OF THE ANORECTUM AND SIGMOID COLON WITH DIGITAL RECTAL EXAMINATION, ANOSCOPY, AND SIGMOIDOSCOPY

LAWRENCE S. FRIEDMAN

Careful, competent examinations of the anorectal area and distal colon are essential for CRC screening and for evaluation of complaints referable to these structures. The anorectal examination is indicated in all patients who are to undergo sigmoidoscopy and should be incorporated into all complete physical examinations in adults.

ANORECTAL EXAMINATION

Digital Rectal Examination

No bowel preparation is necessary, but the physician must establish rapport with the patient by taking a history and performing other parts of the physical examination first. Apprehension and embarrassment may be minimized by explaining each step, describing the anticipated sensations, and draping the patient to expose only the perineum.

Inspection. The patient may be examined in either the knee–chest or left lateral decubitus (Sims') position. After retraction of the buttocks, the perianal skin and anal orifice are inspected for fecal material (reflecting poor hygiene, painful lesions that make cleansing difficult, or incontinence), drainage, dermatoses, scars, prolapsed hemorrhoids, fistulas, fissures, abscesses, hematomas, condylomata, and carcinomas. Lesions are described anatomically (e.g., anterior, right-sided), not with reference to the face of a clock. Perineal and sacrococcygeal tissues should be palpated with the gloved but unlubricated index finger for tenderness, induration, fluctuance, or masses.

Palpation. Digital examination of the rectum is then performed by placing the gloved, lubricated index finger at the anal orifice and gently inserting as the patient bears down. The small finger may be used in patients with painful or stenotic anal lesions. Anesthetic ointment may be helpful if a tender lesion is present. The anal sphincter tone and strength of contraction are noted, and the finger is swept circumferentially as it is advanced into the rectum. Abnormalities sought include fissures, fistulous tracts, abscesses, sessile and pedunculated polyps, and cancers. Rarely, foreign bodies may be encountered. Internal hemorrhoids are not palpable unless they are thrombosed. In inflammatory bowel disease, the mucosa may feel gritty. Stool in the rectum is deformable, which distinguishes it from other rectal masses. The rectal ampulla should be checked carefully (Fig. 56-1); it is often overlooked and may harbor a neoplasm.

Figure 56-1. Digital examination.

The average effective depth of insertion of the index finger is 7.5 cm. In women, care must be taken not to mistake the cervix for a rectal "tumor" along the anterior rectal wall; the cervix is smooth and symmetric. In men, the prostate and, if possible, the seminal vesicles should be examined. Finally, on withdrawal, the examining finger should be inspected for the character of feces and the presence of blood, pus, or mucus. A test for occult blood should be performed unless gross blood is evident.

Anoscopy

Anoscopy may be a useful adjunct to the anorectal examination, particularly in the evaluation of bright red rectal bleeding, perianal pain, or suspected hemorrhoids. Anoscopes are metal or disposable plastic tubes with a diameter of 2 cm at the tip and a length of 7 cm. A built-in light source may be present or an external light source may be required, depending on the make of anoscope. With the patient in the same position as for the anorectal examination, the lubricated anoscope is held in the right hand with the thumb pressing on the obturator as the instrument is introduced with slow, gentle pressure. The instrument is first directed along the longitudinal axis of the anal canal toward the umbilicus and then pointed more posteriorly at the anorectal angle. It is inserted the full length and held in the left hand so that the flange rests against the anus. The obturator is removed, and the anoscope is slowly withdrawn as the mucosa is examined.

The normal rectal mucosa is pink, with a visible delicate network of submucosal vessels. In patients with proctitis, the vascular pattern is typically obliterated and the mucosa may be friable (i.e., it may bleed easily on gentle swabbing). On withdrawal, the anal mucosa is red. Hemorrhoids appear as purple bulges into the lumen; occasionally, blood may be seen to issue from a hemorrhoid. Fissures may be identified at the anal verge.

SIGMOIDOSCOPY

Indications

Screening for Colorectal Cancer. In asymptomatic persons, sigmoidoscopy can be an important screening procedure for early detection of CRC (see above). About one fourth of CRCs are within reach of the rigid sigmoidoscope, and about 50% are within reach of the flexible sigmoidoscope. Asymptomatic rectal cancers discovered by sigmoidoscopy are less advanced and survival rates are better than in patients with symptomatic cancers. Screening by sigmoidoscopy has been shown to reduce mortality from CRC, and in combination with FOBT, is cost-effective. Moreover, detection of polyps on sigmoidoscopy also leads to reduced mortality from CRC by permitting their removal before they undergo malignant transformation. Polyps that are considered at high risk for malignant transformation and that are markers of additional high-risk polyps in the proximal colon are those larger than 1 cm in diameter or with villous features on histologic examination. The optimal frequency of screening in asymptomatic persons over age 50 and at average risk for CRC appears to be every 5 years. (However, because sigmoidoscopy permits visualization of only the distal colon, sentiment is growing that full colonoscopy, perhaps at age 50 or 60, or both, may prove to be a preferable screening strategy.)

Evaluation of Complaints Referable to the Distal Colon. Sigmoidoscopy permits direct visualization of the colonic mucosa. As such, it is an essential part of the evaluation of patients presenting with a host of complaints or problems referable to the large bowel (Table 56-2). Also, sigmoidoscopy can supplement barium studies by permitting direct observation of abnormalities detected on barium enema, such as polyps and other suspected mass lesions. In patients with known inflammatory bowel disease, sigmoidoscopy is useful for monitoring disease activity and response to therapy.

Table 56-2. Indications for Sigmoidoscopy

Rigid Sigmoidoscopy

Preparation. Satisfactory cleansing of the bowel can be achieved in most patients with a single tap water or Fleet Phospho-Soda *enema* administered 45 minutes before sigmoidoscopic examination. If the examination has been scheduled in advance, the patient can be instructed to self-administer one or two enemas at home on the morning of examination. After the preparation, the patient should take nothing by mouth. Adequate preparation is particularly advisable in older persons, who often have large amounts of retained stool in the rectal vault.

For patients with diarrhea or suspected inflammatory bowel disease, it is acceptable to forego enema cleansing before sigmoidoscopy. These patients can often achieve adequate preparation by having a *bowel movement* just before the examination. Moreover, because enemas may induce edema and erythema of the mucosa, prior enema administration may make it impossible for the observer to distinguish subtle mucosal changes caused by proctitis from those induced by the enema.

Because of the low risk for endocarditis associated with sigmoidoscopy in patients with valvular heart disease, *antibiotic prophylaxis* is not recommended except for patients with prosthetic valves, a history of endocarditis, or hemodynamically significant right-to-left cardiac shunt; even in these cases, the benefit of antibiotic prophylaxis is uncertain (see Chapter 16). Sedation and analgesia are seldom necessary but may be used in patients with painful anal lesions.

Contraindications. Contraindications to sigmoidoscopy include acute peritonitis, suspected bowel perforation or infarction, a severely uncooperative patient, and refusal of the patient to give consent. Sigmoidoscopy is not contraindicated in pregnancy.

Technique. The patient is examined in the same position as for the rectal and anoscopic examinations. The left lateral decubitus (Sims') position is better tolerated than the knee–chest position by older and debilitated patients and may be less embarrassing to patients in general. However, the knee–chest position permits a greater range of scope motion. If available, a tilt-table designed for sigmoidoscopy minimizes discomfort for the patient and eliminates the rather awkward position required of the examiner when Sims' position is used.

The sigmoidoscope is a rigid metal or disposable plastic tube, 25 cm long and approximately 1.5 cm in diameter. Newer rigid sigmoidoscopes have distal fiberoptic lighting, a proximal magnifying lens, and a connection for air insufflation. Additional standard equipment includes long cotton swabs, suctioning apparatus, and biopsy and grasping forceps. The entire sigmoidoscopic examination should take from 2 to 5 minutes. However, the goal should never be speed, but rather thoroughness and patient comfort.

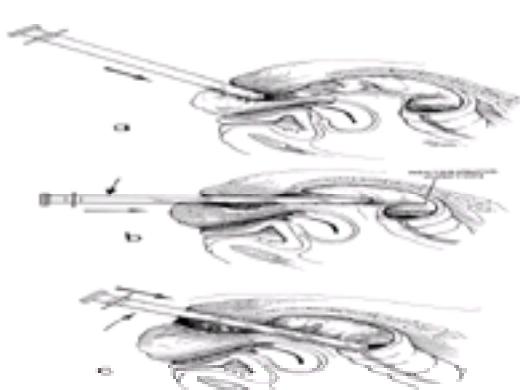
Insertion. The lubricated instrument is inserted with the right hand holding the obturator firmly in place and with gentle pressure against the anal sphincter as the patient bears down. Alternatively, if the rectal examination is performed with the left index finger, the sigmoidoscope may be guided over the withdrawing examining finger to avoid having to dilate the anal sphincter a second time. The sigmoidoscope is initially directed toward the umbilicus and then posteriorly at the anorectal junction (Fig. 56-2).


Figure 56-2. Overview of rigid sigmoidoscopic examination. **A:** Tip of sigmoidoscope is inserted into anal canal in direction of umbilicus. **B:** At anorectal junction (about 3 cm from anus), tip is deflected toward sacrum. **C:** At rectosigmoid junction (about 12 to 15 cm from anus), tip is deflected anteriorly and to the left.

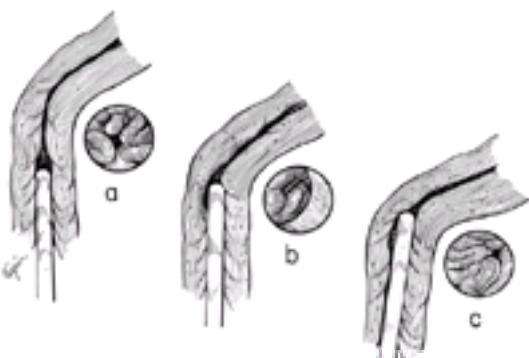
Once past the anorectal ring, the obturator is withdrawn, and the sigmoidoscope is advanced with the lumen in view at all times. Unless stool is present, insertion is easy until the rectosigmoid junction is reached at about 12 to 15 cm from the anus. At this point, the lumen bends sharply forward and to the left. The patient may experience painful spasm and should be reassured and instructed to breathe slowly and deeply to ensure relaxation of abdominal muscles as the instrument is slowly advanced. Air insufflation should be kept to a minimum to avoid painful colonic distention. When a tight bend in the lumen is encountered and the direction of the lumen is not obvious, it is best to withdraw the sigmoidoscope slightly until a smooth crescentic band of mucosa appears in the field of view. This band always represents the anterior aspect of the mucosa as it bends behind the band, and the sigmoidoscope can be advanced again just beyond the band and deflected in the same direction, where the lumen should be expected to appear (Fig. 56-3). It is important not to push the sigmoidoscope blindly and to desist when the mucosa blanches or the patient experiences severe pain.


Figure 56-3. Maneuvering a rigid sigmoidoscope past an angulation in the sigmoid colon. **A:** Advancement of sigmoidoscope through straight portion of colon; view through scope shows concentric lumen with radiating mucosal folds. **B:** As bend in colon is reached, a crescentic band of mucosa is seen in front of the lumen. To maneuver past this angulation, the scope is first withdrawn 1 to 2 cm as the tip is deflected *away* from the lumen. The scope is then readvanced slowly as the tip is

deflected back toward the lumen *behind* the crescentic mucosal band. **C:** Lumen reappears as the bend is traversed.

Depth of Insertion. Although it is desirable to pass the sigmoidoscope the entire 25 cm, complete insertion is often not possible. In fact, even in the hands of an experienced sigmoidoscopist, the average depth of insertion is 16 to 20 cm. Furthermore, it is important to note whether the sigmoidoscope is advancing up the lumen or merely pushing the rectal mucosa.

Examination of the Mucosa. Examination of the mucosa is conducted on slow withdrawal of the instrument. The tip is swept circumferentially to visualize all areas of the wall, and air is injected in small amounts to flatten out folds and allow adequate inspection. As noted earlier, the normal mucosa is pale pink, with a visible network of submucosal blood vessels. Some blood produced from enema tip trauma may be present. The mucosa should be examined and described; any lesions should be noted, and the distance from the anal verge should be recorded. Occasionally, blood may be found to come from a point above the reach of the instrument; this should be noted.

Biopsy Specimens. Biopsy specimens of suspected lesions and abnormal mucosa may be obtained with angled forceps. Mucosal biopsy specimens should be shallow and taken from the posterior rectal wall, where the risk for perforation is small. Bleeding from biopsy sites usually stops with pressure from a swab or by application of silver nitrate sticks. Because of the risk for perforation, barium enema examination should be avoided for at least 5 days after a sigmoidoscopic biopsy.

Complications. Perforations are rare, occurring in no more than 1 in 10,000 sigmoidoscopies; they are more likely if the examiner persists in pushing the sigmoidoscope forward in a bowel that is fixed at any point, as by tumor. Bleeding from biopsy sites is infrequent. Arrhythmias have been reported rarely. Informed consent should be obtained before the procedure.

Flexible Sigmoidoscopy

The flexible sigmoidoscopes used most widely in office practice are fiberoptic instruments that are 60 to 65 cm long with large-caliber suction and biopsy channels, full control of tip deflection by two-hand dials, and controls for air insufflation and water instillation. The diameter of the shaft is 11 mm, making the instrument narrower and longer than the rigid sigmoidoscope. The control dials and buttons are managed with the left hand as the examiner views the colon through the eyepiece; advancement of the instrument up the colon is accomplished with the right hand. Acute angulations of the colon are traversed by various combinations of tip deflection, shaft twisting, and repetitive back-and-forth motions; however, even accomplished sigmoidoscopists may encounter difficulty in advancing the instrument through very sharp angles.

Preparation. The procedure can be performed in the office, usually with no sedation or anesthesia and with a preparation of only one or two Fleet Phospho-Soda *enemas.* Some physicians prefer a more rigorous preparation, such as one bottle of *magnesium citrate* taken orally in addition to two Phospho-Soda enemas. In some offices audio or audiovisual stimulation is used to relax the patient during the procedure.

Competency. Competency in flexible sigmoidoscopy is usually achieved after performance of about 25 examinations under the supervision of a qualified mentor. Newer video-endoscopes with which the colonic lumen is viewed on a television screen rather than through the eyepiece of the sigmoidoscope are generally used in modern endoscopy suites but are too expensive and impractical for most outpatient primary care practices. The flexible sigmoidoscope has not been widely evaluated in a primary care setting staffed by physicians with no prior experience in flexible endoscopy. Experience to date suggests that nearly any physician as well as nurse practitioners and physician assistants can learn to use the flexible instrument, but only with appropriate supervised instruction.

Comparison with Rigid Sigmoidoscopy. The advantage of the flexible sigmoidoscope over the rigid sigmoidoscope is its ability to examine a longer segment of colon. Whereas the average depth of insertion of the rigid instrument is no more than 20 cm, the average depth of insertion for the flexible instrument in the hands of experienced endoscopists is about 50 cm.

Diagnostic Yield. The yield of flexible sigmoidoscopy is greater than that of rigid sigmoidoscopy. For example, in comparative studies, the flexible instrument identified two to six times more neoplasms and detected some abnormalities, such as diverticula, not generally within reach of the rigid sigmoidoscope. The yield of the flexible sigmoidoscope when used for CRC screening by primary care physicians appears to be acceptable in comparison with the yield obtained with the rigid instrument or by experienced endoscopists. The apparent advantages of flexible sigmoidoscopy must be weighed against the observation that as a screening test, it detects only about half of colorectal polyps and cancers. Moreover, patients undergoing either rigid or flexible sigmoidoscopy for gastrointestinal symptoms may still require additional tests, such as a barium enema or colonoscopy, to complete the evaluation. Thus, the decision to perform flexible rather than rigid sigmoidoscopy in a given instance may be more a matter of physician preference and convenience than of an apparent improvement in diagnostic yield. The clearest advantage of flexible over rigid sigmoidoscopy would appear to be in the screening of asymptomatic patients for CRC, in which case a barium enema or colonoscopy would not be performed unless indicated (see above).

Patient Acceptance, Expense, and Convenience. Patients tolerate the flexible instrument as well as or better than the rigid instrument. However, flexible fiberoptic instruments are much more expensive than disposable plastic rigid sigmoidoscopes and more likely to be damaged, and they require occasional costly repairs. In addition, the flexible instrument must be cleaned thoroughly and disinfected between patients according to rigid protocols, as required by the Occupational Safety and Health Administration (OSHA), and the average duration of examination is at least 10 minutes, so that the time involved in using the instrument per patient is much greater for the flexible than for the rigid instrument. Moreover, cleaning and proper care of the flexible sigmoidoscope require a trained assistant. In a busy clinical practice, use of the flexible sigmoidoscope may be less practical and efficient than use of the rigid instrument. Recently, a flexible fiberoptic sigmoidoscope with a disposable sheath has been introduced; in preliminary studies, it appears to be a reasonable alternative to the standard flexible fiberoptic instrument and obviates the need for rigorous mechanical cleaning and disinfection between cases.

Choice of Procedure

- Rigid sigmoidoscopy is certainly acceptable when a careful examination for rectal pathology is desired, when one is monitoring the activity of ulcerative colitis or evaluating the cause of infectious colitis, and when one wants to avoid contaminating a flexible scope. Although it is not as sensitive a screening test for CRC as is the flexible sigmoidoscope, its use in conjunction with FOBT does decrease CRC mortality in a cost-effective manner.
- Flexible sigmoidoscopy is the more sensitive test for CRC screening and is preferred when determining the source of recurrent rectal bleeding, evaluating a radiologically detected lesion in the sigmoid colon, searching for colitis in a patient with normal rectal mucosa, and evaluating a patient with suspected diverticulitis (see Chapter 75). However, it requires more training to use well and is more expensive to maintain.
- In general, it would seem wise for primary physicians to master the technique of rigid sigmoidoscopy and to consider learning the technique of flexible sigmoidoscopy only if willing to commit sufficient time to develop true proficiency. Unless expertise has been achieved, the primary care physician should refer patients in need of flexible sigmoidoscopy to a gastroenterologist or surgeon skilled in performing the examination.

APPENDIX: EVALUATION OF THE PATIENT WITH AN INCIDENTAL ASYMPTOMATIC ELEVATION IN SERUM TRANSAMINASE (AMINOTRANSFERASE) LEVELS

An incidental asymptomatic elevation in serum transaminase (aminotransferase) is not infrequently encountered during routine blood testing. Transaminases are often included in standard multiphasic testing packages, so that their determination in the absence of a true clinical indication is rather common. In settings in which the pretest probability of underlying hepatocellular disease is very low, most elevations are likely to represent false-positive results that warrant only a repeated determination in 4 weeks and cessation of intake of alcohol and any potentially offending drugs. However, before the finding is dismissed, it is important to review the history for risk factors for important conditions associated with long-term subclinical hepatocellular injury.

Differential Diagnosis. The causes of such low-grade, subclinical hepatocellular injury include mild, chronic, active *hepatitis C, hepatitis B*, and hepatitis associated with *autoimmune* disease (including primary biliary cirrhosis). Chronic occult liver injury may also occur in *hereditary hemochromatosis*, the most common genetic disorder among white Americans. Fatty liver is an important cause, resulting in half of instances from surreptitious *alcohol* abuse; *nonalcoholic steatohepatitis* accounts for the remainder of cases. About half of cases of nonalcoholic statohepatitis are a consequence of *obesity, hyperlipidemia*, or *diabetes*, but for another 40% to 50% of cases, no clear precipitant can be found. A rare cause of isolated transaminase elevation is *Wilson's disease*.

Workup. Before a workup is undertaken, the transaminase level should be measured again in 4 weeks, after the patient has refrained from alcohol and any noncritical drugs with potential to cause hepatocellular injury. Once the elevation is confirmed, a focused workup should ensue.

History is reviewed for risk factors for viral hepatitis (see Chapter 57) and alcohol abuse (see Chapter 233), for symptoms of autoimmune disease (see Chapter 146), and for a family history of hemochromatosis or its complications (cirrhosis, heart failure, diabetes, arthritis) not explained by other causes. More commonly, persons with hereditary hemochromatosis may first note fatigue and arthralgias. Medications need to be reviewed in detail. In addition, a review of symptoms pertinent to estimating the severity of hepatocellular injury (fatigue, easy bruising, jaundice) should be included.

Physical Examination should be noted for any etiologic clues, such as hyperpigmentation, arthritis, and liver enlargement. Examining for signs of hepatocellular injury (jaundice, ecchymoses, spider angiomata) is also warranted.

Laboratory Studies can begin with an assessment of the type and severity of hepatocellular injury. Measuring the *alkaline phosphatase* level helps to determine if the problem has a cholestatic component (see above). The *serum albumin* and *prothrombin time* are the best parameters of hepatocellular synthetic function and helpful in determining degree of injury. Potentially useful diagnostic tests should be selected on the basis of clinical suspicion and not simply ordered uncritically as a standard panel for assessment of an isolated SGOT elevation.

If alcohol abuse is suspected, the diagnosis might be supported by a determination of the *SGPT* (ALT) and SGOT (AST); an SGPT-to-SGOT ratio of 2:1 is characteristic of alcoholic liver injury. Risk factors for viral hepatitis are an indication for *hepatitis serology* (e.g., antibodies to hepatitis B virus, hepatitis C virus, and hepatitis B surface antigen; see Chapter 57). Any suspicion of autoimmune disease is an indication foran antinuclear antibody determination (see Chapter 146) in addition to an *antimitochondrial antibody* determination. *Ultrasonography* is helpful to assess suspected fatty liver and the cholestatic pattern on liver function tests (see above).

If the patient has a family history of idiopathic cirrhosis or other features of suggestive of hemochromatosis (fatigue, arthralgias, poor libido, diabetes), the serum *iron, transferrin* (total iron-binding capacity), and *ferritin* should be measured. A transferrin saturation (ratio of serum iron to total iron-binding capacity) above 45% is the screening threshold used by most authorities to diagnose hemochromatosis. The ferritin concentration helps determine the degree of iron overload; treatment is usually indicated when it is above 300 µg/L in men and above 200 µg/L in women. The young patient with concurrent neuropsychiatric disease should be considered for a serum ceruloplasmin determination to check for Wilson's disease.

A key question is the utility of *liver biopsy* in persons who present with incidental transaminase elevation. Biopsy is certainly useful to determine disease extent and severity when a particular condition has been identified before biopsy (e.g., hepatitis C), but the contribution of biopsy to diagnosis in idiopathic cases is less clear. In a review of biopsies performed in such cases, steatosis was found in the vast majority of cases, and chronic hepatitis plus cirrhosis accounted only for about a fourth. One needs to ask if the result will change management of the patient; if so, then biopsy for diagnosis is worth considering. Given the high frequency of occult steatosis, one might take an alternative approach to biopsy in the obese or diabetic person and recommend exercise, diet, and weight loss followed by a repetition of liver function tests.

APPENDIX: MANAGEMENT OF HEMORRHOIDS

Hemorrhoids are a source of much misery, although they are of no consequence unless they become thrombosed, prolapse, or bleed. Therapy is directed toward relief of symptoms and should be accomplished with a minimum of discomfort, cost, and time lost from work. Simple approaches to pain relief and sensible modification in bowel habits to prevent progression constitute the essentials of medical therapy. The primary physician must be certain that symptoms are attributable to hemorrhoids, alleviate any anxiety about neoplasm, provide conservative medical therapy, and decide on the need for and timing of surgery.

PRINCIPLES OF MANAGEMENT

In most cases, it is not necessary to remove hemorrhoids to treat them effectively. Symptomatic relief and a halt to progression can usually be achieved by use of simple local measures and minor changes in diet. For a painful attack, a *cold pack* applied for the first few hours offers considerable relief. Hot *sitz baths* (with a little salt added to the water to make it a more isotonic solution) are soothing and effective when used at least once or twice daily for about 20 to 30 minutes. Softening the stool helps minimize straining and can be accomplished by increasing *dietary fiber* and making short-term use of *stool softeners* (e.g., dioctyl sodium sulfosuccinate). Irritant laxatives should be avoided. Patients should set aside a regular time each day to have an unhurried bowel movement and avoid vigorous wiping. Stubborn itching and inflammation respond well to *topical corticosteroids*; *hydrocortisone cream* and suppositories are adequate and relatively inexpensive. Topical hydrocortisone cream (1%), which can be purchased without a prescription, provides good relief from itching caused by mild inflammation of anal tissue. It has been added to many of the popular over-the-counter preparations, although generic hydrocortisone is the least expensive formulation.

A host of *over-the-counter preparations* are heavily promoted. Many contain a topical anesthetic, such as benzocaine or pramoxine. *Benzocaine* may produce some temporary pain relief, but it is quite sensitizing; the resultant allergic response may actually worsen symptoms. *Pramoxine* is another topical anesthetic found in popular over-the-counter preparations (Anusol, Tronolane Cream, and so forth). It is similar in efficacy to benzocaine but is less sensitizing; it acts within 3 to 5 minutes of application, and effects lasts several hours. However, the cream formulation can still be irritating because of the presence of paraben preservatives. *Preparation H* is among the best-selling and most widely advertised over-the-counter hemorrhoidal therapies. It contains shark liver oil, live yeast cell derivatives, and phenyl mercuric nitrate; none of these agents, singly or in combination, has been shown to have any beneficial effect on hemorrhoids, although they are promoted as being able to shrink hemorrhoids and reduce inflammation.

Hemorrhoids that bleed repeatedly, prolapse, produce intractable pain, or become thrombosed deserve surgical evaluation. Internal hemorrhoids that have been bleeding persistently or have prolapsed can be removed in the surgeon's office with the use of *rubber band ligation*. A rubber band is placed at the base of the hemorrhoid; within a week the lesion sloughs. Multiple attempts are sometimes necessary. *Injection of sclerosing agents* (e.g., 5% phenol in oil) into the upper pole of internal hemorrhoids is another means of dealing with them; the procedure has fallen out of favor because of its association with scarring of the anal canal. *Cryosurgery* is relatively painless and does not require anesthesia, but a foul-smelling discharge is produced for about a week after the procedure, and stricture is occasionally a late occurrence. Excruciatingly painful external hemorrhoids that have become thrombosed can be excised under local anesthesia and the *clot removed*. Excellent nonsurgical results have been reported with the use of heat delivered through an infrared *photocoagulation probe* to treat first- and second-degree hemorrhoids. The heat is directed to the root of the hemorrhoid to interrupt its vascular supply, which causes it to contract.

Definitive *hemorrhoidectomy* is the treatment of last resort. In contrast with the other surgical therapies mentioned, it requires hospitalization, and the recovery period can last several weeks. Moreover, there is a risk for compromising the competence of the anal sphincter. Nevertheless, it does represent a serious treatment option for patients with disabling, refractory disease.

THERAPEUTIC RECOMMENDATIONS

- Advise frequent hot sitz baths for relief of pain. At the initial recognition of pain, the patient can apply a cold pack for the first few hours, then take hot baths three or four times a day.
- If inflammation and itching are present, prescribe a suppository preparation containing a steroid (e.g., hydrocortisone). If symptoms are predominantly external, prescribe 1% or 2.5% hydrocortisone cream.
- Topical anesthetics may be useful for the acute relief of severe pain. If this form of therapy is to be used, an agent that is minimally sensitizing (e.g., pramoxine) should be chosen.
- Treat constipation by having the patient increase dietary fiber and use a stool softener, such as 100 mg of dioctyl sodium sulfosuccinate three times daily. After resolution of acute symptoms, the high-fiber diet should be continued.
- For thrombosed hemorrhoids, the following measures may be helpful:
    1. Instruct the patient to lie prone with ice applied to the thrombosed hemorrhoid.
    2. Prescribe oral analgesics; codeine may be required.
    3. Prescribe stool softeners.
    4. Conservative therapy should be successful in 3 to 5 days; otherwise, refer the patient for surgical removal of the clot, which will relieve the pain promptly.
- Intractable symptoms require surgical therapy. The specific method chosen depends on the surgical expertise available in the community.

PATIENT EDUCATION AND PREVENTION

Instruction concerning proper diet and bowel habits is extremely helpful.

- Advise the patient to increase the intake of dietary fiber; suggest bran, carrots, green vegetables, and fruits with skin. Consider use of a psyllium preparation. Some people find foods such as chili, onions, and alcohol irritating. If this applies to your patient, suggest that they be avoided.
- Emphasize the importance of providing a regular time to have bowel movements. After bowel movements, the patient should avoid vigorous wiping; patting ought to suffice, and it minimizes irritation.
- Instruct the patient not to linger on the toilet or strain at stool. Long periods of standing should be avoided.
- Caution the patient against the use of irritant laxatives.
- At the first sign of recurrent symptoms, institute frequent hot sitz baths.
- Instruct the patient to pat dry rather than wipe or rub.

APPENDIX: USE OF PSYCHOTROPIC DRUGS IN THE ELDERLY

MICHAEL A. JENIKE

PHARMACOKINETIC CHANGES ASSOCIATED WITH AGING

Significant changes in drug absorption and distribution, protein binding, hepatic metabolism, and renal excretion occur in elderly patients. Gastric pH increases and splanchnic blood flow decreases, altering drug solubility and absorption. Total body fat rises from 10% of body weight at age 20 to 24% at age 60, which increases the volume of distribution for lipid-soluble drugs, such as diazepam and its metabolites, and greatly prolongs drug half-life. In addition, total body water may decrease from 25% to 18% in the same period, so that the concentrations of water-soluble drugs, such as ethanol, are higher because of decreased reservoir size. Serum albumin levels decline by 10% to 15%; as a consequence, protein-binding sites are decreased and more free active drug is released into the circulation, raising the risk for toxicity. Drug metabolism slows; the activity of hepatic cytochrome P-450 decreases, as does demethylation. The result is higher levels of unmetabolized drug. After age 40, the glomerular filtration rate and renal plasma flow decline progressively. By age 70, the reduction is about 50%, which prolongs drug action and increases the likelihood of toxicity if the dosage is not adjusted downward.

In addition to these pharmacokinetic changes, decreased levels of dopamine and acetylcholine in the central nervous system can lead to an increase in extrapyramidal and anticholinergic side effects, respectively. An increased tendency to central nervous system disinhibition in the elderly increases the likelihood of drug-associated confusion, sedation, and paradoxical reactions.

Neuroleptic Use. Violence, rage, and psychosis are common problems in patients with Alzheimer's disease. The drugs most commonly used to treat these problems are the neuroleptics (Table 173-1). Initial treatment with neuroleptics is indicated when psychotic symptoms are present, such as paranoia, delusions, and hallucinations. All the neuroleptics are equally effective in treating the above symptoms. The choice of a particular drug is based on its side effects and toxicity. The main side effects of neuroleptics are sedation, orthostatic hypotension, extrapyramidal symptoms, and anticholinergic symptoms. The newer *atypical neuroleptics* (e.g., *clozapine*, *quetiapine*) cause fewer side effects and may provide better treatment for these symptoms (Table 173-2).

A fairly consistent relationship is found between the potency of a neuroleptic and its side effects; as the milligram potency of a neuroleptic increases, the frequency and severity of sedation, orthostatic hypotension, and anticholinergic symptoms decrease, and extrapyramidal symptoms increase. *High-potency neuroleptics*, such as *haloperidol*, *thiothixene*, and *fluphenazine*, are generally safe to use in the elderly, but they should be started at very low doses (e.g., 0.5 mg of haloperidol once or twice daily). Although generally safe, these drugs are more likely than low-potency agents (e.g., chlorpromazine or thioridazine) to produce extrapyramidal symptoms in the elderly. Extrapyramidal symptoms develop in as many as 50% of all patients between the ages of 60 and 80 who are given neuroleptics, and those with brain damage, dementia, or Parkinson's disease are much more sensitive to these effects.

Sedation. Side effects can be used therapeutically. The patient who has trouble falling asleep will find sedating neuroleptics to be more helpful than nonsedating agents. Sedating neuroleptics may also be used to calm an agitated patient during the day. More commonly, however, sedation is an unwanted side effect. Daytime sedation may cause or aggravate nighttime insomnia, and sedation may also increase confusion and disorientation in the demented patient. As disorientation and confusion increase, the patient typically becomes more agitated.

Postural Hypotension. One of the most severe dangers entailed in the use of neuroleptics is the possibility of inducing *orthostatic hypotension*, which can lead to falls and fractures, stroke, or even heart attack. Hypotensive episodes are especially apt to occur at night when an elderly patient awakens and gets up to urinate.

Extrapyramidal Effects. The most troubling extrapyramidal symptoms are akathisia, parkinsonism, and akinesia. The newer atypical neuroleptics adequately treat these symptoms with fewer side effects. *Akathisia* is a feeling of motor restlessness associated with a subjective sensation of discomfort, often described as anxiety. Sleep is usually disturbed because the patient is unable to find a comfortable, motionless position. Sometimes, this restlessness is misinterpreted as an increase in psychotic symptoms and is treated with increased doses of neuroleptic dosage. A most effective treatment for akathisia is lowering the dose or switching to an atypical neuroleptic. Akathisia is also reported with the SSRIs.

Neuroleptic-induced *parkinsonism* appears to be identical to the postencephalitic or idiopathic forms. An occasional patient will be exquisitely sensitive to this side effect, and as little as one dose of a high-potency agent may precipitate the syndrome. In an effort to reduce the use of anticholinergic medications, it is best to reduce the dose and consider a switch to the newer atypical neuroleptics.

Tardive Dyskinesia. Tardive dyskinesia, one of the unfortunately common and severe side effects of any neuroleptic agent, is manifested by a wide variety of movements, including lip smacking, sucking, jaw movements, writhing tongue movements, chorea, athetosis, dystonia, tics, and facial grimacing. In severe cases, speech, eating, walking, and even breathing can be seriously impaired. The onset is gradual, usually developing after long-term, high-dose administration, but on rare occasions it can occur with short-term or low-dose use. Advancing age correlates not only with increased prevalence but also with severity. Once tardive dyskinesia has developed, it is much less likely to reverse in an elderly patient than it is in a younger one.

The best way to *prevent* tardive dyskinesia is to avoid the use of neuroleptics. Obviously, these drugs are sometimes required, but they should not be used when indications are unclear or when less potentially toxic drugs may be as efficacious. Neuroleptics should never be used to treat simple anxiety or uncomplicated depression, nor should they be given for long periods to patients with an *acute* psychotic episode. It is important to make a baseline examination before starting a patient on neuroleptics and to note any early signs of tardive dyskinesia, such as fine vermicular movements or restlessness of the tongue, mild choreiform movements of the fingers or toes, and facial tics or frequent eye blinks. The patient should be monitored for the development of early tardive dyskinesia at least every 3 months. Currently, no consistently effective agents are available to treat tardive dyskinesia. In view of the significant risk to the elderly patient and the ineffective treatment options, physicians should avoid the use of neuroleptic drugs in elderly patients whenever possible.

APPENDIX: STRATEGIES FOR STRESS MANAGEMENT

WILLIAM E. MINICHIELLO

Appendix: Strategies for Stress Management

Stress is not harmful when managed effectively. With the increased awareness of the impact of stress on the body has come a variety of stress-reducing techniques derived from behavior therapy. Stress management training enables the patient to condition his or her body to cope more adaptively with stress or anxiety. As part of a comprehensive treatment program, the primary care physician may choose to train the patient in one or more of the self-regulatory procedures. Relaxation training is by far the most effective of the procedures.

Before proceeding to train the patient in relaxation as a self-control procedure, the physician should advise reduction or elimination of caffeine from the patient's diet, because relaxation training is aimed at lowering the patient's autonomic arousal level and caffeine augments arousal.

Progressive deep muscle relaxation, autogenic training, and diaphragmatic breathing represent the major techniques practical for use in the primary care setting.

PROGRESSIVE DEEP MUSCLE RELAXATION

Progressive deep muscle relaxation is probably the most extensively used and most effective relaxation technique today for the treatment of anxiety and stress-related problems. A brief modified version can be taught to the patient in one session. The rationale for the technique is the view that anxiety and relaxation are mutually exclusive; that is, anxiety cannot be experienced when the muscles are relaxed.

Progressive deep muscle relaxation is a simple procedure contrasting tension with relaxation. Because a person generally has very little awareness of the sensation of relaxation, one is asked first to tense a set of muscles as hard as one can until they can feel tension in the muscles. Then one allows those muscles to relax and tries to become aware of ("to feel internally") the difference between tension and relaxation.

This relaxation technique entails the systematic focus of attention on specific gross muscle groups throughout the body. The patient is instructed to actively tense each muscle group for 10 to 15 seconds, after which they are told to let go of the tension in the muscles, observe the difference, and relax the muscles. The sequence of tensing the muscles, letting go of the tension, and noting the difference between tension and relaxation is systematically applied to a host of muscle groups starting at the head and ending at the toes (Table 226.5).

Table 226.5. Progressive Deep Muscle Relaxation Instructions to Patients:

AUTOGENIC TRAINING

Autogenic training is a relaxation technique composed of a set of exercises that are intended to induce heaviness and warmth in the muscles through mental imagery.

Autogenic training typically involves the patient sitting comfortably in an armchair in a quiet room with the eyes closed. Verbal formulas are introduced (e.g., "my arm is heavy"), and the patient is instructed to visualize and feel the relaxation of the muscle being focused on while silently repeating and passively concentrating on that formula. The formulas, which consist of verbal somatic suggestions, are intended to facilitate concentration and "mental contact" with the parts of the body indicated by the formula.

Training consists of six psychophysiologic exercises, which are practiced several times a day. The training begins with the theme of heaviness (e.g., "my arm feels heavy and relaxed"). The second group of formulas involve warmth (e.g., "my arm feels warm and relaxed"). After warmth training, the patient continues with passive concentration on cardiac activity (e.g., "my heartbeat feels calm and regular"). The fourth exercise focuses on breathing and respiration. In the next exercise, the patient focuses on warmth in the chest and abdomen, and in the last exercise the focus is passive concentration on cooling of the forehead.

In modern practice, the time and the six standard exercises have been condensed so that a whole round can be practiced in a very brief period of between 5 and 10 minutes. In this condensed version, the autogenic training phrases are focused primarily on the physiologic aspect used in the training, interspersed with general suggestions for relaxation. Each phrase is said slowly, allowing time for the patient to begin to feel some awareness of the effect of the suggestion (Table 226.6).

Table 226.6. Autogenic Training Instructions to Patients:

DIAPHRAGMATIC BREATHING

The quickest and simplest method of relaxation is to breathe slowly and deeply from the belly. Diaphragmatic breathing is an effective means of coping with and reducing stress.

For centuries, students of yoga and zen have been aware that a mastery of breathing could slow heart rate, lower blood pressure, and calm the body. Diaphragmatic breathing involves parasympathetic nervous system stimulation. Diaphragmatic breathing prevents the possibility of hyperventilation and, after 50 to 60 seconds of such breathing, brings a feeling of quiescence to the body and reduction in bodily symptoms of stress.

Training in diaphragmatic breathing can be done either sitting or lying down. In either position, a pillow should be placed at the small of the back to force the belly out. Breathing should begin by pushing the stomach out as inhalation takes place slowly and deeply. Care should be taken to minimize the movement of the chest with each inhalation. The word "relax" should be said silently before exhaling, and the stomach should fall with exhalation. While breathing in, the stomach should be pushed out; while breathing out, the stomach should come in (Table 226.7).

While sitting or lying down with a pillow at the small of your back

1. Breathe in slowly and deeply by pushing your stomach out.

2. Say the word "relax" silently to yourself prior to exhaling.

3. Exhale slowly, letting your stomach come in.

4. Repeat entire procedure 10 times consecutively, with emphasis on slow, deep breaths.

Practice should take place 5 times per day, 10 consecutive diaphragmatic breaths each sitting. Time for mastery is after 1–2 weeks of daily practice.

Table 226.7. Diaphragmatic Breathing Instructions to Patients:

APPENDIX: SCREENING FOR DOMESTIC VIOLENCE

Domestic violence is a prevalent and potentially fatal condition that frequently goes unrecognized, especially in the office setting. Estimates of the life-time risk for battering for women range from 10% to 30%. Barriers to recognition include the reluctance of the patient to bring up the problem, time pressures, and physician discomfort in dealing with it. Moreover, the presentation may be subtle, nonspecific, or confusing. Nonetheless, the screening and timely diagnosis of domestic violence are essential tasks for the primary care physician because prompt intervention can be life-saving, not only by protecting the patient from harm by a partner but also by protecting her from self-harm (one in every four women who attempt suicide have been victims of domestic violence).

Clinical Presentation. The vast majority of victims of domestic violence are women, outnumbering men in a ratio of 9:1. The condition occurs among people of all ages (e.g., elder abuse) and sociodemographic groups. A wide range of office presentations is possible, with chronic pain or chronic gynecologic symptoms often prominent. Unexplained headache, worsening symptoms of a chronic condition, depression, anxiety, dyspareunia, severe premenstrual symptoms, irritable bowel symptoms, and alcohol abuse are among the presenting manifestations. In addition to physical harm, patients are at increased risk for somatization disorders, complications of pregnancy, sexually transmitted diseases, eating disorders, substance abuse, and noncompliance with medical regimens. Repeated visits to the emergency room for "falls" or forearm injuries (sustained during attempts at self-defense) are characteristic, as are findings such as multiple ecchymoses in various stages of healing. Other characteristics of trauma include a central distribution of injuries, involvement of the head and face, and hearing loss. Being accompanied to the office or emergency room by an overly aggressive partner is also typical.

Screening and Diagnosis. Given the frequency and importance to health of domestic violence, the problem should be screened for on a regular basis as part of the periodic health examination. A more in-depth consideration of the diagnosis is indicated when a patient reports chronic pain, unexplained worsening of a chronic condition, or one of the other typical presentations of domestic violence noted above. A *sine qua non* of the evaluation is that the patient be examined alone by a qualified health professional without the spouse, partner, family members, or friends being present. Although patients rarely present to the office complaining of domestic violence, they often demonstrate considerable relief and a willingness to discuss it once the subject is broached by the primary care physician.

A few simple screening questions preceded by a general comment about the importance of checking for domestic violence usually suffice:

Do you ever feel unsafe at home?

Has anyone at home hit you or tried to injure you in any way?

These questions have been validated for diagnostic accuracy, demonstrating a sensitivity of 71% and a specificity of 85%. Some authorities also suggest a few questions that can elicit evidence of fear of a partner's intimidating or controlling behavior:

Have you ever been afraid of your partner?

Has anyone ever threatened you or tried to control you?

Others have proposed the mnemonic SAFE to help facilitate asking questions that address **S**afety, **A**buse, **F**riend or family awareness, and **E**mergency escape plan.

If the response to any of these questions is positive, the physician should obtain a full description of the problem and perform a pertinent physical examination for any evidence of injury. Confidentiality is essential to patient safety, and all records (including telephone numbers and billing diagnoses) should be handled carefully with patient protection as the priority.

Obtaining Help. An essential component of the visit that uncovers domestic violence is to arrange for professional help. Information on local services can be obtained by calling the National Domestic Violence Hotline (1-800-799-SAFE). Patients appreciate knowing that the help to be offered is professional, typically free of charge, and designed to provide for safety and counseling. Having a member of the primary care team, preferably a trained social worker, help the patient access community services is often welcomed.
