Cough Suppressants, including narcotics such as *codeine* and non-narcotic agents such as *dextromethorphan*, are effective and useful symptomatically, especially in allowing the patient to sleep uninterrupted by cough. In many patients, a decongestant is even more effective in suppressing cough because postnasal drip accounts for much of the cough stimulus. These agents are commonly available in combination with expectorants, although they may be prescribed alone, which is more sensible therapy.

Zinc is thought to inhibit viral attachment and replication and improve cellular immune function. Such effects have stimulated interest in its use as a treatment for the common cold. The results of well-designed, controlled studies utilizing zinc gluconate lozenges have been equally divided between showing efficacy and showing no benefit. In the studies with positive findings, adequate blinding has been questioned because zinc lozenges have a distinct taste that may alert study subjects to their allotted treatment. The studies with negative findings have been criticized for subtherapeutic doses or ineffective preparations. One highly publicized study of 100 patients recruited from hospital employees demonstrated a significant reduction (nearly 40%) in the duration of illness, and also in the duration of coughing, nasal drainage and congestion, hoarseness, headache, and sore throat. The lozenges in this study contained 13.3 mg of zinc, and patients were instructed to take them every 2 hours while awake (average of six per day). Side effects included nausea and a bad taste in the mouth, experienced by most of the patients. Patients may be informed of the possible benefit of zinc lozenges but should be forewarned about the likely side effects.

Echinacea. Extracts from plants of the genus *Echinacea* have gained widespread acceptance in Germany as a treatment for the common cold. These plant products are postulated to have immunomodulator activity, such as macrophage activation and interleukin production. Although many randomized trials have suggested a benefit in the reduction of symptoms, the interpretation of results is complicated by the variety of species used (*E. purpurea, E. pallida*, and *E. angustifolia*) and the different plant parts (root or herb) and formulations (tablets, liquid extracts, capsules). Further studies based on standardized preparations and validated outcome measures will be needed before recommendations may be made for or against the use of *Echinacea*.

Other Agents and Combination Preparations. Americans spend nearly a billion dollars annually on over-the-counter cold remedies. Most contain a combination of ingredients, including first-generation sedating antihistamines, sympathomimetic amines, and analgesics. Some even contain more than one antihistamine or sympathomimetic. Antitussives, *atropine, caffeine, vitamin C, belladonna alkaloids*, and expectorants are other common additives. *Antacids, laxatives, quinine*, and *papaverine* are found occasionally. In general, these combination preparations should not be recommended as first-line therapy. As noted above, the vitamin C included has not been shown to have any significant effect, even when given in gram doses.

Management of Influenza

If the diagnosis of influenza is confirmed or highly suspected, several medications may be useful in decreasing the duration of symptoms if administered within the first 48 hours of the illness. *Amantadine* and *rimantadine* are oral antiviral drugs effective against influenza A only. Rimantadine is more expensive but has fewer side effects, notably less central nervous system effects. The dosage for both drugs is 100 mg twice daily except in the elderly, in whom decreased drug clearance allows for once-daily dosing. The drug should be discontinued after 3 to 5 days (or earlier if symptoms resolve) to decrease the opportunity for drug resistance, which may occur in up to one third of treated patients.

Neuraminidase inhibitors, zanamivir and oseltamivir, are newly approved agents for the treatment of influenza. These drugs are sialic acid analogues that inhibit the viral neuraminidase enzyme, essential to replication for both influenza A and influenza B. Early randomized trials of these agents show a decrease in the duration of illness of 1 to 1.5 days if the drug is administered within 48 hours of symptom onset, similar to the effect seen with the older agents. Zanamivir is administered by an inhaler twice daily; oseltamivir is given as a pill (75 mg) twice daily. The advantage of these newer agents is their activity against both influenza A and influenza B; they have not been in use long enough to determine whether viral resistance will be problematic. In addition, because the average cost of these agents is at least 10 times greater than that of influenza vaccine, vaccination is clearly the more cost-effective method to avoid flu symptoms.

PATIENT EDUCATION

Among the most frustrating experiences in primary care practice is the request by patients suffering from a cold for *antibiotics*. Explaining that antibiotics have no role in an uncomplicated viral upper respiratory infection can be time-consuming at best and has the potential to develop into a power struggle. A proactive approach is to send educational materials to patients at the beginning of the upper respiratory infection season. Pamphlets and other informational materials are much appreciated by patients and can help cut down on unnecessary visits and telephone calls. They should include helpful hints at self-care and the indications for seeking medical attention (e.g., high fever; marked pain or tenderness in an ear or sinus; increasingly purulent sputum, dyspnea, pleuritic chest pain). The role of antibiotics in the treatment of viral upper respiratory infection should also be reviewed (i.e., only for complications such as otitis and sinusitis), in addition to the risks of unnecessary antibiotic therapy (e.g., allergic reactions, alteration of bacterial flora, emergence of resistant strains). Unnecessary office visits and telephone calls have been reduced by as much as 30% to 40% through well-designed educational efforts.

THERAPEUTIC RECOMMENDATIONS

Prevention is difficult, but *hand washing*, keeping fingers away from mucous membranes, and avoidance of droplet exposure may help. Relief from cold symptoms and

avoidance of complications are facilitated by rest, adequate fluid intake, aspirin, and perhaps inhalation of steam. Taking a *cough suppressant* before bed (e.g., 15 mg of codeine sulfate) and using a *sympathomimetic* nasal decongestant spray for a few days (e.g., phenylephrine; see Chapter 219) may aid in symptomatic management and are superior to expensive combination agents. Symptoms of incapacitating rhinorrhea and sneezing not wellcontrolled by *first-generation antihistamines* may be treated with a short course of *ipratropium* nasal spray (two sprays of a 0.06% solution in each nostril four times daily). Proactive patient education just before the beginning of the cold season may help reduce unnecessary office visits, telephone calls, and requests for antibiotics. Zinc and *Echinacea* remain popular among patients, but their efficacy has not been clearly demonstrated. *Second-generation antihistamines* and antibiotics are of no use in an uncomplicated viral upper respiratory infection.

CHAPTER 51 MANAGEMENT OF SARCOIDOSIS

Sarcoidosis is a disease characterized by the formation of noncaseating granulomas, particularly in the lungs but also throughout the rest of the body. The precise cause remains unknown, but activation of T-cell lymphocytes in the lung plays an important role in the pathogenesis of granulomas. In the United States, sarcoidosis is 10 times more prevalent in African-Americans than in whites; people of Scandinavian descent also have a high incidence of the disease. Women outnumber men. Onset is most often between the ages of 20 and 45.

Although a large percentage of patients with sarcoidosis are asymptomatic, diverse and clinically important syndromes do result. Granuloma formation in the lung can be especially damaging, as can involvement in a number of other organ systems (e.g., eye, gastrointestinal tract). Once the diagnosis is established, the prime management decision regards the need for corticosteroid therapy. Improved methods of monitoring disease activity have enhanced the clinician's ability to treat sarcoidosis effectively while minimizing the risk for adverse effects from long-term steroids. The primary physician must know the most efficacious means of establishing the diagnosis, determining disease activity, and deciding on whether therapy with systemic steroids is needed, and for how long.

PATHOPHYSIOLOGY, CLINICAL PRESENTATION, AND COURSE

Pathophysiology. The cause of sarcoidosis is unknown. A variety of infectious and exogenous agents have been suggested as inciting factors, but whether one or several agents are involved remains conjectural. It is suspected that the granulomas and inflammatory reactions of sarcoidosis are caused by an abnormal immunologic response to a provocative agent in susceptible hosts.

Although the cause of sarcoidosis is unknown, the pathogenesis of granulomatous inflammation is being clarified. Bronchoalveolar lavage studies reveal that the early stage of pulmonary sarcoid consists of an alveolitis, with an increased number of T lymphocytes. Helper T cells predominate, and "activated" lymphocytes, capable of secreting various soluble mediators or lymphokines that may recruit monocytes and transform them into the macrophages of granulomas, are increased in number. The alveolitis of early disease and subsequent granulomatous inflammation are reversible, either spontaneously or with corticosteroid therapy, but the fibrosis that characterizes advanced chronic sarcoidosis is irreversible.

In contrast to the lungs, in which the numbers and activity of helper T cells are increased, the peripheral blood of patients with sarcoidosis may show a decreased number of T lymphocytes; this may account for the depressed cell-mediated immunity and cutaneous anergy observed in many such patients. However, the blood of patients with sarcoid often reflects increased activity of B lymphocytes, which accounts for the hypergammaglobulinemia and elevated antibody levels and circulating immune complexes that are often observed.

The granulomas of pulmonary sarcoidosis often resolve spontaneously, leaving the lung morphologically unscathed. However, in about 20% of patients, the process is more destructive and is characterized by interstitial fibrosis, obliteration of capillaries, and destruction of the pulmonary architecture. The end stage is characterized by the formation of cystic spaces interspersed with bands of connective tissue.

Clinical Manifestations of sarcoidosis reflect the sites of granulomatous inflammation. The most common presentation, especially in young adults, is *bilateral hilar adenopathy*, which occurs in 50% of patients and is often detected on routine chest radiography. About 25% present with bilateral hilar adenopathy and *pulmonary infiltrates*, and 15% present with infiltrates alone. Disease in the hilum is not associated with invasion or compression of the bronchi or nodal calcification. *Erythema nodosum* or *uveitis* (manifested by red, watery eyes) may accompany hilar adenopathy. Some patients exhibit *cough, shortness of breath, wheezing* or chest discomfort, in addition to constitutional symptoms of *fever, malaise*, and *fatigue*.

Although pulmonary symptoms are the most frequent, sarcoidosis may present with extrathoracic disease, including *hepatomegaly, splenomegaly*, or uveitis. Other presenting manifestations include *fever of unknown origin*, granulomatous *hepatitis*, salivary and lacrimal gland enlargement, *arthritis*, peripheral *adenopathy*, and skin lesions. *Hypercalcemia* as a consequence of increased sensitivity to vitamin D is reported in 10% to 30% but is sustained in only 2% to 3%. Cardiac conduction abnormalities, such as heart block, and neurologic abnormalities, including facial palsies, are each seen in about 5% of cases. In addition, many unusual presentations have been reported.

DIAGNOSIS

The diagnosis of sarcoidosis is sometimes a clinical challenge because the condition may be hard to distinguish from other interstitial lung diseases (see appendix to this Chapter). However, *asymptomatic bilateral hilar adenopathy*, with or without uveitis or erythema nodosum, is likely to be a manifestation of sarcoidosis. In a retrospective series of 100 patients with bilateral hilar adenopathy, conducted before the advent of AIDS, all 30 patients who were asymptomatic had biopsy-proven sarcoidosis. Moreover, 50 of 52 with bilateral hilar adenopathy and negative physical examination findings also had the disease. All 11 patients with neoplasms were symptomatic, and nine had easily identifiable extrathoracic tumor on physical examination. Among symptomatic patients, all with erythema nodosum or uveitis had sarcoid. Thus, in the patient with bilateral hilar adenopathy who is asymptomatic and HIV-negative, and who has negative physical examination findings or erythema nodosum or uveitis, a biopsy is not necessarily required to confirm the diagnosis of sarcoidosis. Nevertheless, some clinicians prefer to obtain a tissue diagnosis in all casesof sarcoidosis, including those with asymptomatic bilateral hilar adenopathy.

A decision to perform a *biopsy* must be made by viewing the potential for discovering treatable conditions and balancing this probability against the risks associated with the procedure. For the tissue diagnosis of hilar adenopathy, *mediastinoscopy* is the most direct approach and is usually well tolerated. For the documentation of pulmonary sarcoid, *fiberoptic bronchoscopy* with *transbronchial biopsy* is favored. This procedure has a reported sensitivity of 60% to 80%. In addition, bronchoscopy allows direct visualization of the bronchial tree, so it can be helpful in ruling out tumor and obtaining samples of secretions by *bronchoalveolar* lavage for laboratory study. The major complication of transbronchial lung biopsy is pneumothorax; this is infrequent when the procedure is performed by someone with experience.

In patients with extrathoracic sarcoidosis, accessible sites for biopsy include skin lesions and enlarged peripheral lymph nodes. Biopsy of conjunctivae, salivary glands, and liver may reveal noncaseating granulomas, even if clinical evidence of sarcoid in these tissues is absent. Because of the low morbidity associated with salivary gland and conjunctival biopsies, these may be particularly useful. It must be remembered that the histologic appearance of sarcoid granulomas is not etiologically specific. Therefore, the other known causes of noncaseating granulomas must be ruled out, including tuberculosis, syphilis, berylliosis, brucellosis, Q fever, biliary cirrhosis, Wegener's granulomatosis, drug reactions, and local sarcoid reactions in nodes draining solid tumors. Hodgkin's disease is particularly difficult to exclude with mediastinoscopy in patients presenting with unilateral or asymmetric hilar adenopathy.

The *Kveim test* has also been used in the diagnosis of sarcoidosis. The test requires the intracutaneous injection of heat-sterilized human sarcoid tissue, usually spleen. A positive reaction consists of the development of epithelioid granulomas detected on skin biopsy of the injection site at 4 to 6 weeks. The delay period, variability of the material available for injection, and high incidence of false-positive and false-negative results (resulting from impure batches of antigen) have limited the usefulness of the Kveim reaction. Furthermore, Kveim antigen is not readily available.

Other abnormalities that may be present in patients with sarcoidosis include cutaneous anergy, hyperglobulinemia, abnormal serum liver chemistries, and elevated levels of lysozyme; none of these findings is specific, but together they are supportive of the diagnosis. Similarly, films of the bones of the hands may reveal changes suggestive of sarcoid.

Serum levels of *angiotensin-converting enzyme* (ACE) are elevated in about 70% of patients with active sarcoidosis, but ACE determinations lack both sensitivity and specificity for establishing a diagnosis of sarcoidosis. ACE levels have been studied as markers of disease activity and therapeutic responsiveness, but results have

proved disappointing in clinical practice (see below). The same is true of *scanning with gallium 67* (^{67}Ga), although it can help identify extrathoracic disease.

STAGING, NATURAL HISTORY, AND CLINICAL COURSE

Staging. Intrathoracic sarcoidosis can be divided into *four stages*. In *stage 0*, the chest radiographic appearance is normal. In *stage I*, only bilateral hilar adenopathy is present; most patients are asymptomatic, the lung parenchyma appears normal on chest the film, and pulmonary function tests show normal mechanics, although the carbon monoxide diffusion capacity (DLCO) may be impaired. In *stage II*, both hilar adenopathy and pulmonary infiltrates are present; pulmonary function tests show predominantly restrictive defects. In *stage III* disease, pulmonary infiltrates are present, accompanied by obstructive and restrictive defects; however, hilar adenopathy has resolved. *Stage IV* is marked by advanced fibrosis, bullae, and cysts.

Natural History. Patients with clear lungs and asymptomatic hilar adenopathy have an excellent prognosis. In one large series of untreated cases, complete remission occurred in more than 75% within 5 years. In 50% with untreated pulmonary parenchymal involvement, complete resolution was seen within 2 years. In one third of those in whom clearing did not occur, severe fibrosis developed. Overall, at 5 years, 87% were clinically well, 10% had died of respiratory failure, and 3% were disabled by pulmonary disease.

Most natural history data derive from referral centers. In a report from a nonreferral setting, 86 patients were followed for 10 years in a primary care practice; pulmonary fibrosis developed in only 12, and none experienced respiratory failure or cor pulmonale. This latter study suggests that the course of sarcoid may be more benign than has been reported from referral centers, which are more likely to attract complicated cases.

In general, patients with stage I disease have an 80% chance of spontaneous remission, those with stage II disease have about a 50% remission rate, and those with stage III have about a 20% to 40% chance of spontaneous remission. Stage IV represents irreversible, advanced disease.

Extrathoracic Complications are infrequent. Hepatic granulomas are often present, but the development of clinically symptomatic *granulomatous hepatitis* is much less common; hepatic failure and portal hypertension are rare. Cranial and peripheral neuropathies tend to occur early in the disease and are usually transient; however, in some patients, significant neurologic damage is seen. *Uveitis* affects about 15%, comes on acutely, and often resolves spontaneously. More worrisome is chronic iridocyclitis; it presents as pain and blurring of vision, and cataracts, secondary glaucoma, and blindness may eventually develop. As noted above, *hypercalcemia* persists in about 2% to 3%, although it may be found transiently in up to 30%. Cardiac granulomas are found in 20% of sarcoidosis cases that come to autopsy, but fewer than 5% of patients experience difficulties with conduction or impulse formation. Rarely, infiltration of the myocardium produces pump failure.

The course of patients with sarcoid may occasionally be complicated by *infections* such as tuberculosis, aspergillar fungus balls, candidiasis, and cryptococcosis, attributable in part to the disease and in part to the use of long-term steroid therapy.

PRINCIPLES OF MANAGEMENT, THERAPEUTIC RECOMMENDATIONS, AND MONITORING

The *goals* in the treatment of sarcoid include *relief of symptoms* and *prevention* of significant impairment of organ function. As noted earlier, the natural history of sarcoid is variable, but often favorable. Hence, the indications for therapy are frequently unclear. Patients who present with stage I disease(asymptomatic bilateral hilar adenopathy or erythema nodosum) usually have a benign course, so that no treatment is indicated unless symptoms develop. Even patients with stage II or III disease may undergo spontaneous remission, and it is not possible to identify whose disease will progress and whose will remit. No evidence is available to indicate that treatment in the early phases of pulmonary sarcoid prevents progression to pulmonary fibrosis.

The view that emerges from available studies is that treatment should be reserved for patients who are symptomatic and have evidence of active pulmonary disease (dyspnea on exertion, abnormal results of pulmonary function studies, infiltrate on chest x-ray films). Gallium scanning and ACE determinations have also been used to provide evidence of disease activity, but in clinical practice they have not proved to be particularly accurate. Additional indications for treatment include important extrathoracic disease, such as uveitis, conduction abnormalities, hypercalcemia, neuropathy, and severe skin involvement (see below).

The principal treatment for sarcoidosis is *systemic corticosteroid therapy*. The great variability in the clinical course of the disease and the previous lack of sensitive indicators of disease activity have made it difficult to document rigorously the efficacy of steroid therapy. Older studies relied on such crude measures as symptoms, radiographic findings, and pulmonary function test values. Recent evaluations examining the effect of corticosteroids on more direct indicators of the disease process (see below) have found marked suppression of the alveolitis, but little influence on anatomic abnormalities present before the initiation of steroid therapy.

Most authorities recommend commencing with large doses of steroids (e.g., 40 to 60 mg prednisone), given on a daily basis for anywhere from 6 weeks to 6 months, then tapering or switching to alternate-day therapy if measures of disease activity indicate response. Improvement is usually evident by 2 to 3 weeks. Steroid therapy is most effective if instituted before the development of pulmonary fibrosis. However, there is no evidence that prophylactic treatment is worth the adverse effects of long-term steroid use (see Chapter 105).

Steroids consistently produce subjective improvement in dyspneic patients with early sarcoidosis and may even reduce pulmonary infiltrates when they are secondary to alveolitis or granulomatous changes. Lung volumes usually improve, but not necessarily the diffusion capacity, which may be permanently altered by destructive changes. Relapses after cessation of therapy are frequent, so that close monitoring is necessary for at least 12 months after discontinuation of treatment. *Alternate-day steroid therapy* (e.g., 15 to 25 mg every other day) has proved successful as a maintenance program in some patients, controlling disease when given after an initial course of daily steroids; this approach minimizes the adverse effects of long-term steroid therapy (see Chapter 105).

Adrenal corticosteroids are also indicated for active ocular disease. Every patient with sarcoid should have an ophthalmologic examination, especially if visual symptoms develop. Topical steroids may be used, but systemic therapy is usually added. Treatment is also indicated in the presence of significant or progressive involvement of any other organ. Onset of hepatitis, facial nerve palsies, meningitis, myocardial conduction defects, hypercalcemia, or persistent constitutional symptoms (fever, fatigue) are all indications for treatment.

In an effort to improve treatment outcomes or to avoid or minimize the toxic effects of prolonged steroid therapy, other approaches have been tried. Inhaled steroids have been used in several randomized trials, either alone or after a course of systemic steroids. At present, the evidence does not support a role for inhaled steroids. Because of its ability to complement systemic steroid therapy in rheumatoid arthritis, methotrexate has been used by some investigators. Case series suggest a modest improvement with a regimen that is well tolerated and able to decrease dependence on steroids, but this has not been documented in a randomized study. A small, randomized trial suggests that chloroquine may be effective. A randomized trial of cyclosporin A does not support its use.

Monitoring. Whenever steroid therapy is undertaken, an objective documentation of the response to treatment is essential. Because the predominant pathologic process in sarcoidosis is an alveolitis leading to granuloma formation, and because corticosteroids work by suppressing the alveolitis, the optimal means of monitoring disease activity and response to therapy would be to follow measures of the alveolitis. It has not been possible to distinguish between the extent of alveolitis and anatomic derangement by means of *chest radiography* and *determination of lung volumes and diffusion capacity*. Although these parameters are certainly useful for assessing the severity of disease, they are relatively insensitive measures of disease activity and suboptimal for judging the adequacy of therapy and the need for continued treatment. Even the sensitivity of the diffusion capacity for measuring disease extent has come under question. In one study, the diffusion capacity was well preserved, whereas lung volumes and measures of oxygenation (e.g., alveolar–arterial oxygen gradient and oxygen saturation) showed declines.

Attempts to improve on such crude measures of disease activity have been discouraging. Parameters generally reflective of inflammation, such as the erythrocyte sedimentation rate and serum globulin levels, have proved inadequate. Initial studies of *determination of ACE levels, gallium scanning*, and serial *bronchoalveolar lymphocyte counts* were encouraging, but a later controlled study found these tests no more sensitive for monitoring and managing steroid therapy than the combination of serial chest radiography and measurement of the diffusion capacity and lung volumes. Some authorities still argue that following the levels of ACE (which is believed to be produced by epithelioid cells within the sarcoid granuloma) can be useful in patients with very high levels before therapy, a situation most common in stage II disease.

Until better tests are devised (an ongoing effort), the best available approach to monitoring appears to be either serial determinations of the diffusion capacity and lung volumes together with chest radiography, or serial determinations of the ACE levels if the initial serum ACE level is markedly elevated.

PATIENT EDUCATION

Serious consequences of sarcoidosis are relatively infrequent. The nature of the disease should be carefully explained, with emphasis on its relatively benign, self-limited nature in the asymptomatic patient. Patients who are treated with steroids should be counseled about side effects and the risks inherent in such treatment (see Chapter 105). Careful follow-up must beemphasized in both the asymptomatic patient (to detect the development of functional abnormalities) and the patient with symptoms (to document objective benefits of treatment). Patients should be instructed about early signs of important complications, such as red eyes, blurred vision, eye pain, and dyspnea on exertion, so that therapy is not unnecessarily delayed.

CHAPTER 52 APPROACH TO THE PATIENT WITH ACUTE BRONCHITIS OR PNEUMONIA IN THE AMBULATORY SETTING

WILLIAM A. KORMOS

INTRODUCTION

Although most respiratory tract infections seen in the office setting are limited to the upper airway (see Chapter 50, Chapter 218, Chapter 219, and Chapter 220), the differential diagnosis should include lower respiratory tract infection in patients who present with a productive cough, dyspnea, and pleuritic chest pain. In such patients, four questions need to be addressed: (a) Is the process limited to the trachea and bronchi, or is a pneumonia present? (b) Is a diagnostic workup indicated or can empiric treatment be started? (c) Are antibiotics indicated and, if so, which ones? (d) Can the patient be safely treated as an outpatient or is hospital admission necessary? These basic questions are becoming increasingly germane as new strategies emerge for cost-effective management and concerns grow about the rising frequency of antibiotic-resistant organisms. The assessment and decision-making process become considerably more complicated if the patient is HIV-positive (see Chapter 13) or immunosuppressed for other reasons.

PATHOPHYSIOLOGY AND CLINICAL PRESENTATION

Mechanisms

Microorganisms gain access to the lower respiratory tract through inhalation or aspiration. Generally, normal defense mechanisms in the upper and lower respiratory tract protect against infection. Organisms are entrapped by the mucus-producing cells and ciliated epithelium that line the nasal mucosa and oropharynx. Local production of immunoglobulin A in the nasal mucosa prevents bacterial adherence. The cough reflex removes large particles from the lower airways, and ciliated epithelium and mucus in the bronchial tree capture particles too small to be removed by coughing. Alveolar fluid contains complement and immunoglobulin that act as opsonins, and pulmonary macrophages then eliminate bacteria. If the burden is high, macrophages may produce cytokines, including tumor necrosis factor and interleukin-1, to recruit neutrophils to the area.

Infection of the lower respiratory tract occurs when the inoculum or the virulence of a microorganism overwhelms the host defenses. Cigarette smoke interferes with ciliary function and macrophage activity, and alcohol use may increase aspiration (by interfering with the cough reflex) and promote colonization in the upper airway by gram-negative bacteria. Deficiencies in humoral immunity occur in adults with common variable immunodeficiency, hematologic malignancies, or splenectomies. These people are more susceptible to infection with encapsulated organisms such as *Streptococcus pneumoniae* and *Haemophilus influenzae*. Patients with HIV infection have deficiencies in both cell-mediated and humoral immunity, which predisposes them to infection by numerous organisms.

The presentations of bronchitis and pneumonia are similar. Cough may be productive or nonproductive of sputum, and associated symptoms, including fever, chest discomfort, and fatigue, may be present in both entities. Pleurisy or dyspnea tends to suggest more extensive involvement, as seen in pneumonia. "Classic" community-acquired pneumonia presents with a sudden chill followed by fever, pleuritic pain, and productive cough. The "atypical pneumonia" syndrome, associated with *Mycoplasma* or *Chlamydia* infection, often begins with a sore throat and headache followed by a nonproductive cough and dyspnea. Physical examination findings may be misleading, especially in the patient with underlying lung disease. Evidence of consolidation on the lung examination (bronchial breath sounds, egophony) is indicative of pneumonia but is present in few outpatients. The chest x-ray film in acute bronchitis usually reveals no infiltrate or signs of consolidation, in contradistinction to the x-ray film in pneumonia. But even this most clear-cut distinction between bronchitis and pneumonia can be misleading because changes of chronic lung disease can simulate new infiltrates in some patients with bronchitis, whereas dehydration can minimize radiographic abnormalities in patients with pneumonia. The clinical presentations are, in part, a function of the causative organism.

Gram-Positive Organisms

Streptococcus pneumoniae. *Streptococcus pneumoniae* is still the most common cause of pneumonia, accounting for 30% to 50% of all cases of bacterial pneumonia. It is especially likely to be the agent infecting healthy young ambulatory patients, but it may affect all age groups. It is also responsible for acute exacerbations in patients with chronic bronchitis, but its role in acute bronchitis in healthy persons is unclear. Classic clinical features of pneumococcal pneumonia include abrupt onset of fever with a single rigor, cough with rusty sputum, and pleuritic chest pain. Radiologic evidence of lobar consolidation is typical, but infiltrates can be patchy, especially in patients with chronic lung disease. The sputum Gram's stain reveals abundant polymorphonuclear leukocytes and gram-positive diplococci (classically lancet-shaped) in pairs or short chains.

The most common complication of pneumococcal pneumonia is bacteremia, which occurs in about one third of patients. Blood-borne distant sepsis (e.g., septic arthritis, peritonitis, meningitis) is much less common. Sterile pleural effusions are common, whereas empyema is less frequent.

Staphylococcus aureus. *Staphylococcus aureus* is the etiologic agent in up to 10% of cases of bacterial pneumonia. Except in infancy, when it can be a primary infection, staphylococcal pneumonia most commonly follows a viral respiratory tract infection, particularly *influenza*. It may also occur as a nosocomial infection or as a result of bacteremic seeding of the lungs, especially in patients who have staphylococcal endocarditis or are IV drug abusers. Patients with staphylococcal pneumonia of respiratory or bloodstream origin are usually extremely ill. *S. aureus* produces tissue necrosis, and the distinctive feature of staphylococcal pneumonia is the tendency to produce multiple small lung abscesses. Healing usually leaves some degree of residual fibrosis. Abundant polymorphonuclear leukocytes and gram-positive cocci in pairs, clumps, and clusters are found on the sputum Gram's stain. Local suppurative complications, including lung abscess, empyema, and pneumothorax, are relatively common. Bacteremia with metastatic seeding of distant sites, such as endocardium, bone, joints, liver, and meninges, may occur.

Group A Streptococci. Group A Streptococci are a rather uncommon cause of infection, but this type of pneumonia has occurred in epidemics, especially in closed groups such as military units. Occasionally, streptococcal pneumonia can occur after primary influenza pneumonia. Streptococcal pneumonia usually begins abruptly with fever, cough, and severe debility. Chest pain is prominent in most patients. The distinctive clinical and radiologic feature is rapid spread in the lung, with resultant early empyema formation. Initially, the empyema fluid may be thin, possibly because of the many enzymes elaborated by group A streptococci, but later frank purulence occurs. Other complications, such as lung abscess, bacteremia, metastatic infection, and poststreptococcal glomerulonephritis, are uncommon. In patients with streptococcal pneumonia, the sputum Gram's stain reveals numerous polymorphonuclear leukocytes and gram-positive cocci in pairs and short to long chains.

Gram-Negative Organisms

Haemophilus influenzae. *Haemophilus influenzae* has long been recognized as a common cause of bronchitis in adults with chronic lung disease; however, recognition of this organism as a cause of frank pneumonias, sometimes with bacteremia, is increasing. Most cases of bronchitis are caused by untypeable strains of *H. influenzae*, but pneumonias are often caused by the more invasive encapsulated strains, especially type b. Radiographically, a bronchopneumonia pattern is typical. Abundant polymorphonuclear leukocytes and small, pleomorphic, gram-negative coccobacillary organisms are the characteristic findings in the sputum of patients with pneumonia or bronchitis cased by *H. influenzae*. Complications of *H. influenzae* pneumonia in adults are uncommon, but in patients with underlying chronic lung disease, the illness may be particularly severe, with development of hypoxia and respiratory failure.

Klebsiella pneumoniae. *Klebsiella pneumoniae* typically produces pulmonary infection in debilitated patients, especially *alcoholics*, and *Klebsiella* pneumonia is one of the few gram-negative bacillary pneumonias seen commonly in ambulatory patients. It usually presents as an acute illness; rarely, it may cause chronic

pneumonitis. The organism has a high propensity to produce tissue necrosis, which accounts for the hemoptysis, dense lobar consolidation, and high incidence of abscess formation seen in this illness. Sputum may appear dark red and mucoid ("currant jelly" sputum). Abundant polymorphonuclear leukocytes and large gram-negative bacilli, occasionally with thick capsules, are characteristically seen on sputum Gram's stain. Lung abscess and empyema may occur.

Other Gram-Negative Bacillary Pneumonias. *Other gram-negative bacillary pneumonias* were once rare but have increased during the past 15 years and now account for up to 20% of cases of bacterial pneumonia. They are principally hospital-acquired infections and remain rare in the ambulatory population. Patients with gram-negative bacillary pneumonia are typically debilitated from other illnesses or elderly and frequently have received antibiotic therapy, during which their normal respiratory flora are replaced with these otherwise unusual pathogens. Abundant polymorphonuclear leukocytes and gram-negative bacilli are seen on sputum Gram's stain. Complications, including lung abscess, empyema, and bacteremia with metastatic spread of infection, may occur.

Moraxella (Branhamella) catarrhalis. *Moraxella (branhamella) catarrhalis* is a gram-negative coccus that morphologically resembles organisms of the *Neisseria* family but differs in biochemical and DNA characteristics. It is found in the oropharynx of normal hosts and was not considered pathogenic until the 1980s, when it was established as the cause of lower respiratory tract infection in some patients with chronic obstructive pulmonary disease. In more than 80% of *Moraxella catarrhalis* infections, an *underlying pulmonary disease* is present. Diabetes, alcoholism, malignancy, and steroid use are other known risk factors. Cases appear to be concentrated in the *winter* months, perhaps indicating a relation to preceding viral infection. The typical lower respiratory tract infection that ensues is mild and sometimes even self-limited. The organism is readily identified by Gram's stain, and almost all sputum cultures are positive for organisms. Chest radiography shows an interstitial or interstitial–air space infiltrate. Bacteremia is rare, and full recovery with prompt response to antibiotics is the rule, although almost all isolates are positive for *b*-lactamase.

Bordetella pertussis. *Bordetella pertussis*, a gram-negative pleomorphic bacillus, is a frequently overlooked cause of acute bronchitis. Acquired immunity from childhood wanes after 15 to 20 years, so that young adults are rendered susceptible to pertussis. Several studies have shown that pertussis accounts for up to 25% of patients with acute bronchitis lasting two or more weeks. The disease typically has three phases. The *catarrhal phase* is indistinguishable from an upper respiratory infection, with rhinorrhea, low-grade fever, and mild congestion lasting 1 to 2 weeks. Patients are contagious in this stage and early into the next stage, the *paroxysmal phase*, which lasts for 2 to 4 weeks and is characterized by severe paroxysms of nonproductive coughing, with 10 to 30 coughs in a row. Posttussive syncope and vomiting are not uncommon; the characteristic "whoop" is absent in adults because of their larger airways. Finally, the symptoms gradually resolve during the next 1 to 3 months in the *convalescent phase*. The nasopharyngeal culture, which is used in children to establish the diagnosis, is often negative for organisms by the time adults seek medical attention. A single elevated pertussis serology has been advocated as a rapid means of diagnosing pertussis.

Legionnaires' Disease

First identified in the 1976 Philadelphia hotel outbreak, Legionnaires' disease is now recognized as an important cause of community-acquired pneumonia. *Legionella pneumophila*, an aerobic, fastidious, small, gram-negative bacillus, has been reported as the causative agent in 5% to 10% of all cases of community-acquired pneumonia and in up to 30% of cases of severe community-acquired pneumonia. The organism survives in water and, to a lesser extent, soil; infection is acquired by inhalation of contaminated aerosols or microaspiration of contaminated water. Epidemics have been traced to contaminated cooling systems, whirlpool baths, and potable water; nosocomial infections have occurred through contaminated hospital water supplies. Risk factors for *Legionella* infection include cigarette smoking, chronic lung disease, and immunosuppression. *L. pneumophila* is responsible for more than 90% of all cases; of the 14 serotypes of *L. pneumophila* identified, serogroup 1 is responsible for the majority of these cases. The next most common *Legionella* species is *L. micdadei* (the Pittsburgh pneumonia agent), which can cause cavitary lung disease in immunosuppressed patients.

The spectrum of clinical illness resulting from *Legionella* infection ranges from mild upper respiratory disease (Pontiac fever) and self-limited atypical pneumonia to multifocal pneumonia and respiratory failure. After a short prodrome, the full-blown form of Legionnaires' disease begins acutely with high fever, nonproductive cough, and dyspnea. *Pleuritic chest pain* occurs in about one third of cases. Systemic manifestations such as *diarrhea* or *confusion* are often seen but are not specific to legionellosis.

Relative bradycardia occurs in a few patients, but in most cases the physical examination findings are nonspecific. Chest radiography shows interstitial infiltrates or areas of patchy consolidation with characteristic rapid progression. Extrapulmonary findings are uncommon but include myocarditis, pericarditis, rhabdomyolysis, and renal dysfunction. Sputum is typically absent or scant. The sputum Gram's stain fails to reveal pathogens, but *L. pneumophila* can be cultured on a specialized buffered charcoal yeast extract agar. *Legionella* urinary antigen is very sensitive for disease caused by *L. pneumophila* serogroup 1 (about 70% of all cases) and is easy to obtain.

Mixed Flora

Aspiration pneumonias. Aspiration pneumonias are usually mixed infections caused by aerobic and anaerobic streptococci, *Bacteroides*, and *Fusobacterium*. These organisms are normal flora of the upper airway that cause pneumonia if they attain a foothold in the lung parenchyma. Predisposing factors include alteration of consciousness (drugs, anesthesia, alcohol, head trauma) and diminution of the gag reflex, which permits aspiration to occur. Patients usually are mildly to moderately ill but can be toxic, especially if lung abscess or empyema occurs. Hospitalized patients, ambulatory patients receiving antibiotics, and edentulous patients have altered respiratory flora and fewer anaerobic organisms, if any. Aspiration of mouth organisms in such persons may result in staphylococcal or gram-negative bacillary pneumonia, as discussed previously, rather than the mixed aerobic–anaerobic infection considered here. The sputum from patients with aspiration pneumonia may be malodorous and characteristically shows abundant polymorphonuclear leukocytes and mixed flora, including gram-positive cocci in pairs and chains and pleomorphic gram-negative rods on Gram's stain. Lung abscess and empyema are fairly common complications of aspiration pneumonia, especially if therapy is delayed.

Nonbacterial Organisms

Mycoplasma pneumoniae. *Mycoplasma pneumoniae* is a cell wall–deficient organism that accounts for 10% to 25% of cases of community-acquired pneumonia. It is a leading cause of the *atypical pneumonia syndrome* (fever, dry cough, nonspecific infiltrate on chest film) and also a cause of acute bronchitis in otherwise healthy adults. The organism spreads by way of respiratory droplets and appears to have a long incubation period; onset of illness tends to be insidious. The disease often begins with headache, sore throat, and malaise, then progresses to a nonproductive cough. The physical examination findings are usually unimpressive in comparison with the *patchy peribronchial infiltrates* seen on chest x-ray films. Bullous myringitis has been reported in *Mycoplasma* pneumonia, but it is actually uncommon in clinical practice. Skin examination may show *erythema multiforme*, which is highly correlated with *Mycoplasma* infection in the patient with pneumonia. Laboratory studies reveal a normal white blood cell count and differential in most cases. The sputum is scant, with a predominance of mononuclear cells and no organisms. Sputum culture is not practical because a special medium is required and results do not become available for 2 weeks. Testing for the organism by polymerase chain reaction is a new technique with high sensitivity and specificity, although not widely available. *Cold agglutinins* are present in approximately 50% of cases. *Mycoplasma* pneumonia is usually a mild, self-limited illness, but it can produce severe pneumonia in children with sickle cell anemia, in immunosuppressed hosts, and in the elderly. Uncommon complications include hemolytic anemia, aseptic meningitis, Guillain-Barré syndrome, and myopericarditis.

Chlamydia pneumoniae (TWAR). *Chlamydia pneumoniae (TWAR)* is an obligate intracellular organism that causes an atypical pneumonia or acute bronchitis. It appears to account for 10% to 20% of cases of community-acquired pneumonia, with higher rates in young adults. *C. pneumoniae* appears to spread from person to person by respiratory droplets. The prodrome resembles that of *Mycoplasma pneumonia*, with headache and sore throat followed by a dry cough, but the chest radiograph shows less extensive involvement. The diagnosis is difficult because culture requires tissue culture techniques that are not routinely performed. Serology (acute and convalescent titers) has been used to establish the diagnosis, and, as in *Mycoplasma* pneumonia, polymerase chain reaction is an upcoming (but not proven) new technology. The infection is usually self-limited; rare fatalities have been reported in debilitated patients.

Viruses. *Viruses* are the most common cause of acute bronchitis, accounting for more than 80% of all cases. Viral pneumonia resembles an atypical pneumonia and is clinically indistinguishable except when it is part of a distinctive systemic viral illness, such as rubeola in children or varicella in adults. Many viruses are capable of producing lower respiratory tract infections, including influenza virus, adenoviruses, respiratory syncytial virus, and parainfluenza virus. Cytomegalovirus is a common cause of viral pneumonia in the immunocompromised host. The most important cause of viral pneumonia is influenza, which can be recognized by its epidemic spread and marked systemic symptoms, such as fever and myalgia. Influenza pneumonia may be mild or a fulminant illness capable of causing lethal respiratory failure. Bacterial pneumonia, especially of the pneumococcal, staphylococcal, or streptococcal variety, is a frequent complication.

Psittacosis. *Psittacosis* is caused by a member of the *Chlamydia* group of obligate intracellular parasites, which are also responsible for lymphogranuloma venereum and trachoma. The disease is transmitted from parrots or other birds (including pigeons and turkeys) to humans. The clinical features of psittacosis are

indistinguishable from those of other nonbacterial pneumonias, with prominent headache, nonproductive cough, and fever. Occasionally, a faint macular rash or splenomegaly develops.

Q Fever. *Q fever*, caused by *Coxiella burneti*, is unique among rickettsial infections in that pneumonia is prominent, no rash is associated, and spread is through inhalation of infected dust particles rather than by way of the bite of an insect vector. The organisms reside principally in animals; human contact with cattle, sheep, goats, or infected animal hides or hide products is the most important epidemiologic factor and is often the only clue to diagnosis. The clinical features of Q fever are similar to those of the other nonbacterial pneumonias, except that hepatitis occurs in up to one third of patients.

Fungi and Other Opportunistic Organisms. Immunosuppressed patients (e.g., those taking corticosteroids, HIV-positive patients) are at heightened risk for a community-acquired opportunistic infection (e.g., *Aspergillus*, *Candida*, or *Pneumocystis*; see Chapter 13). HIV-positive patients are also at increased risk for *primarytuberculosis* (see Chapter 49). However, some fungal infections may occur in immunocompetent hosts. For example, exposure to spore-containing dusts may lead to *histoplasmosis* (in the Midwest) or *coccidioidomycosis* (in the Southwest), characterized in the initial phases by a nonproductive cough, flulike illness, liver or splenic enlargement, alveolar infiltrates, and sometimes hilar adenopathy; however, most often the chest radiographic findings are normal.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of community-acquired pneumonia is listed in Table 52-1. In most epidemiologic studies, *S. pneumoniae* is the most common cause, followed by *H. influenzae*, influenza virus, and *Legionella*.

Bacterial
Streptococcus pneumoniae
Haemophilus influenzae
Legionella species (most often *L. pneumophila*)
Staphylococcus aureus
Klebsiella pneumoniae (and other *Enterobacteriaceae*)
Moraxella catarrhalis
Streptococcus pyogenes
Mixed aerobic/anaerobic organisms (aspiration)

Nonbacterial
Mycoplasma pneumoniae
Chlamydia pneumoniae
Chlamydia psittaci
Mycobacterium tuberculosis
Coxiella burneti (Q fever)
Viral (influenza virus, adenovirus)
Pneumocystis carinii
Fungi

Table 52-1. Differential Diagnosis of Pneumonia in Ambulatory Patients

In addition to the conditions listed in Table 52-1 and detailed above, noninfectious diseases can occasionally mimic infectious processes. Bronchial asthma (see Chapter 48) and hypersensitivity pneumonitis (see Chapter 51) are common examples. The radiologic findings associated with chronic pulmonary diseases, especially chronic bronchitis (see Chapter 47) and bronchiectasis (see Chapter 41), may be misleading if previous x-ray films are not available. Atelectasis, pulmonary infarction, pulmonary edema (see Chapter 32), and lung tumors may also be confused with pneumonia.

WORKUP

The first task is to differentiate lower respiratory tract infection from the other causes of cough (see Chapter 32, Chapter 41, Chapter 42, and Chapter 51) and from upper respiratory infection (see Chapter 50, Chapter 219, and Chapter 220). The predominant symptom of a patient presenting with a lower respiratory tract infection is usually cough, either productive or nonproductive of sputum. A predominant symptom of nasal discharge, sore throat, or ear pain can direct the workup away from the lower respiratory tract. Once a lower tract infection is suspected, the focus quickly shifts to the task of diagnosing pneumonia or bronchitis. Unfortunately, the distinction cannot be made reliably on the basis of any single element of the history or physical examination. A search for a specific cause is important if the presentation is unusual, unique exposures are present, or the patient is immunosuppressed.

History. Symptoms of pneumonia were previously classified as "typical" (productive cough, rigors, pleurisy) or "atypical" (nonproductive cough with a prodrome of headache and sore throat). These classifications originally were developed to discriminate pneumococcal pneumonia from pneumonia caused by "atypical" organisms, such as *Mycoplasma* and *Chlamydia*. However, the overlap in symptoms of pneumonia of different causes is substantial, so that this classification is unreliable. As stated above, the type of cough and the presence of dyspnea and fever are also unreliable to differentiate bronchitis from pneumonia.

The history is most useful to determine additional *comorbid conditions* that may influence prognosis or clarify etiology. Advanced age, congestive heart failure, cerebrovascular disease, active malignancy, and renal or liver disease all predict a poorer outcome in patients with pneumonia. In addition, patient characteristics may increase the likelihood of particular organisms. Alcoholics have a higher incidence of infection with gram-negative organisms, especially *K. pneumoniae*, and patients with chronic lung disease are often colonized with *H. influenzae* and *M. catarrhalis*. Nosocomial pathogens, including resistant organisms and *Pseudomonas*, should be considered in nursing home residents. HIV-positive patients are at risk for infection with a number of opportunistic pathogens, such as *Pneumocystis carini* and *Mycobacterium tuberculosis*.

The history may also be useful in *identifying unusual exposures* or epidemiologic associations to raise the possibility of specific causes. Patients should be assessed for close contact with birds (psittacosis), livestock (Q fever), or rabbits (tularemia). A patient residing in or traveling to the southwestern United States (coccidioidomycosis) or the Midwest (histoplasmosis) may acquire an acute fungal pneumonia, which is usually self-limited without treatment except in immunocompromised hosts. Patients who are at high risk for tuberculosis exposure (immunosuppressed, homeless, exposed to known contact) should be assessed for mycobacterial infection.

Physical Examination. No single physical examination finding can definitively diagnose pneumonia, although the clinician should focus on the vital signs and pulmonary examination to assist diagnosis and prognosis. High fever (>104°F), hypothermia, tachypnea, and tachycardia are all associated with an increased 30-day mortality. Conversely, several studies have demonstrated that the presence of entirely normal vital signs decreases the probability of pneumonia in outpatients to less than 1%. The pulmonary examination in pneumonia often demonstrates crackles, although patients with bronchitis may have similar findings. The classic findings of lung consolidation (dullness to percussion, egophony, bronchial breath sounds) are more specific for pneumonia but are found in fewer than 25% of patients with radiographic evidence of pneumonia. Some physical findings may have etiologic significance. Erythema multiforme is associated with *Mycoplasma* pneumonia, and confusion is seen more often in *Legionella* infection.

Laboratory Studies. In the patient with acute bronchitis, laboratory testing is often unnecessary. However, if pneumonia is suspected, posteroanterior and lateral *chest radiography* is required to confirm the diagnosis. In addition to indicating the extent of disease, the chest x-ray film may also show a pleural effusion, which is associated with a poorer outcome. Unless the pleural effusion is minimal, *thoracentesis* should be performed to assess for the presence of an empyema or complicated parapneumonic effusion. Fluid is sent for Gram's stain, culture, cell count, and determination of glucose, protein, and lactate dehydrogenase levels and pH (see Chapter 43).

The value of routine sputum collection for *Gram's stain* and culture remains controversial. In acute bronchitis, the predominance of viral and atypical bacterial organisms makes these tests unlikely to influence treatment decisions. For the patient with pneumonia, the American Thoracic Society has recommended empiric treatment without an aggressive etiologic workup, but more recently the Infectious Disease Society of America has advocated performing sputum Gram's stain and culture in all patients hospitalized with community-acquired pneumonia. This recommendation recognizes the limitations of Gram's stain and culture but also argues for the importance of detecting resistant or atypical organisms and tailoring antibiotic treatment according to culture results. With the increasing presence of resistant organisms, it is reasonable to obtain a specimen for Gram's stain and culture if the patient is producing sputum.

If a sputum sample is obtained, it is essential to ensure that it is adequate. The specimen is obtained from a deep cough, with the use of nebulized saline solution if necessary. For a causative organism to be predicted accurately, the Gram's stain should show fewer than 10 epithelial cells and more than 25 polymorphonuclear

cells per low-power field. Interpretation needs to be performed by an experienced observer. Small gram-negative rods may be overlooked by an inexperienced observer, and inadequate decolorization results in misclassification of gram-negative organisms as gram-positive. *Pneumococcal* infections show gram-positive, lancet-shaped diplococci; gram-negative cocci suggest *Moraxella*, and gram-negative coccobacillary forms are indicative of *H. influenzae*. Despite attempts to obtain an adequate specimen, upper respiratory contamination, fastidious pathogens, and delay in transportation all limit the utility of the sputum culture, results of which are negative in about 50% of cases. Ideally, all cultures should be obtained and sent before antibiotics are started, but failure to obtain a sputum specimen should not delay necessary treatment.

In hospitalized patients, additional tests, including a complete blood count, assessment of renal function, and determination of electrolytes, are obtained. Serum liver enzymes are frequently elevated in patients with pneumonia, regardless of the cause. An *arterial blood gas* may be obtained if the patient has an underlying pulmonary disease or the clinical picture warrants the test. *Blood cultures* are positive in about 10% to 15% of patients and may be the only accurate method of identifying the causative organisms. Blood for two sets of cultures should be drawn from different sites before initiation of antibiotic therapy.

Detection of *Legionella urinary antigen* is an accessible and rapid method for diagnosing Legionnaires' disease. The test is very sensitive for *L. pneumophila* serogroup 1, which accounts for more than 70% of cases of pneumonia in humans. The antigen persists in the urine even after antibiotics have been started and may persist for months after infection. A *Legionella* urinary antigen test should be performed in all patients with a clinical picture suggestive of legionellosis. Legionnaires' disease can also be diagnosed in 3 to 5 days by culture of the organism on special media. Serology may also be used to detect infection, but the delay in results makes this a less useful test. A single *antibody titer* of 1:256 is presumptive evidence, but confirmation requires demonstration of a fourfold rise in titer between acute and convalescent specimens.

Additional testing in patients with community-acquired pneumonia is usually unnecessary. Measurement of acute and convalescent serologic titers can confirm infection with *Mycoplasma*, *Chlamydia*, *Coxiella burneti*, or viral agents. Recognition of influenza is important because contacts can be protected by prophylactic use of amantadine; diagnostic confirmation is worth seeking when influenza is suspected. In the HIV-infected patient with pneumonia, an induced sputum sample or bronchoalveolar lavage is stained for *Pneumocystis* and *M. tuberculosis* (see Chapter 13).

PRINCIPLES OF MANAGEMENT

General Measures

Admission versus Outpatient Management. Many patients with community-acquired lower respiratory tract infections can be managed on an outpatient basis, provided that they are alert, reliable, have help available to them, and have no signs of serious compromise (see Indications for Admission). In the Pneumonia Patient Outcomes Research Trial (PORT), about 50% of patients were identified to be at low risk for complications and appropriate for outpatient treatment. These patients had a 30-day mortality of less than 1%. Therapeutic serum levels can be achieved with oral antibiotic regimens for patients treated at home. See Therapeutic Recommendations.

Symptomatic and Supportive Measures. Patients with bronchitis or pneumonia often ask for medication to relieve the cough that prompted them to seek medical care. Suppression is not encouraged in patients with acute cough because the cough reflex remains an important defense mechanism. Adequate *hydration* is essential to help clear secretions; this can be achieved by fluid intake and local airway humidification. *Expectorants* such as guaifenesin may be helpful to some patients in loosening the sputum, although they have not been proved to make a significant difference in outcome. *Pulmonary physical therapy* may help mobilize secretions, but prospective trials have failed to demonstrate that this time-honored intervention improves outcome (see Chapter 41 and Chapter 47).

In some patients, persistent coughing results in severe musculoskeletal chest pain or respiratory fatigue. Nocturnal cough may interfere with sleep and prevent the patient from getting adequate rest. In these cases, several treatments may be offered. In two small trials of patients with acute bronchitis, b_2-agonists, such as albuterol, have decreased the duration of cough. Expiratory flow rates can be decreased in these patients, as in those with reactive airway disease. Because the persistent cough in bronchitis appears to be related to bronchial irritation, not to continuing infection, this treatment makes physiologic sense. However, its use is limited by the lack of large studies, side effects of the medication, and time required to teach inexperienced patients how to use inhalers. *Cough suppressants*, which directly diminish the cough reflex, include dextromethorphan and codeine. These medicines may provide temporary relief, especially when taken before bed (see Chapter 41). Although the tablet form is equally effective, patients may prefer a syrup formulation for cough suppression. Fever, another bothersome symptom, can be controlled with aspirin or acetaminophen (see Chapter 11).

Oxygen therapy may be required in hospitalized patients with pneumonia. In general, treatment should be titrated to the patient's respiratory status and not be focused on a specific oxygen saturation or concentration. Lung consolidation in pneumonia functions as a shunt, and an increase in oxygen may not result in improved arterial oxygenation. In addition, patients with chronic lung disease who retain carbon dioxide may experience respiratory depression with excessive oxygen therapy (see Chapter 47).

Antibiotic Therapy. Antibiotics are a cornerstone of initial management of *pneumonia*. Because most etiologic testing requires 24 to 48 hours, initial treatment decisions are usually empiric, based on best estimate of specific underlying pathogen(s). Therapy is then modified in response to diagnostic test results and the patient's response to therapy. For most bacterial infections, continued treatment for 10 to 14 days is recommended. In *acute bronchitis* (which is usually of viral origin in otherwise healthy persons), empiric use of antibiotics does not improve outcomes. Nonetheless, the empiric prescribing of antibiotics for acute bronchitis remains a common practice, particularly in response to patient demand.

Specific Conditions

Acute Bronchitis. At least eight randomized, placebo-controlled trials involving use of doxycycline, trimethoprim/sulfamethoxazole, or erythromycin have failed to show a benefit of empiric antibiotic therapy in healthy patients with acute bronchitis. In most studies, cough resolved at 1 week regardless of treatment, and persistence of cough for 2 weeks was not unusual. These smaller trials have been combined in two separate systematic reviews that have confirmed the lack of benefit of antibiotics in these patients. Newer, more potent antibiotics, such as azithromycin, have fared no better in randomized controlled trials. Despite this evidence, several studies have suggested that physicians prescribe antibiotics for more than 60% of outpatients with acute cough and no underlying lung disease. Epidemiologic studies show that relatively few of these patients actually have pneumonia as the cause of their cough. Healthy patients with acute bronchitis should be treated with conservative measures for cough and counseled about the natural history of the disease.

Updated: 6/4/02

The one exception to this approach is the patient with *pertussis*. Early antibiotic therapy with erythromycin can effectively treat *B. pertussis* infection, but most adults who seek medical attention are in the paroxysmal phase, when tracheal damage has already occurred. However, they may still be infectious in the early paroxysmal phase, and treatment can decrease the transmission of *B. pertussis*. Therefore, the patient with documented or suspected pertussis is treated with 500 mg of *erythromycin* four times daily for 7 to 14 days. Prophylactic treatment with the same regimen (adjusted for weight in children) is recommended for household members and close contacts, especially unvaccinated infants. In the patient intolerant of erythromycin, trimethoprim/sulfamethoxazole or a second-generation macrolide (e.g., azithromycin, clarithromycin) may be substituted.

Acute Exacerbation of Chronic Bronchitis. Antibiotics are effective in relieving symptoms and preventing deterioration of lung function in patients with established chronic bronchitis. *S. pneumoniae*, *H. influenzae*, and *M. catarrhalis* are the common pathogens in these patients. A second-generation *b*-lactam, such as cefuroxime, is the treatment of choice. Alternatives include a second-generation macrolide or trimethoprim/sulfamethoxazole. Additional treatment depends on the patient's condition and underlying lung function (see Chapter 47).

Community-Acquired Pneumonia. Antibiotics are clearly indicated for the treatment of community-acquired pneumonia, although no randomized trials have been completed. Evidence consists of the significant decrease in pneumonia mortality since the introduction of antibiotics and the adverse outcomes associated with delayed or inappropriate antibiotic therapy in patients with pneumonia. Increasing drug resistance, notably penicillin-resistance in *S. pneumoniae*, has complicated the empiric selection of antibiotics. The initial treatment is directed at the most common pathogens, and patients are classified by age, comorbidities, and severity of pneumonia.

Healthy Young Adults. In persons less than 60 years old, the most common organisms are *S. pneumoniae*, *Mycoplasma*, *Chlamydia*, and *Legionella*. All these organisms are covered adequately *erythromycin* (500 mg four times daily), which is the first-line treatment. Although macrolide resistance is increasing in *S.*

pneumoniae, observational studies have validated this approach as an effective, inexpensive strategy. Penicillins or cephalosporins will not cover the atypical organisms in this age group. Alternative agents include *doxycycline* (100 mg twice daily) or the second-generation macrolides. Newer fluoroquinolones, such as levofloxacin, have adequate activity against the pathogens and are well tolerated. Experience with these agents is limited, however, and indiscriminate use will certainly translate into resistant strains. Older fluoroquinolones (e.g., ciprofloxacin) have less activity against the pneumococcus and are not recommended.

Older Adults and Patients with Comorbidities. *S. pneumoniae* remains the most common cause of pneumonia, but *H. influenzae*, *M. catarrhalis*, and other gram-negative organisms are alternative possibilities. The atypical organisms such as *Mycoplasma* and *Chlamydia* are unusual in this population. Therefore, the recommended first-line treatment is a *second- or third-generation cephalosporin*. *Cefuroxime* (although not officially approved for pneumonia) is a common choice because it has adequate activity against the common pathogens and is available in twice-daily dosing. Alternatives include *b*-lactam/*b*-lactamase inhibitor combinations (e.g., amoxicillin/clavulanate), second-generation macrolides, and fluoroquinolones with adequate pneumococcal coverage.

Patients who are ill enough to be hospitalized for pneumonia often require *parenteral antibiotic therapy*. The causative organisms are similar to those described above, but the potential for worsening respiratory status is higher in these sicker patients. Empiric treatment may be selected based on the patient characteristics described in the first two groups, but therapy is often broadened in sicker patients to cover potentially resistant organisms and a wider spectrum of organisms. For patients with severe pneumonia and an inconclusive Gram's stain, the first-line treatment is a *third-generation cephalosporin* (e.g., 1 g of ceftriaxone daily) *plus a macrolide* in a dose sufficient for *Legionella* infection (e.g., 1 g of erythromycin four times daily). For patients in whom fluid overload is a concern, erythromycin may be equally divided between oral and IV doses. Therapy can then be narrowed after results of diagnostic tests, such as *Legionella* urinary antigen and blood cultures, become available. Focused therapy may also be initiated on presentation when an adequate Gram's stain is highly suggestive of a particular pathogen (see Table 52-3). Alternative empiric parenteral treatments include *azithromycir* and several *fluoroquinolones*. These alternatives offer the advantage of single-agent therapy.

Table 52-3. Pathogen-Specific Therapy for Lower Respiratory Tract Infections

Antibiotic Resistance in *S. pneumoniae*. Previously, *S. pneumoniae* was almost universally susceptible to penicillin. However, resistance to penicillin, mediated by mutations in penicillin-binding proteins, was first reported in the 1960s in Australia. During the past decade, these resistant organisms have become an increasing concern in the United States. Approximately 25% of pneumococci in the United States have intermediate penicillin resistance (mean inhibitory concentration, or MIC, of 0.1 to 1.0 μmg/mL), and up to 10% are highly penicillin-resistant (MIC >2.0 μmg/mL). These highly resistant organisms are often cross-resistant to multiple antibiotics, including trimethoprim/sulfamethoxazole and erythromycin. Fortunately, parenteral penicillin appears to achieve adequate levels in the tissues for the effective treatment of pneumococci with intermediate resistance. For highly resistant organisms, alternative agents are recommended. Fluoroquinolone resistance has been very low in *S. pneumoniae*; however, as these agents are used more frequently, resistant strains are being reported. The increasing prevalence of pneumococcal resistance to antibiotics serves to emphasize the need to vaccinate high-risk patients (see below); more than 85% of resistant organisms are serotypes contained in the 23-valent vaccine.

THERAPEUTIC RECOMMENDATIONS

Treatment for lower respiratory tract infections is tailored to the clinical syndrome and likely pathogens. Table 52-2 summarizes the empiric antibiotic recommendations for the various clinical syndromes, and Table 52-3 describes the recommendations for specific pathogens.

Table 52-2. Empiric Treatment for Lower Respiratory Tract Infections

MONITORING THERAPY

Clinical improvement is best indicated by improved vital signs. The Pneumonia PORT validated temperature, respiratory rate, heart rate, and blood pressure as reliable measures of stability. On average, patients achieved "normal" vital signs at a median of 3 days after hospitalization. However, patients were often not completely "afebrile" (temperature <99°F) until day 6. Once patients reached clinical stability, indicated by normal vital signs along with a normal mental status and an ability to take oral medication, deterioration in clinical status was rare (<1%).

Repeating chest radiography at frequent intervals is wasteful if the patient is progressing well clinically. The clearing of radiologic findings often lags far behind clinical resolution; the continued presence of a slowly resolving infiltrate is neither a sign of poor response to therapy nor indicative of a serious prognosis. This is particularly true of pneumococcal or *Legionella* pneumonia, in which radiography may still show an infiltrate months later. However, when the patient's condition is worsening or fever is not resolving, radiographic examination is important for the detection of complications such as lung abscess and empyema. In addition, the possibility of unusual or resistant organisms should be considered in these patients, and antibiotic therapy appropriately adjusted.

PATIENT EDUCATION

Patients with lower respiratory tract infections need to be educated about their natural history. As stated above, patients with acute bronchitis often have a persistent cough for 1 to 2 weeks. However, these patients usually show an overall improvement by the end of the first week. In patients with pneumonia, the recovery period is much longer. More than 50% of patients with pneumonia continue to report fatigue and cough 1 month after diagnosis. Patients with persistent symptoms often require more outpatient visits during follow-up.

Patients can monitor their own temperature at home if treated in the outpatient setting. Persistent fever, worsening respiratory status, or increasing confusion are reasons to seek medical attention. Patients who smoke should be strongly urged to quit if they have not already done so. In fact, this is an excellent opportunity to

encourage patients to quit because many do at this time (see Chapter 54).

Patients who recover from community-acquired pneumonia are eligible to receive pneumococcal and influenza vaccinations. Patients who are elderly (>65 years), have congestive heart failure or obstructive lung disease, are immunosuppressed, or have undergone splenectomy are also candidates for vaccination. The *polyvalent pneumococcal vaccine* (see Chapter 6 and Chapter 47) incorporates 23 capsular types of pneumococci, which together account for about 90% of cases of pneumococcal pneumonia in the United States. Revaccination after 5 years is now recommended for immunosuppressed persons, patients with functional asplenia, and elderly persons who received the initial vaccination before age 65. The influenza vaccine, composed of a purified inactivated virus, is modified each year to include prevalent strains of influenza A and influenza B. Hypersensitivity to eggs is a contraindication to influenza vaccination. The vaccines may be given at the same time without an increase in side effects or decrease in immunogenicity.

INDICATIONS FOR ADMISSION

As mentioned previously, one of the most important decisions in the care of the patient with a community-acquired lower respiratory infection is selecting the proper setting for care. The decision is obvious in the case of a healthy young patient with an acute bronchitis or a seriously ill patient with overt respiratory compromise. In between are the many patients who are elderly or have underlying cardiopulmonary disease and present in the ambulatory setting with a lower respiratory tract infection; they are a source of concern.

Many studies have examined large numbers of patients with community-acquired pneumonia to determine predictors of poor outcome. Common predictors of worse outcome in these studies include advanced age, comorbidities, and abnormal vital signs. It is important to note that these trials often excluded immunosuppressed patients, who have an overall worse prognosis and are likely to require hospitalization. A useful prediction rule described by Fine et al. has been validated on more than 38,000 inpatients with pneumonia and the more than 2,200 patients of the Pneumonia PORT (Fig. 52-1 and Table 52-4). Patients with none of the comorbidities or vital sign abnormalities indicated in Fig. 52-1 are assigned to class 1 (low risk). Remaining patients are assigned a point score based on the system listed in Table 52-4. Patients with point totals below 90 have a low mortality (<1%) and a low risk for deterioration (<6%) and may be considered for outpatient therapy. Of course, any prediction rule does not replace clinical judgment; these rules perform poorly in extreme or unusual circumstances. For example, a 20-year-old man with hypotension, tachycardia, and hypoxia would have a low score but clearly requires hospitalization, if not intensive care.

Table 52-4. Pneumonia Port Scoring

In addition, the decision for hospitalization will depend on the *quality of the home environment* and the *ability to tolerate oral therapy*. Alternative options, such as home IV therapy and subacute care facilities, have become increasingly practical and cost-effective, especially in the era of managed care.

CHAPTER 53 APPROACH TO THE PATIENT WITH LUNG CANCER

Lung cancer continues to be the leading cause of cancer deaths in the United States and is the second most common cause of cancer death among men and women, trailing prostate and breast cancers, respectively. Cigarette smoking accounts for 95% of lung cancers in men and 85% of those in women (see Chapter 54). Once established, most forms of lung cancer are minimally responsive to therapy, although important exceptions exist. The primary physician needs to be skilled in prevention (see Chapter 54); alert to early signs of lung cancer (see Chapter 41, Chapter 42, and Chapter 44); capable of conducting the workup, staging, and monitoring of the disease; and knowledgeable about treatment options and their effects on survival and quality of life.

PATHOLOGY, CLINICAL PRESENTATION, AND COURSE

The common types of bronchogenic carcinoma are designated as squamous cell, adenocarcinoma, large-cell, and small-cell. Each has its own epidemiologic and clinical characteristics, although, with the exception of small-cell disease, they share a similar natural history and response to therapy. Consequently, lung cancers are often classified as small-cell (SCLC) and non–small-cell (NSCLC).

Small-cell Lung Cancer (formerly known as oat cell carcinoma) is typically central in location and accounts for 25% of cases. Growth is rapid, with 50% to 75% of patients manifesting evidence of metastatic disease beyond the chest at the time of clinical presentation and initial staging. These tumors derive from endocrine cells of the bronchial mucosa and can produce a variety of paraneoplastic syndromes (see Chapter 92). Untreated, the course of illness is rapid, with a median survival of only a few months. However, these tumors are very responsive to chemotherapy (see below).

Non–Small-Cell Lung Cancer. A fourth to a third of patients with NSCLC present with localized disease (stages I and II).Another fourth to a third have locally or regionally advanced disease (stages IIIa and b), and a third to a half present with advanced disease and distant metastases (stage IV). Survival is a function of stage at the time of presentation, with nearly 40% of the first group surviving 5 years, 7% of the second group, and fewer than 1% of patients in the last group (Table 53.1).

STAGE	TUMOR	NODES	METASTASES	FIVE-YEAR SURVIVAL
I	T1 or T2	N0	M0	50%
II	T1 or T2	N1	M0	30%
IIIa	T1-2 or T3	N1 or N0	M0	15%
IIIb	any T	any N	M0	<5%
IV	any T	any N	M1	0%

Staging for small-cell lung cancer is designed as either "limited disease" (confined to the thorax) or "extensive disease" (metastasis outside the thorax). T1: lesions up to 3 cm in diameter; T2, lesions >3 cm; T3, invasion of mediastinum, diaphragm, or chest wall; T4, invasion of heart, great vessels, or malignant pleural effusion; N0, no nodal involvement; N1, tracheobronchial or hilar node involvement; N2, ipsilateral mediastinal nodes; N3, contralateral or supraclavicular nodes; M0, no metastasis; M1, systemic metastasis. Adapted from Mountain CF. A new international staging system for lung cancer. Chest 1986;89(suppl 4):225S, with permission.

Table 53.1. Staging and Survival in Non–Small-Cell Lung Cancer

Squamous cell (epidermoid) carcinoma is the most common lung cancer. It accounts for more than 40% of all cases. Like most other bronchogenic carcinomas, it is strongly associated with smoking. Most of these tumors occur centrally and can produce bronchial obstruction. They tend to ulcerate and may cause bleeding.

Adenocarcinomas account for about 25% of lung cancers and many of those that present peripherally. They sometimes arise in areas of fibrosis secondary to prior pulmonary parenchymal damage. Cancers of this cell type are less closely associated with smoking than others.

Undifferentiated large-cell carcinomas are, in most instances, probably a form of adenocarcinoma. Unlike well-differentiated adenocarcinomas, they are often centrally located and bronchoscopically visible as an endobronchial mass lesion. These cancers tend to metastasize hematogenously relatively early, leading to disease in the bones, liver, and brain.

Clinical Presentation is partially a function of tumor location; *central endobronchial* lesions may produce symptoms *early* in the course of illness. *Hemoptysis, cough, sputum production*, and a *localized wheeze* are among symptoms reported in early phases; however, the frequency with which these symptoms are noted in early disease is low. Hemoptysis occurs as a presenting symptom in only 7% to 10% of patients with lung cancer, although up to 40% will report hemoptysis at some time in their illness. On occasion, a systemic syndrome, such as hypertrophic osteoarthropathy (see Chapter 45), peripheral neuropathy, or inappropriate secretion of antidiuretic hormone, may precede other evidence of disease (see Chapter 92). Symptoms of *advanced disease* include *anorexia, weight loss, nausea* and *vomiting, hoarseness* (recurrent laryngeal nerve involvement), *pleuritic chest pain, bone pain*, and *neurologic deficits*.

In patients who present with metastasis or in whom metastasis later develops, the most frequently involved sites include local or regional *lymph nodes* within the chest (25% to 45%), *liver* (30% to 45%), *bone* and *bone marrow* (20% to 40%), and *central nervous system* (20% to 35%).

Clinical Course and Prognosis. Overall 5-year survival remains at a dismal 13%, essentially unchanged in the past three decades. The poor prognosis is related in part to the advanced stage of disease at the time of diagnosis. Unfortunately, local and regional disease is most often asymptomatic. Because the median survival for patients with lung cancer is less than 12 months, late metastasis is rare. Important exceptions to these dim statistics exist, however—in particular, the improved survival for patients with SCLC and those with NSCLC whose tumors are surgically resectable.

As noted above, the clinical course is different for SCLC and NSCLC. For *NSCLC*, clinical course and survival are a function of the surgical pathologic stage. The staging scheme for NSCLC has been revised according to the tumor–node–metastasis (TNM) system (see Table 53.1 and Chapter 86). Survival improves markedly with surgical resectability. For example, those patients whose disease is confined to the lung (stage I) have a 5-year survival approaching 50%. With involvement of the hilar and mediastinal lymph nodes, survival rates decrease significantly, but less so than was previously thought if complete tumor resection is achieved. Unfortunately, only a small minority of patients present with surgically curable disease. Screening efforts have failed to provide satisfactory early detection (see Chapter 37). Preliminary data suggest that monoclonal antibodies directed against some tumor antigens may correlate inversely with prognosis.

SCLC differs substantially from NSCLC in that the prognosis is more independent of anatomic distribution at the time of diagnosis. Before the advent of contemporary chemotherapy, median survival was 1 to 3 months; it has increased several fold to 7 to 16 months, depending on the extent of disease. Five-year survival remains poor (5% to 10%) because of the high probability of metastasis, even among those who present with limited disease.

WORKUP AND STAGING

The basic approach to diagnosis and staging is to begin with noninvasive studies and proceed to increasingly invasive studies only as necessary. Staging is performed to determine prognosis and treatment and, in particular, to assess resectability of the tumor. The advent of computed tomography (CT) has greatly facilitated the noninvasive assessment of hilar and mediastinal node involvement. Invasive studies should be considered only if the results will have a marked effect on treatment plans. Many patients with lung cancer have concurrent chronic lung disease and may be seriously compromised by a complication of an invasive study.

The histopathologic diagnosis of lung cancer may be obtained with a variety of procedures, ranging from sputum cytology to thoracotomy (see Chapter 37 and Chapter 44).

Diagnosis. *Chest radiography* is the primary diagnostic modality; the appearance of the lesion and its doubling time are helpful in distinguishing benign from malignant disease. Although the detection of lesions as small as 3 mm has been reported, most lesions are not visible until they are at least 5 mm or more in diameter. The finding of a calcified nodule can behelpful, especially if the pattern of calcification is eccentric (see Chapter 44).

Chest CT aids diagnosis by confirming the presence of a suspected lung mass and, if calcium is present, by clarifying its calcification pattern. CT has become critical to staging by determining the presence and extent of hilar and mediastinal node involvement (see below).

Sputum cytology may provide evidence of lung cancer and even cell type. Test sensitivity ranges from 25% to 75%, depending on the site of the tumor. Optimal collection requires obtaining three deep, first morning samples. The presence of pulmonary histiocytes indicates an adequate specimen. A negative cytologic examination result does not rule out cancer, especially in patients with peripheral lesions.

The yield of cytologic testing can be greatly enhanced by the use of *fiberoptic bronchoscopy* complemented by *washings, brushings*, or *forceps biopsy*. With centrally located, visualized lesions, washings provide a diagnosis in nearly 80% of instances; for brushings, the yield is 92%, and for forceps biopsy, it is 93%. The yield falls in the case of peripheral lesions; it is 20% to 30% for peripheral lesions less than 3 cm in diameter, and about 40% to 70% for those larger than 3 cm. The complication rate is low in experienced hands, with hypoxemia, hemorrhage, pneumothorax, or laryngospasm occurring in 0.1% to 0.3% of cases. On occasion, *transbronchial biopsy* is deemed the best means of establishing the diagnosis (e.g., in suspected alveolar cell carcinoma; see Chapter 51). The risk for pneumothorax rises to 5%.

With peripheral lesions, *percutaneous transthoracic fine-needle biopsy*—usually guided by CT or chest fluoroscopy—has proved accurate in the diagnosis of lung cancers. Reports on the diagnostic accuracy of these radiologically guided procedures quote sensitivity in excess of 90% and specificity above 95% when they are performed by skilled radiologists using "fine-needle" techniques that allow not only aspiration but also removal of a tiny core of material. However, sensitivity and specificity may be compromised by the occasional inadequacy of the specimen obtained, which is sometimes an aspirate of cytologic material rather than a solid core of tissue; in such instances, the architectural relationships may be obscured or unavailable in cytologic specimens. Pneumothorax ensues in close to 30%, but it is usually small, of little clinical consequence, and resolves spontaneously without the need for a chest tube. Hemorrhage is rare unless a vascular lesion is sampled. For patients with limited pulmonary reserve, who may be unable to tolerate any degree of pneumothorax, a controlled thoracotomy may be preferable to needle aspiration.

Scalene node biopsy is indicated when these peripheral nodes are noted to be enlarged; it can save the patient extensive testing for both diagnosis and staging.

Staging is performed to determine the prognosis and select therapy. The principal challenge is to assess surgical candidacy, which requires an accurate evaluation of hilar and mediastinal lymph nodes. If contralateral involvement of the regional nodes by tumor is noted, the patient is placed in stage IIIb and is not considered for curative surgical therapy; however, ipsilateral disease is no longer de facto grounds for eliminating a patient from surgical candidacy. The challenge is to evaluate the regional nodes accurately.

Chest radiography contributes to staging by providing data on tumor size, and it may show evidence of spread to the chest wall or regional nodes if marked involvement is present, although sensitivity is low.

Chest CT with contrast has been used extensively in the hope of improving the sensitivity of radiologic staging. Although the sensitivity and specificity of CT in the diagnosis of mediastinal disease appear to be reasonable for patients with clinical stage I disease who have a lung lesion larger than 3 cm (T2, N0, M0), results for those with earlier stage I disease (T1, N0, M0; lung nodule <3 cm) have been disappointing. False-positive and false-negative rates of 5% to 10% have been reported for the diagnosis of contralateral mediastinal node involvement in such patients. This has led some authorities to warn against reflexively ordering CT for patients with early stage I disease or depending too heavily on the findings for decision making (e.g., determining surgical candidacy solely on the basis of a result of CT). For patients with a pulmonary lesion larger than 3 cm, CT with contrast continues to be a useful noninvasive step to assess the hilum and mediastinum, but a negative CT result does not rule out microscopic spread from central or late peripheral lesions.

CT is sensitive for the detection of metastasis below the diaphragm (to liver and adrenals); upper abdominal views should be obtained at the time of chest CT. Positive findings, confirmed by needle biopsy, would indicate stage IV disease, for which surgery is inappropriate.

For judging tumor involvement of the chest wall, magnetic resonance imaging (MRI) is superior to CT. MRI is also better for assessing disease in the superior sulcus and defining subcarinal nodal involvement.

Although symptomatic metastasis to head and bone is relatively common, routine use of *head CT* and *bone scanning* is wasteful unless clinical evidence of disease referable to these sites is present (see Chapter 86).

More invasive staging techniques are indicated when the patient's surgical candidacy remains in question after CT. Many thoracic surgeons believe that all patients should undergo *mediastinoscopy* for evaluation of the mediastinum and hilum before thoracotomy because the presence of microscopic tumor in the contralateral mediastinum is a contraindication to resection. Under general anesthesia, a cervical incision is made and mediastinal node biopsy is carried out under direct visualization. They argue that the sensitivity of CT is insufficient, even in the setting of more advanced or central disease, in which the likelihood of microscopic nodal involvement is high. The debate and efforts to improve mediastinal staging continue.

Advances in the techniques of needle biopsy and fiberoptic endoscopy have enhanced the roles of *transthoracic* and *transbronchial needle aspiration biopsy* in the staging of lung cancer. These techniques offer a less morbid alternative to mediastinoscopy for the tissue-based assessment of mediastinal spread. They do not require general anesthesia or a formal surgical procedure and can be performed under CT guidance. Mediastinoscopy can be reserved for those in whom the results of these procedures are inconclusive.

The rest of staging is determined by the tumor cell type. For patients with inoperable *NSCLC*, further staging is of little value because the information will have minimal impact on decision making and estimation of prognosis. Staging is considerably different for patients with *SCLC*. Because the diseaseusually presents with evidence of bilateral nodal involvement, the issue is extent of disease rather than resectability. The goal is to distinguish between limited and extensive disease (the latter implies spread beyond the hemithorax of origin and regional nodes). Marrow invasion is present in almost 25% of patients, and marrow biopsy is performed routinely. CT of common sites of metastatic disease (e.g., brain) may also be useful if the result will affect plans for therapy (see below).

PRINCIPLES OF MANAGEMENT

Small-Cell Disease

Small-cell disease is biologically unique among bronchogenic cancers in that the cells are extremely sensitive to chemotherapy and radiation, probably in part because of their rapid rate of proliferation. Surgical treatment is usually not possible because 85% of patients have extensive disease at the time of presentation. Irrespective of whether disease is limited to the chest or disseminated, the treatment of choice is *combination chemotherapy*. For patients with limited disease, *radiation* is given as adjunctive therapy. As noted above, survival irrespective of stage has been prolonged fourfold to fivefold by chemotherapy. However, cure rates are very low. Only about 10% of limited-stage patients survive 5 years, and those who survive 2 years have a greater than two-thirds chance of relapse. Essentially all patients with extensive disease die within 2 years.

Chemotherapy. Since the introduction of combination chemotherapy in the 1970s, survival rates have improved modestly, and considerable progress has been made in reducing treatment morbidity, complexity, and duration. The use of a reduced-dose regimen of *etoposide* plus *cisplatin* after a course of three-drug therapy (cyclophosphamide, doxorubicin, vincristine) has improved survival and reduced marrow suppression. Shorter courses of therapy (no more than 4 to 6 months) are standard; longer courses are without additional benefit. In the elderly, single-dose etoposide appears to provide up to 80% of the response without significant

compromise of survival.

Radiation. Patients with limited disease show a 90% response rate to irradiation. Survival appears to improve when radiation is used as an adjunct to chemotherapy, although toxicity increases. The optimal means of combining both modalities is under active study, with preliminary data on a synergistic effect noted for concurrent use of cisplatin and radiation. Prophylactic radiation of the cranium decreases the risk for clinical brain metastases, but in the absence of a proven survival benefit, the question of whether the considerable toxicity is justified remains controversial. Cranial irradiation among patients in complete remission has been shown to produce a modest reduction in relative risk for death (0.84) and for recurrence or death (0.75).

Surgery has almost no role in SCLC because of the nearly universal occurrence of occult disease beyond the initial lesion.

Non–Small-Cell Disease

Surgery offers the only possibility for cure. The procedure of choice is a *thoracotomy with resection.* About 35% to 45% of patients presenting with NSCLC have potentially resectable disease, but only 60% have a successful resection. For the latter group, the 5-year survival or cure rate ranges from 25% to 40%. Thus, at best, fewer than 10% of patients who present with NSCLC can expect a cure. Two concurrent trends dominate the surgical approach to NSCLC: expanding candidacy to patients with stage IIIa disease, and reducing the extent of resection in patients with stage I disease. Patients with a single ipsilateral mediastinal lesion are now considered surgical candidates. Previously, mediastinal nodal involvement was considered incurable, but those with ipsilateral disease that can be grossly removed have shown a 5-year survival ranging from 15% to 30%.

Patients with localized disease are being treated with less radical, more conservative surgery. The goal is to preserve as much functional lung tissue as possible, especially in patients with underlying lung disease. Previously, pneumonectomy was performed in more than 70% of patients and included hilar in addition to mediastinal lymph nodes. A regional excision that employs wedge or segmental resection for stage I peripheral lobe lesions is now preferred. The general surgical dictum is to employ the minimal degree of surgery necessary to remove all macroscopic evidence of tumor.

Surgical excision is particularly indicated for nodules with long doubling times or long disease-free intervals, especially if the nodules are solitary and not associated with extrathoracic disease. The subsequent use of radiation therapy may augment local control, allowing for less extensive surgery.

Radiation Therapy is used for both curative intent and palliation. Preoperative radiation therapy may promote the resectability of tumors and possibly extend survival rates. In patients with tumors of the superior sulcus, preoperative radiation therapy has improved the likelihood of cure despite contiguous extension of such tumors to bone or the chest wall. In general, when surgery is used in combination with prior radiation, the resection must almost always be a pneumonectomy, and in principle, all sites that were diseased before the radiation therapy must be resected.

When radiation is used as sole therapy with a *curative intent*, results have been disappointing. Patients with NSCLC respond poorly to irradiation as a curative therapy, but good intrathoracic control of tumor, even eradication, can be achieved. In a major randomized trial of definitive radiation therapy for patients with unresectable stage III cancer, higher rates of regression and better disease control in the chest were observed with the use of high-dose therapy (60 Gy). However, no improvement in baseline 5-year survival, which remained at 5%, was noted. Although radiation may achieve local control, it does little to prevent relapse, which most often is the result of distant metastases. This has led to attempts to combine chemotherapy with irradiation (see below).

Chemotherapy has a far more limited role in NSCLC than in SCLC. It has been used as adjuvant therapy before surgery in patients with extensive but surgically resectable disease (e.g., stage III), after surgery, and in patients with inoperable disease who are undergoing radiation therapy. The goals are to improve local control and decrease the risk for distant metastasis. Results have been modest at best, but some improvements in survival are being noted. *Cisplatin* in particular has shown promise, although its side effects can be disabling (see Chapter 88). A metaanalysis of trials comparing surgery with surgery plus chemotherapy showed a relative reduction in short-term mortality risk of 13%, which produced an absolute mortality reduction of 5% at 5 years. The same metaanalysis included trials comparing radical radiotherapy with radical radiotherapy plus chemotherapy. Again, the relative reduction in short-term mortality risk was 13%; this produced an absolute mortality reduction of 4% at 2 years. Cisplatin has even produced some improvement in survival for patients with stage IV disease, although the improvement in survival has to be weighed against drug-induced morbidity. Studies indicate that patients who have undergone chemotherapy for NSCLC vary widely in their estimation of the survival benefit that would be necessary to justify toxicity. The majority do not consider the best estimate of median survival benefit (approximately 3 months) sufficient to justify the toxicity. Further refinement of chemotherapy and its use in combined-modality programs offers promise, but much work remains to be done.

Management of Stage III Disease deserves special comment because more than 60% of patients with NSCLC present with inoperable disease. In the majority of patients with stage III bronchogenic carcinoma, distant metastases develop regardless of control of the primary tumor. Survival is a function of the rate and extent of systemic dissemination. Substantial advances in therapy are required before genuine hope can be offered to the patient with this stage of disease. Encouraging developments include the improved survival associated with the surgical treatment of stage IIIa disease, and with the concurrent administration of cisplatin-based chemotherapy and radiotherapy for stage IIIb disease.

MONITORING

Because little can be done for metastatic disease, the monitoring of patients with surgically resectable and potentially curable lung cancer is specifically directed at searching for new primary tumors in this high-risk population. Chest radiography is indicated at regular intervals, ranging from every 3 months during the first 2 years to every 4 to 12 months in later years. Routine monitoring for recurrent disease outside the chest is unnecessary in the absence of specific symptoms suggesting bone, liver, or brain metastasis.

The monitoring of patients with extensive disease is directed at assessing the efficacy of therapy. One needs to select one or more objective measures of tumor burden (see Chapter 86) that can be followed conveniently to gauge response to treatment. Chest radiography, CT, and bronchoscopy are commonly used.

MANAGEMENT OF COMPLICATIONS

Superior Vena Cava Syndrome. Obstruction of the superior vena cava by lung tumor produces the classic clinical syndrome of facial edema, proptosis, suffusion of the conjunctivae, and dilation of the veins of the upper thorax and neck. Asymptomatic neck vein distention is an early manifestation. In late stages, the patient may have relentless headache. In patients with lung cancer, the syndrome is invariably caused by tumor extending into the right side of the mediastinum and compressing the venous system adjacent to the mediastinal lymph nodes. The secondary effects of compression are thrombosis and tumor invasion; without treatment, neurologic function may be compromised. The histopathologic types of lung cancer that lead to the syndrome are variable, but most commonly the culprit is undifferentiated SCLC (see Chapter 92).

The approach to evaluation and therapy has undergone some revision in recent years. Previously, it was believed that emergency radiation therapy was indicated regardless of whether a tissue diagnosis was available; the view was that the risk of an invasive procedure to obtain tissue outweighed the potential contribution to the design of a treatment plan. More recent data indicate that the risk of evaluation in patients lacking a tissue diagnosis is low and that chemotherapy may be superior to radiation in some instances (e.g., SCLC). Because superior vena cava syndrome may be the initial presentation of lung cancer, the issue of need for tissue diagnosis is frequently encountered in this setting. When the result will change the mode of therapy, tissue diagnosis should be attempted, with care taken to minimize risk to the patient.

Even when a tissue diagnosis is not obtained, the response to radiotherapy is rather good; in unselected series, more than 70% of patients demonstrate a response. Although patients with superior vena cava syndrome secondary to lung cancer have an inoperable tumor, their prognosis is no worse than that of other patients with stage III lung cancer.

Malignant Pleural Effusion is another important complication. It occurs in 10% to 15% of patients with carcinoma of the lung and may be secondary to direct pleural implantation or a consequence of mediastinal obstruction to lymphatic drainage of the pleural surface. Only 20% to 30% of pleural effusions that develop as a consequence of bronchogenic carcinoma are cytologically confirmed, and many are transudates. Pleural biopsy is often required for definitive diagnosis.

The median survival for patients in whom a malignant pleural effusion develops is less than 3 months; therefore, the effusion should be monitored and treated only when it causes significant respiratory discomfort. The use of intrapleural chemotherapeutic agents (e.g., bleomycin, fluorouracil) or chemical irritants (e.g., tetracycline, talcum powder, quinacrine) may be effective in 50% to 60% of patients. The specific choice of agent for sealing the pleura is determined by the associated morbidity of the treatment. The chemotherapeutic agents such as bleomycin and fluorouracil are relatively innocuous. On the other hand, nitrogen mustard and the "inert" irritants may result in a major secondary inflammatory response with reactive effusion and fever. Quinacrine (Atabrine) must be instilled repeatedly during a 5- to 7-day period for maximal effect. Radiation therapy to the mediastinum or to the pleura has been of limited effectiveness. Surgical drainage with an intrathoracic tube for 2 to 3 days may result in a secondary inflammatory response adequate to seal the pleural space.

Tumor Humoral Syndromes are associated with SCLC. Because the tumor is derived from endocrine cells of the bronchial mucosa, it is capable of producing adrenocorticotropic hormone, antidiuretic hormone, and even, on occasion, serotonin. The clinical pictures that may result are Cushing's syndrome, inappropriate secretion of antidiuretic hormone, and carcinoid syndrome, respectively. In an autopsy series of 85 patients with SCLC, it was found that those who manifested a paraneoplastic syndrome tended to have a more benign clinical course and longer survival; in addition, the incidence of metastases to the central nervous system was significantly lower in these patients.

Complications of Surgical Therapy include prolonged air leakage from a bronchopleural fistula and postoperative intrapleural infection with development of empyema. Both are potentially serious and require prompt surgical attention. Pulmonary insufficiency is uncommon as a result of careful preoperative pulmonary evaluation of candidates for resection; however, pneumonia in the remaining lung can lead to respiratory compromise.

Complications of Chemotherapy are related to the use of such agents as cisplatin, cyclophosphamide, doxorubicin (Adriamycin), methotrexate, and nitrosoureas (see Chapter 88). The use of certain chemotherapeutic agents (e.g., nitrosoureas, methotrexate) during the induction phase of radiation therapy in patients with SCLC is suspected of causing some late complications seen in long-term survivors, such as other malignancies.

Complications of Radiation Therapy include radiation pneumonitis, esophageal stricture, pericardial and myocardial fibrosis, rib fractures secondary to radiation-induced osteonecrosis, and radiation fibrosis.

PATIENT EDUCATION

Most lay persons believe that lung cancer is fatal. Although the prognosis and efficacy of treatment are indeed poor in most types of lung cancer, the patient with a newly discovered, suspect pulmonary nodule needs to know that differences in prognosis can be significant, according to tissue type and stage of disease at time of presentation. During the workup and staging, this background information can help sustain patient and family through a worrisome period of uncertainty and provide a rationale for the procedures that need to be carried out.

Once the diagnosis and extent of disease are known, the prognosis and treatment options should be shared with the patient and family. When surgical cure is a genuine possibility and the patient can tolerate the surgery, it should be urged. However, in lung cancer, in which the prognosis is often so poor, the treatment plans should be formulated jointly, and the patient's preferences and willingness to undergo treatment should be elicited and respected. A realistic assessment for the patient and family of prognosis and the pros and cons of treatment are essential for effective decision making. All too often, inappropriately aggressive forms of therapy are rushed into, mostly for the sake of "doing something." Studies have found that socioeconomically advantaged patients tend to undergo more aggressive forms of therapy, although when disease stage is controlled for, no evidence of improved survival is found.

Patients with incurable disease need to know their prognosis, which is best explained at a level of detail consistent with their desire to know. The news of lung cancer in a loved one is very upsetting to family members, who will try to shield the patient from the information. Facilitating communication between family and patient is essential to preserving the patient's quality of life and helping the family to cope (see Chapter 87).

CHAPTER 54 SMOKING CESSATION

NANCY A. RIGOTTI

INTRODUCTION

Cigarette smoking is the major preventable cause of death in the United States. Strong evidence documents benefit from cessation of smoking, even for the elderly and patients in whom chronic tobacco-related disease has already developed. Although the health risks of smoking are widely recognized and the prevalence of smoking has fallen dramatically in the past two decades (from 40% to about 25%), millions of Americans continue to smoke, a substantial fraction more heavily than ever, and adolescents continue to take up the habit in large numbers. Nevertheless, many people are eager to quit and often come to the primary physician for advice. Numerous studies have shown that physicians can change a patient's smoking habits. Extensive evidence indicates that pharmacotherapy increases the likelihood of successful quitting. The primary care physician needs to be expert in motivating patients to quit and in advising them on the best means to accomplish their goal. This requires knowledge about available smoking cessation techniques and an appreciation of how and when to use them.

EPIDEMIOLOGY OF SMOKING AND QUITTING

Since 1964, when the Surgeon General's Report first publicized the health risks of smoking, cigarette smoking by adults in the United States has declined. This decline in the percentage of the population that smokes is averaging about 1.1 percentage points per year, with the percentage of smokers falling to about 25%. This decrease is largely attributable to the increasing number of smokers who have quit, rather than to a fall in the number of smokers taking up the habit. About 30% of smokers report attempting to quit each year. As less addicted smokers quit, the proportion of heavy smokers (>25 cigarettes per day) has increased from about one in four to one in three. Smoking in adolescence—the time when smoking usually begins—has fallen little since its peak in the 1970s. Adolescent girls are smoking in numbers comparable with those in boys; the historical gender difference continues to narrow. This is worrisome because women who smoke during the reproductive years incur special risks with pregnancy and oral contraceptive use. Smoking is increasingly prevalent among populations that are nonwhite, poor, or of low educational status.

Most smokers claim that they are aware of the health hazards of smoking and would like to quit but have difficulty doing so. Although the success rate for any single attempt at quitting is low, smokers who repeatedly try to quit increase their likelihood of success. Lighter smokers are more successful than heavier smokers. Smokers most likely to quit are those who expect their attempt to succeed, have a strong belief in their personal control over events, feel competent and personally secure, and have a good social support system. The smoking habits of the spouse and, in some studies, friends are important; those with nonsmoking spouses are more likely to succeed. Patients with *depression* or a history of depression have a hard time initiating smoking cessation and a poor success rate (40% that of patients who are not depressed) when they try.

More than 90% of former smokers quit on their own without assistance from physicians, groups, patches, gum, hypnosis, acupuncture, or psychological counseling. Those who benefit most from an assisted method are heavy, more addicted smokers. Their chance of successfully quitting is about half that of smokers who quit on their own. Receiving advice from a physician about smoking cessation doubles the chance of a patient making an attempt to quit. Smokers who quit using the "cold turkey" approach are more likely to remain abstinent than those who taper. Reducing cigarette consumption somewhat and switching to a different brand can be part of a smoker's preparation for quitting—being especially helpful in building a sense of confidence and control—but are no substitute for setting a definite date for abrupt and total cessation.

Health concerns are the most common reasons given by former smokers for quitting. However, the risks for lung cancer and heart disease are less often cited than are minor smoking-related ailments such as cough, dyspnea, and sore throat. Minor symptoms may successfully motivate a smoker to quit by making personally salient the more serious health risks of smoking. Illness in one smoker can influence other smokers to quit (e.g., the friend or family member in the intensive care unit), as can personally sustaining a serious smoking-related illness, such as a heart attack. The likelihood that a smoker will quit increases with the severity of the illness. Although fewer than 5% of smokers in the general population quit each year, cessation rates are higher among persons with newly diagnosed coronary heart disease. Many studies report that approximately one third of smokers surviving a myocardial infarction stop smoking permanently. Increased rates of cessation are also reported in smokers with chronic obstructive pulmonary disease. During pregnancy, 20% of women smokers stop smoking, but the majority resume smoking after delivery. Many smokers quit temporarily when they have an acute respiratory illness.

Other reasons for quitting cited by former smokers include a desire to exert self-control over one's life, aesthetic objections to the smoking habit, and fear of setting a bad example for others. The cost of cigarettes exerts little influence among adults.

WHY PEOPLE SMOKE

Smoking is a complex behavior initiated and maintained for different reasons. The influence of peers and parents appears to be most important in the initiation of smoking. Adolescents whose parents and friends smoke are more likely to begin smoking. Once the smoking habit is established, it is sustained by many factors.

Both pharmacologic and psychological models have been proposed to explain what maintains smoking behavior. The *psychological model* regards smoking as a learned behavior that continues because it is rewarding to the smoker. Certain situations, such as finishing a meal, become strongly associated with smoking and trigger the urge to smoke. Smokers also use cigarettes to handle environmental stress and regulate emotions, especially strong negative emotions like anger.

A strong association between *depression* and smoking has been documented. Depressed patients are more likely to be smokers and, as noted above, less likely to attempt quitting or succeed at quitting. It is hypothesized that smoking may represent a form of self-medication for the depressed patient, with nicotine alleviating a dysphoric mood through activation of central neuroreceptors. Such a response would strongly reinforce smoking and might trigger a craving for cigarettes during times of depressed mood. Moreover, withdrawal of nicotine during an attempt at smoking cessation might trigger symptoms of depression, which has been reported in studies of patients with a history of depression who attempt to quit.

The *pharmacologic model* emphasizes physical addiction to nicotine. The evidence for smoking as an addiction is strong, and nicotine has been established as the addicting substance in tobacco smoke. According to this model, the smoker smokes to maintain a constant blood level of nicotine and thereby avert the *withdrawal syndrome*, characterized by falls in heart rate, blood pressure, and basal metabolic rate and changes in electroencephalographic rhythms and rapid-eye-movement (REM) sleep patterns. Craving for nicotine is the most common subjective symptom of withdrawal, but other symptoms include restlessness, irritability, inability to concentrate, daytime drowsiness and fatigue, sleep disturbances, headache, nausea, alteration in bowel habits, and increased appetite. Symptoms begin within hours after cessation of smoking, but their duration and severity are highly variable, representing different degrees of nicotine addiction among smokers. No simple test is available to measure nicotine addiction, but heavily addicted smokers tend to have their first cigarette shortly after arising (i.e., within 30 minutes), smoke more and stronger cigarettes, and have difficulty not smoking for even a few hours.

The pharmacologic model can explain initial difficulties with cessation but cannot explain why smokers have difficulty remaining abstinent after the first few days or weeks. In fact, the majority of smokers who stop temporarily resume smoking within a few months.

TECHNIQUES FOR SMOKING CESSATION

The methods of smoking cessation range from unassisted "cold turkey" to formal treatment programs administered in a group setting, with a host of interventions in between. As noted, the majority of smokers quit in unassisted fashion. As might be expected from the multidimensional nature of the smoking problem, no single

method suffices. The most effective approaches address both principal components of the smoking problem: (a) nicotine addiction and (b) behavioral dependency on cigarettes. Combining a number of approaches into a personalized, comprehensive program appears to be the most successful strategy.

Strategies that combine pharmacologic and behavioral techniques appear to be the most effective. Pharmacologic methods are used to relieve symptoms of nicotine withdrawal, freeing the patient to focus on behavioral efforts (Table 54-1 and Table 54-2).

I. Assess smoking habits
  A. Smoking and quitting history
  B. Interest in cessation
  C. Identify potential motivating factors
II. Advise every smoker to stop smoking
III. Motivate the smoker to attempt to quit
  A. Emphasize benefits of cessation
  B. Focus on short-term changes
  C. Tailor to the clinical situation
    1. Asymptomatic smoker
    2. Acute respiratory illness
    3. Chronic cardiopulmonary illness
    4. Pregnancy
IV. Ask for a commitment to quit
V. Help the smoker to quit
  A. Physician counseling/nurse counseling
  B. Self-help materials
  C. Nicotine patch or gum
  D. Referrals to formal smoking withdrawal programs
  E. Anticipate problems
    1. Withdrawal symptoms
    2. Weight gain
VI. Follow-up
  A. Put smoking on the problem list
  B. Follow-up visits with nurse or physician
  C. Continued monitoring at each visit

Table 54-1. Smoking Cessation Strategy for Office Practice

Table 54-2. Behavioral Program for Smoking Cessation

Maintaining long-term tobacco abstinence remains the challenge in smoking cessation treatment. Short-term cessation rates of 70% to 80% are common among programs. However, a predictable and rapid return to smoking follows initial cessation. A 1-year cessation rate of 30% to 35% is considered the standard for an effective smoking cessation program.

Pharmacologic Methods

The principal pharmacologic approach is to relieve symptoms of withdrawal by continuing some nicotine exposure, although at reduced and tapered doses. Nicotine delivery is most often achieved transdermally with nicotine patches or through the oral mucosa with nicotine chewing gum. Newer approaches include nicotine nasal spray and nicotine inhalers. Other pharmacologic approaches to minimizing withdrawal symptoms have included the use of clonidine, minor tranquilizers, and drugs that mimic the autonomic effects of nicotine. An alternative pharmacologic approach is the use of antidepressants, especially bupropion, an atypical antidepressant with both dopaminergic and adrenergic effects. Bupropion became available as a prescription drug in 1998 as Zyban, a trade name specific for smoking cessation.

Transdermal Nicotine. Transdermal nicotine ("the patch") represents a second-generation form of nicotine reduction therapy, developed after the introduction of nicotine gum more than a decade ago (see below). It provides a convenient means of maintaining nicotine exposure and preventing nicotine withdrawal symptoms while the smoker addresses the behavioral component of the smoking problem. Once the habit is broken, nicotine supplementation is stopped. A smoker on nicotine reduction therapy is already being weaned from nicotine because the pharmacokinetic properties of the patch differ from those of inhaled smoke. The levels of nicotine delivered transdermally are more constant than the peaks and troughs characteristic of smoking.

The *effectiveness* of the patch is related to its ease of administration. In randomized clinical trials of at least 6 months' duration, nicotine patches have been shown to be superior to placebo in helping smokers to stop smoking; the cessation rates of smokers using the nicotine patch were approximately double the rates of smokers receiving placebo patches. In 1996, nicotine patches became available without a prescription. The rationale for this decision of the Food and Drug Administration was to make replacement therapy more accessible because of its proven effectiveness in multiple trials. Since then, several trials have demonstrated the 6-month quit rates obtained with over-the-counter nicotine patches to be 2.5 to 2.8 times those achieved with placebo patches.

Patches are not a panacea, nor are they appropriate for everyone. They should be used only by smokers who (a) want to quit and are willing to set a quitting date; (b) have a significant amount of nicotine addiction (i.e., smoke more than one pack per day, smoke their first cigarette within 30 minutes of arising, had withdrawal symptoms on prior attempts at quitting); (c) will not smoke while using the patch; and (d) will follow a behavioral program (individual or group) in conjunction with patch use.

Proper use of nicotine patches involves beginning patch application on the day of quitting. The patch is applied to any nonhairy skin site and worn for 16 or 24 hours. Because of possible skin irritation, the patch site should be rotated. Once applied, the patch is impervious to external water (shower, swimming), but it can come loose with perspiration. For this reason, it should put on after exercise. Most patches come in multiple strengths. Most smokers should use the patch for 2 to 3 months and start with the strongest dose (21 mg/d), then gradually taper to lower-dose patches (14 mg/d and 7 mg/d). Those who weigh less than 100 lb are advised to begin with the 14 mg/d strength. A typical program might use the 21 mg/d patch for 4 to 6 weeks, with a switch to the 14 mg/d strength for 2 to 4 weeks and then to the 7 mg/d patch for 2 to 4 weeks. Some argue that patients who smoke less than one pack per day can begin with a 14 mg/d patch, but such patients may not be sufficiently addicted to nicotine to need the patch in the first place.

Side effects are relatively few. The most common is skin irritation, which is usually minor. It is reduced by frequent changes in patch location. Insomnia is also reported, probably caused by the stimulant effect of a constant level of nicotine. The 16-hour patch might be useful for patients bothered by insomnia, or a 24-hour patch can be removed at bedtime. Rash, headache, nausea, vertigo, myalgia, and dyspepsia have been reported, but dependence and abuse have not, although experience is still too limited to rule out the possibility. Isolated cases of myocardial infarction have been reported in patients who continue to smoke while using the patch. In clinical trials, only 5% of patients stopped therapy because of side effects. Because of the vasoconstrictive action of nicotine, patients with recent myocardial infarction, unstable angina, peripheral vascular disease, or serious arrhythmias and women who are pregnant or breast-feeding should avoid patch use.

Patient education is critical. Many patients view the patch as a simple, passive means of quitting, one that requires little effort on their part. Some even continue to smoke while using the patch, under the mistaken belief that it should be used for tapering. Proper patient selection and education are essential to the safe and effective use of the patch. The effectiveness of the patch is enhanced by behavioral smoking cessation therapy.

Nicotine Chewing Gum. Nicotine chewing gum was the original form of nicotine reduction therapy. It also provides an oral substitute for cigarettes. Nicotine is released from the gum during chewing and absorbed through the oral mucosa, resulting in blood levels lower but more constant than those achieved by smoking. Exposure to the other harmful constituents of cigarette smoke is avoided. In some studies, patients using the gum also gained less weight after cessation of smoking than smokers not using the gum. The preparation initially available contained 2 mg of nicotine. A 4-mg gum was approved for use in 1993 and is probably more

effective. Both 2-mg and 4-mg preparations became available without a prescription in late 1995.

Nicotine gum is more effective than placebo when used in conjunction with a behavioral program for self-selected, motivated smokers attending a smoking withdrawal clinic; 1-year cessation rates of 30% to 50% have been reported, representing an advance over rates attained with behavioral treatments alone. The gum, like the patch, may be especially useful in smokers heavily addicted to nicotine. When the gum is used by less motivated patients, cessation rates are lower, and its effectiveness is less certain. Like the patch, the gum is effective only for helping the patient to quit; it is not a substitute for behavioral therapy. Studies of long-term abstinence show little benefit from gum use without a behavioral program.

To use the gum, smokers are instructed to pick a target date when they will stop smoking. After that, they chew the gum whenever they have an urge to smoke, usually consuming a dozen pieces daily at the onset. Gum use should continue for 2 to 3 months. Dependence develops in 5% to 10% of users, who have difficulty stopping. It is important to emphasize to the patient that the best results are obtained when gum use is accompanied by a program that teaches behavioral skills.

Side effects are mostly a consequence of overly vigorous chewing and release of excess nicotine—sore jaw, mouth irritation or ulcers, nervousness, dizziness, nausea, vomiting, hiccups, intestinal distress, headache, and excess salivation. To reduce these symptoms, smokers should chew the gum very slowly, just enough to detect a slight tingling taste in the mouth. Contraindications to use are the same as those for the transdermal patch (see above).

In addition to side effects, factors limiting effectiveness include poor compliance (as many as 35% use the gum for too short a period), improper chewing technique, and adherence to dental appliances and bridgework. Smokers starting the gum need detailed instruction in its proper use. Nicotine absorption may be compromised by the consumption of acidic beverages (e.g., coffee, carbonated drinks). By lowering the pH of saliva, they block nicotine absorption when ingested during or immediately before gum use. Not drinking acid beverages around the time of gum use solves the problem.

Nicotine Nasal Spray. Nicotine nasal spray was developed to provide more rapid delivery of nicotine and thereby mimic more closely the effect of smoking a cigarette. The delivery device is similar to a nasal antihistamine spray, and one or two doses are taken per hour for a period of about 3 months. As with gum and transdermal patches, the quit rates with the device have proved to be about twice those attained with placebo. Nasal and throat irritation, rhinitis, sneezing, and tearing are common side effects. The role of the nasal spray as an alternative to gum and patches is yet to be defined. It is available only by prescription at the beginning of 2000.

Nicotine Inhalers. Nicotine inhalers were introduced as a prescription drug in 1998. The inhaler is a plastic rod with a nicotine plug that delivers nicotine to the buccal mucosa when drawn upon. The pharmacokinetics are similar to those of nicotine gum, as is the effect on quit rates. Its role as an alternative to gum and patches also remains to be defined.

Bupropion. Bupropion, an antidepressant, has proved to be as effective as nicotine replacement therapy, doubling quit rates in comparison with placebo. It is the ideal pharmacologic approach for smokers who prefer not to use nicotine replacement or who have been unable to quit with nicotine replacement. It is equally effective among persons with and without a history of depression. Bupropion is generally started 1 week before the ordained quit date. The usual dosage is 300 mg/d, and treatment is generally continued for 2 to 3 months. Bupropion has been used together with nicotine replacement, and some evidence suggests that the combination is more effective than either approach alone, although results have been conflicting. The most common side effects are dry mouth and insomnia. An increased risk for seizure was an early concern, but that has faded with use of the slow-release preparation at the dosage of 300 mg/d. Nevertheless, alternative treatment is advisable in patients with a history of seizure or other risk factors.

Other Agents. *Clonidine*, the centrally acting adrenergic blocker, has been shown to lessen the symptoms of opiate and alcohol withdrawal and has been tried for smoking cessation. Results of initial studies were encouraging, but randomized, controlled studies with sufficient follow-up found clonidine to be no better than placebo.

Lobeline (Nikoban). *Lobeline* (*Nikoban*), a non-nicotine substitute with autonomic effects that mimic those of nicotine, is no more effective than placebo. *Minor tranquilizers* have been prescribed as a means of blunting the anxiety and irritability of nicotine withdrawal, but they are no better than placebo. Furthermore, because daily use of these agents for more than a few days is associated with significant risks for tolerance and dependency (see Chapter 226), they are not appropriate for use in smoking cessation, in which daily use for several weeks is required.

Antidepressant Therapy. *Antidepressant therapy* with agents other than bupropion may have a role in the pharmacologic support of smoking cessation. Nortriptyline proved effective in a small, randomized trial, producing a quit rate of 14% at 6 months versus 3% for placebo. Other controlled trials of antidepressant therapy are in progress.

Behavioral Methods

The behavioral model of smoking has inspired a host of techniques to manipulate environmental cues that trigger or reward smoking. These techniques form the core of most smoking cessation programs (see Table 54-2).

Strategies for Stimulus Control. Strategies for stimulus control require smokers to identify and control the environmental stimuli that trigger smoking. Cues are first identified by *self-monitoring*. For example, smokers might be asked to carry a sheet of paper wrapped around their cigarette pack on which they record the circumstances in which each cigarette is smoked. Environmental cues, identified from this daily log, are then progressively avoided or modified so that they no longer trigger smoking. The behavior is separated from the triggers by *progressive restriction* of the situations in which smoking is permitted. At a point in the relearning process, smoking stops altogether.

Controlled studies have not demonstrated impressive long-term cessation with this approach alone. Smokers may decrease their cigarette consumption but are less successful at total cessation, and those who stop have a high relapse rate. By itself, the technique is more effective in preparing the smoker to quit than in achieving long-term cessation.

Aversive Conditioning Techniques. Aversive conditioning techniques pair an unwanted act like smoking with an unpleasant stimulus to make the act less likely to occur. The most effective aversive stimulus is cigarette smoke, which is unpleasant even to a heavy smoker. In the best-known technique, *rapid smoking*, the smoker is required to inhale every 6 seconds until unable to tolerate further smoking because of nausea, headache, or light-headedness. *Smoke holding* is a variation on rapid smoking, believed to produce similar aversive effects with less health risk. A related technique is *satiation*; smokers purposely double or triple their base smoking rate for up to a day before cessation. The safety of rapid smoking and satiation has been a concern because of the smoker's intense exposure to nicotine and carbon monoxide. However, no serious medical complications have been reported with supervised use of rapid smoking among healthy people and even those with mild cardiopulmonary disease, although the technique is not advised for those with more symptomatic heart or lung disease.

Rapid smoking and other aversive techniques are effective for initial abstinence, producing high rates of short-term cessation, but relapse occurs soon unless other techniques are employed.

Hypnosis. Hypnosis is of great interest to patients, many of whom hope it offers an effortless way to stop smoking. Most studies evaluating hypnosis have been uncontrolled, with small samples and brief follow-up; they report abstinence rates of 20% to 25% at 1 year, comparable with the standard achieved by behavioral programs. The elements identified as most predictive of success include multiple sessions, supportive therapists, motivated clients, and individualized hypnotic suggestions based on specific motivations for smoking.

Acupuncture. Acupuncture, like hypnosis, is widely requested by smokers. Needles are inserted at acupuncture points, often around the ear. Advocates claim the procedure can reduce the urge to smoke and even lead to long-term cessation. Success appears related to belief in the efficacy of acupuncture. Randomized, control trials are few; those that are available found no long-term benefit when acupuncture was used alone. Acupuncture might prove useful for the temporary relief of withdrawal symptoms in addicted patients.

Organized Group Programs. Both nonprofit and commercial organizations offer group programs for smoking cessation. Most programs have a high dropout rate and have not been adequately evaluated. The oldest and best known is the Five-Day Plan, developed in 1963 with the sponsorship of the Seventh Day Adventist Church.

Participants meet on five consecutive nights, and the program is low in cost. Techniques used are health education, encouragement to quit, and nonspecific support.

Adding behavior modification techniques to group programs has improved their effectiveness. SmokEnders, a commercial program, consists of weekly meetings run by former smokers. In one long-term study, 70% of participants were not smoking at the end of the program, and 39% remained abstinent 4 years later. However, on repeated analysis, the long-term cessation rate was 24%, equivalent to the standard rates achieved with other behavioral programs. The American Cancer Society and the American Lung Association offer similar group programs at lower cost. More intensive group programs with extended follow-up offered in the medical setting have achieved better results. Patients who appear to benefit most from such programs are women, middle-aged persons, those who are heavy smokers and have made multiple attempts to quit, and persons who are better educated. Overall, however, fewer than 5% of smokers who successfully quit use a group program.

Individual Aids. Booklets, audiovisual aids, telephone services, and nonprescription filters are available to help smokers who wishes to quit on their own. Few have been evaluated. *Self-help manuals* range from booklets with practical tips on how to quit to longer books containing comprehensive programs of behavior modification. Many are available at minimal cost through nonprofit organizations like the American Cancer Society, the American Lung Association, and the National Cancer Institute. Use of the American Lung Association manuals has produced cessation rates of 12% at 1 month and 5% at 1 year.

These groups also sponsor *telephone services* that provide education, encouragement, advice, and referrals. In the largest randomized controlled trial to date, significantly more smokers offered immediate and repeated telephone counseling were abstinent at 1 month compared to controls (23.7% vs. 16.5%); at 1 year, the rates were still significantly different, but decreased (9.1% vs. 6.9%). **Updated: 11/5/02**

A series of progressively stronger *filters*, which gradually restrict the delivery of tar and nicotine from a smoker's own cigarettes, has not proved effective.

ROLE OF THE PHYSICIAN

Counseling Smoking Cessation. Because health is the most common reason given by former smokers for quitting, the physician is in a unique position to encourage smoking cessation. The potential importance of the physician's role is underscored by the fact that smokers in whom symptoms of cardiopulmonary disease develop or who become pregnant are more likely to quit. Such patients are particularly motivated to quit and are more responsive to intervention efforts. The chances of making an attempt to quit are doubled by a physician's urging and advice. Providing no more than brief advice to stop smoking to all patients has been shown to be more effective than doing nothing to promote cessation, and it is a cost-effective medical practice. Doing more (i.e., brief, structured smoking cessation counseling) has, in randomized controlled trials, increased patients' efforts to stop smoking and, in some trials, their rates of long-term smoking cessation as well. Surveys indicate that physicians are not taking advantage of their opportunity to alter their patients' smoking habits. Fewer than one half of current smokers recall being told to quit by a physician. In fact, a physician's advice can make a difference. Physicians who devote more time to counseling smokers can expect to be even more effective. In one study, a regularly scheduled follow-up visit for smoking counseling was more effective than one-time advice. The physician can be most effective by advising all smokers to quit and providing additional counseling to susceptible smokers—those with respiratory symptoms or a recently diagnosed serious, smoking-related disease. Physician components identified by the National Cancer Institute as particularly helpful to the cessation effort include making the office a smoke-free site, identifying all smokers in the practice, asking them at each visit about smoking and advising cessation at every appropriate opportunity, helping them set a quit date, providing them with educational and self-help materials, advising nicotine reduction therapy or bupropion when indicated, and arranging follow-up to sustain cessation. A team approach in which a nurse provides more in-depth counseling and follow-up after the physician's introduction to cessation can enhance outcomes and reduce the expenditure of the physician's time (see Table 54-1).

Preventing Relapse. *Follow-up* is critical. Studies of physician intervention show that scheduling follow-up visits to discuss smoking increases patients' cessation rates. The importance of continuing to work with the former smoker throughout the first year of cessation cannot be overemphasized, particularly the person with evidence of nicotine addiction. Such patients need to be prepared by the physician to recognize and manage nicotine withdrawal symptoms, prescribed a nicotine reduction program, and followed up within 2 weeks of quitting. Only after a full year of cessation can the patient be considered an ex-smoker. In the interim, repeated visits for reinforcement and support are essential to a successful outcome.

Weight gain must be addressed. Failure to do so risks ignoring a major cause of late relapse. Weight gain may be particularly upsetting to the person who quits out of a desire to improve appearance and personal hygiene. Nicotine increases energy expenditure. After cessation, the loss of such excess expenditure leads to weight gain unless caloric intake is decreased or physical activity is increased. Most smokers gain some weight after they stop smoking, with men averaging 2.8 kg and women 3.8 kg. The risk for large weight gain (>13 kg) is low; it occurs in about 10% of men and 13.5% of women. African-Americans and heavy smokers (>15 cigarettes per day) are also at increased risk. However, weight gain does not cancel the health benefits of smoking cessation. The physician needs to prepare the patient who plans to quit for the risk of weight gain. Prescribing a program of *exercise* (see Chapter 18) can be one of the best complements to the smoking cessation effort, facilitating weight control and providing an enhanced sense of well-being.

Depression also requires attention. Before the patient attempts to quit, the physician should evaluate the patient for an underlying depression (see Chapter 227) because it can be a major cause of smoking and a barrier to successful cessation (see above). If major depression is present, it must be treated before smoking cessation is attempted. As noted above, bupropion has proved to be equally effective at supporting cessation in patients with and without a history of depression, which suggests that its effectiveness in smoking cessation is independent of any beneficial effects on depression. Nevertheless, bupropion may well be the drug of choice in these situations because of the potential for both salutary effects. Patients with a history of depression, but who are not depressed before quitting, are at increased risk for a relapse during the withdrawal period. Depression needs to be watched for and responded to (see Chapter 227).

RECOMMENDATIONS

A smoking cessation strategy for office practice is summarized in Table 54-1.

1. *Assess smoking habits.* Smoking habits should be assessed as a part of every encounter in ambulatory practice. A smoking history should be taken from all smokers to assess the patient's current interest in quitting and anticipate difficulties with cessation, such as a high level of nicotine addiction or lack of social support. The smoker's prior cessation efforts and current medical and social situation can help guide treatment recommendations.
2. *Advise every smoker to stop smoking.* A firm statement to stop smoking should be made to all smokers at every visit. Total cessation is the goal.
3. *Motivate the smoker to attempt to quit.* This is the physician's primary role. The strategy should focus on health concerns, tailored to the individual's clinical situation. The approach should be positive, emphasizing the benefits of cessation and including short-term benefits, such as increased exercise tolerance or improved taste and smell. The contribution of smoking to any of the patient's current symptoms should be emphasized.

   The asymptomatic smoker may be the most difficult one to motivate. Most smokers do have minor smoking-related symptoms that would improve with cessation, such as morning cough or limited exercise tolerance. Smokers unable to quit for their own sake may do so for their children's health or to ensure a safe pregnancy.

   Smokers with an *acute respiratory illness* commonly stop smoking for a few days on their own. The physician can suggest that the smoker take advantage of the period of reduced desire to stop smoking permanently. For the smoker with a *chronic disease* associated with smoking, the physician should point out the potential for reduced symptoms, improved function, and slowed progression of disease. Radiologic or pulmonary function tests are not recommended for asymptomatic smokers because they do not detect early disease, and normal results may falsely reassure smokers that their health is not being jeopardized.

   Smokers reluctant to attempt cessation often harbor a specific concern, such as a fear of failure, weight gain, withdrawal symptoms, or the loss of a pleasurable habit or way to handle life stresses. Helping the smoker to clarify this concern and develop arguments to the contrary can be helpful. If the smoker remains unwilling to consider cessation, the physician should stop with a strong antismoking recommendation but should make a renewed effort at subsequent visits.
4. *Ask for a commitment to quit.* Encourage smokers to set a date on which they will stop smoking, preferably within 4 weeks. Ideal quitting dates are milestones, such as a birthday, anniversary, or New Year's Day, or times when life stresses are minimized, such as the first day of a vacation. The physician should record the date in the medical record, as a reminder to follow the patient's progress.
5. *Help the smoker quit.* The physician should be prepared to offer a personalized and detailed cessation program that will maximize the patient's chances of success and build confidence. Specific behavioral suggestions should be offered (see Table 54-2). Smokers concerned about weight gain should be advised to begin a concurrent exercise program and keep low-calorie snacks readily at hand. The addicted heavy smoker should be educated about withdrawal symptoms and considered a candidate for nicotine reduction therapy (transdermal nicotine patch, nicotine gum, or in special circumstances the newer prescription nasal spray or inhaler), especially someone with a history of severe withdrawal or marked weight gain on prior attempts. The patch or gum should be advised in

conjunction with a behavioral program; it is not as effective by itself. Total abstinence is a precondition to prescribing reduction therapy, and the patient should be warned of the potential risks of smoking while using nicotine replacement. Smokers in whom cough and sputum production increase immediately after cessation should be reassured that this is temporary and common and represents a return of ciliary clearance activities in the respiratory tract.

Most smokers will initially elect to stop on their own, and an individual attempt should be the physician's initial recommendation. These smokers will benefit from self-help material. For heavy smokers who have failed unassisted quitting attempts, consideration of an assisted program is indicated. Providing information about and referral to such community smoking cessation programs is important.

If an underlying depression is present, it should be treated specifically before cessation is attempted. If depression develops subsequently, it too should be treated directly (see Chapter 227).

6. *Follow-up.* Continued monitoring of the smoking habit is essential. Listing the problem on the patient's medical problem list will remind the physician to manage it as part of the patient's continuing care. One or more return visits for follow-up will increase patients' success rates. The first follow-up should be scheduled shortly after the quit date. At follow-up, smokers who quit should be congratulated but cautioned of the need to maintain vigilance against relapse. Ex-smokers should be monitored carefully during the first year after cessation, which is when most relapses occur. For smokers whose attempts to quit have been unsuccessful, the physician should focus on positive aspects, such as the length of time the smoker was abstinent, and encourage another attempt. Through careful questioning, the physician can help the patient determine what circumstances caused the effort to fail and then encourage the patient to learn from the experience so as to increase the chance of success in the next attempt to quit.

PART 5 GASTROINTESTINAL PROBLEMS

CHAPTER 55 SCREENING FOR GASTRIC CANCER

Gastric cancer is among the most common malignancies worldwide. It is the leading cause of cancer death in Japan, where population-based screening programs have been sponsored for many years. For unknown reasons, the incidence of gastric cancer in the United States has been decreasing at a rate of 2% to 4% annually for the past several decades. During the 1930s, the death rate for gastric cancer was greater than 30 in 100,000; during the 1970s, the rate was approximately 10 in 100,000. At present, Americans have approximately a 1% chance of acquiring a gastric malignancy during their lifetime. Nevertheless, mortality remains high; approximately 75% of the 25,000 Americans in whom gastric cancer develops each year eventually die of the disease. *Helicobacter pylori* infection has been classified as a carcinogen because of its association with an increased risk for gastric cancer, so that new prevention strategies have become possible by screening for the risk associated with infection.

The usual insidious onset of the disease and the lack of suitable screening tests have heretofore thwarted preventive measures. Advances in endoscopic instrumentation, allowing more complete visualization of the stomach, have raised questions about unmet potential in preventing gastric cancer deaths among high-risk populations. The primary care physician must understand the natural history of gastric cancer and the limitations of diagnostic tools in the detection of early disease.

EPIDEMIOLOGY AND RISK FACTORS

The international variation in the incidence of gastric cancer is marked. Among the countries with the highest incidence are Japan, Chile, Finland, and Iceland. Incidence also varies, predictably, with age and sex. Gastric cancer is twice as likely to develop in men in most countries. More than 60% of cases occur in people over age 65. Fewer than 10% of cases occur in people younger than age 30. The incidence among nonwhites and people in low socioeconomic groups in the United States is twice that among whites and the more well-to-do.

Genetic factors do not play a major role in determining the risk for gastric cancer. It has been documented that migrants from areas of high risk (e.g., Japan) eventually acquire the lower rates of their new home (e.g., the United States). A genetically determined minor risk factor for gastric cancer is blood group; people with type A blood have a 10% increase in risk for the development of gastric cancer.

A number of environmental factors have been suggested as explanations for the geographic variability of gastric cancer incidence. Phenol, present in all smoked foods, and the high salt concentration in salted fish and meat products have been linked to the high incidence of gastric cancer in Finland, Iceland, and Japan. Talc-treated rice has been implicated in Japan and Northern China. Provinces in Chile with high gastric cancer rates are agricultural, with high concentrations of nitrate present in the soil and drinking water. Nitrosamines, derived from nitrates and secondary amines, are suspected causes of gastric cancer in Chile and, to a lesser extent, in the United States, where nitrates and nitrites are used as food additives in meat and fish.

A number of pathologic conditions, including gastric polyps and adenomas, have been associated with an increased risk for stomach cancer. Gastric polyps are relatively infrequent; a prevalence of less than 0.5% has been documented in one autopsy series. The vast majority of polyps are hyperplastic and not associated with an increased cancer risk. People with adenomas, particularly villous adenomas, have the same risk for cancer when the adenomas are found in the stomach as when they are in the colon. Some authorities have argued that peptic ulcer disease predisposes patients to gastric cancer. Carcinoma is found in approximately 3% of surgically resected gastric ulcers. It is likely, however, that ulceration follows carcinoma rather than vice versa. This association is the basis for the clinical practice of taking biopsy specimens from suspected or persistent gastric ulcers, or resecting them.

A number of studies have demonstrated a statistical association between atrophic gastritis and gastric cancer. Achlorhydria and atrophic gastritis are common. Prevalence increases with age. An annual incidence of gastric cancer of 1% among patients with atrophic gastritis has been demonstrated in one study with yearly radiographic examination. The atrophic gastritis associated with pernicious anemia is also a risk factor for gastric cancer. Evidence indicates that patients with perniciousanemia have at least a fourfold increase in risk. Some studies have found even higher rates.

Prior gastric surgery for benign ulcer disease has long been considered a risk factor for subsequent gastric cancer. Increased risk was not evident early after surgery, but several Scandinavian studies suggested that those who lived more than 10 to 15 years after surgery faced a twofold to threefold increase in gastric cancer risk. Recommendations for annual endoscopic examination followed. More recently, a large, population-based study conducted in Olmstead County, Minnesota, found gastric cancer to be no more common among patients with prior gastric surgery than among the population at large.

NATURAL HISTORY OF GASTRIC CANCER AND EFFECTIVENESS OF THERAPY

Gastric cancer typically has an insidious presentation. The most common initial symptom is epigastric discomfort. Later symptoms include early satiety, indigestion, weight loss, and other systemic symptoms. The percentage of patients who survive 5 years has not improved significantly in recent years; it remains at 20% of unselected cases. The patients who are operated on early in the course of their disease have a 60% to 90% 5-year survival rate. Some population-based studies from Japan confirm that 5-year survival rates of 70% can be achieved among patients with gastric cancer detected by screening. Furthermore, follow-up for 15 years suggests that the cancer death hazard rate decreases rapidly for 7 years after detection and treatment of cancer, and then remains very low. Other studies from Japan question the value of screening, especially among people younger than 50 years of age.

Among highly selected patients with "early gastric cancer," defined as gastric cancer confined to the mucosa or submucosa but not extending to the muscularis propria, resection may be curative for as many as 95%. Intensive screening efforts in Japan have increased the proportion of gastric cancers detected in this early stage from approximately 5% to 30%. Efforts have not been as successful elsewhere, where fewer than 10% of cases meet criteria for early gastric cancer. The duration of the asymptomatic detectable period is unknown, but early gastric cancer has been found as long as 3 years after biopsy specimens were originally misread as benign. The natural history of early gastric cancer appears to include protracted cycles of healing and ulceration.

SCREENING AND DIAGNOSTIC TESTS

None of the tests generally used in the United States for the *diagnosis* of gastric carcinoma are suitable for wide screening efforts.

Gastric Cytology. The collection and examination of specimens for gastric cytopathologic analysis, unlike that for cervical cytopathology, is a laborious process. Samples must be obtained either by endoscopic scraping or by gastric lavage. Examination of the resulting slides usually takes 2 to 3 hours rather than the several minutes sufficient for the screening examination of cervical Papanicolaou smears. Many studies have demonstrated the sensitivity of gastric cytopathology studies to be approximately 90%. It is not known how much this figure is influenced by the spectrum of disease—that is, how sensitive cytology can be for the early, curable cancer. Specificity in a laboratory with experienced personnel should be approximately 97% to 98%. False-positive results are often found in association with healing gastric ulcer and other gastric pathology. Although cytopathology is useful for further diagnosis in documented cases of abnormality of gastric mucosa, it cannot be recommended for indiscriminate screening.

Endoscopy. Similarly, endoscopy must be considered a diagnostic rather than a screening procedure. Its sensitivity in making the diagnosis of gastric cancer is 90%. However, recent evidence suggests that endoscopic visualization is much less sensitive for early cancers, with a visual diagnosis being made in fewer than 50% of

cases in some series. Multiple biopsies of any and all suspected lesions can increase the sensitivity to 90%.

Diagnostic Radiology. The sensitivity of contrast studies in the diagnosis of gastric cancer has been reported to be as high as 95%. Obviously, however, it is least sensitive in cases of early disease and is too expensive and time-consuming to be considered a screening test in asymptomatic patients. In Japan, where gastric cancer is the leading cause of cancer death, radio-graphic techniques have been adapted to mass screening. These modifications in the standard contrast studies have been shown to have a sensitivity and specificity of 90%.

Stool analysis for occult blood (described in detail in Chapter 56) is an appropriate screening procedure for all gastrointestinal malignancies. Yearly guaiac testing has been recommended as part of the general screening for all adult patients. This is especially important for patients with an identified increased risk for gastric cancer, such as those with a history of pernicious anemia or documented atrophic gastritis.

Too little is known about the role of *H. pylori* infection or the effect of its treatment on gastric cancer risk to justify screening asymptomatic persons at this time.

CONCLUSIONS AND RECOMMENDATIONS

- Despite a significant downward trend in incidence, gastric cancer remains a disease of high morbidity and mortality.
- The yearly analysis of stool for occult blood is indicated in all adult patients. This is especially important for those with a history of pernicious anemia, atrophic gastritis, *H. pylori* infection, or other gastric pathology.
- The value of gastric cytology, endoscopy, and contrast studies as routine procedures in high-risk patients is unproven. They are diagnostic procedures and should generally be reserved for symptomatic patients or patients with occult blood demonstrated by stool analysis.

CHAPTER 56 SCREENING FOR COLORECTAL CANCER

MICHAEL J. BARRY

INTRODUCTION

Colorectal cancer (CRC) is a common malignancy in both men and women, accounting for about 10% of cancer deaths. Americans face a lifetime risk of CRC of approximately 1 in 17. The majority of CRCs that present with signs or symptoms have already spread beyond the intestinal wall, resulting in a poor 5-year survival rate. However, cancers detected and removed while still localized are associated with a 5-year survival rate in excess of 80%. The long asymptomatic period, the availability of tests that can identify localized disease, and the effectiveness of early therapy suggest that screening for CRC should be a primary care priority. Evidence from multiple randomized trials has now confirmed that such screening can reduce the risk for CRC mortality.

EPIDEMIOLOGY AND RISK FACTORS

The incidence of colorectal cancer is greater in economically developed societies. The high-fat, low-fiber *diet* prevalent in Western societies has been implicated in the etiology of these cancers. Whether intake of dietary fiber among Americans is associated with the risk for CRC has been harder to prove.

Advancing *age* is an important risk factor, with the incidence of CRC rising from about 75 in 100,000 in the sixth decade to 300 in 100,000 in the eighth decade.

Family history is also a risk factor. Having a first-degree relative with CRC raises personal risk twofold to threefold, with risk greatest when cancer has been diagnosed at an early age and when more than one first-degree relative has been affected. Newer evidence suggests that a family history of larger adenomatous polyps also increases the risk for CRC. Autosomal dominant familial adenomatous polyposis confers a risk for CRC of about 50% by age 40, and a number of other familial cancer syndromes also increase risk greatly. Genetic testing is available for one of them, hereditary nonpolyposis colon cancer.

Ulcerative colitis, particularly pancolitis of more than 10 years' duration, increases a patient's risk for CRC fivefold to 10-fold, although isolated left-sided ulcerative proctitis probably confers substantially less or no additional risk. Controversy remains as to whether Crohn's disease is associated with a clinically significant increase in risk for CRC.

In some observational studies, the use of aspirin or NSAIDs has appeared to be associated with a lower risk for CRC. However, among subjects randomized to aspirin in the Physicians Health Study, the incidence of CRC was no lower than the incidence in controls.

Almost all CRCs are believed to arise from *adenomatous polyps*. The prevalence of adenomatous polyps increases with age, occurring in 30% of 50-year-olds (3% >1 cm), 40% of 60-year-olds (4% >1 cm), and 50% of 70-year-olds (5% >1 cm). Once a person has had an adenomatous polyp removed, it has been suggested that their future risk for CRC is higher. However, the magnitude of future risk, if any, is uncertain, especially if the index polyp is small (<1 cm). Because of this association between adenomatous polyps and CRC, it is not surprising that a family history of polyps has also been shown to increase risk for cancer.

Patients with *resected CRCs* have a threefold increase in risk for metachronous cancer in other locations of the colon. Recurrences of index cancers are usually extraluminal and not amenable to detection by endoscopic screening.

The prevalence of *synchronous colonic neoplasia* is high and important to consider in the evaluation of the patient with a positive screening test result. Synchronous adenomas occur in 40% to 50% of patients with an index polyp; 3% to 5% with a carcinoma will harbor a second one.

NATURAL HISTORY OF COLORECTAL CANCER AND EFFECTIVENESS OF THERAPY

Sporadic polyps are common lesions, with the most common being small, hyperplastic outcroppings of the colonic mucosa that do not have a malignant potential. Adenomas are truly neoplastic and may include malignant foci. The risk for malignancy increases with the size of the adenoma, ranging from 0.5% of colonoscopically removed polyps from 0.5 to 0.9 cm in diameter to 25% or more of polyps greater than 3 cm in diameter. Histology also affects cancer risk. Villous adenomas are the polyps with the highest malignant potential, and they tend to be larger and more sessile than tubular or mixed tubulovillous adenomas, which are associated with less risk (Table 56-1). About 10% of polyps have villous histology, tubular adenomas account for 70%, and the remainder have mixed histology. The probability and time frame for the development of a nonmalignant polyp into an invasive cancer are not well defined, although these are important variables in estimating the effectiveness of screening strategies. Interestingly, although the prevalence of polyps increases with age (see above), average polyp size does not, which suggests that most polyps do not progressively enlarge.

DIAMETER (CM)	PERCENTAGE CANCEROUS
<0.5	0.5
0.5–0.9	1
1.0–1.4	1.8
1.5–1.9	6
2–2.4	10
2.5–3.4	23
≥3.5	29

From Behringer GE. Changing concepts in the histopathologic diagnosis of polypoid lesions of the colon. Dis Colon Rectum 1970;13:1196, with permission.

Table 56-1. Polypoid Lesions of the Colon and Rectum: Relation of Size to Cancer (1,116 Polypoid Lesions, Massachusetts General Hospital, 1954-1963)

Symptoms occur late in the course of CRC growth. The duration of the asymptomatic detectable period is estimated to be several years. When cancers are found after symptomatic presentation, 60% have already disseminated to regional nodes or distant organs. Five-year survival rates vary dramatically with the stage of disease at the time of diagnosis. Patients whose tumors are confined locally to the bowel wall (Dukes stage A) or pericolic fat (Dukes B) have an 80% 5-year survival, whereas those whose tumors exhibit regional lymph node metastases (Dukes C) have a 46% 5-year survival; this drops to 5% with distant metastases (Dukes D).

SCREENING TESTS

Digital Examination

Only about 10% of CRCs are within reach of the examining finger. Although many experts recommend performing this time-honored examination annually among

patients who are older than 40 years, there is little evidence to support the practice to screen for CRC.

Fecal Occult Blood Testing

Intermittent occult bleeding occurs with some asymptomatic CRCs and large polyps. Serial sampling of stools for occult blood can be performed to identify this bleeding. Guaiac-impregnated filter paper slides (Hemoccult II and others) are capable of detecting small amounts of fecal blood, which will be present in some patients with CRC. The fact that colonic tumors selectively enrich the stool surface with blood enhances the sensitivity of guaiac testing of stool samples. Stool sampling is best performed serially because of the intermittent nature of the bleeding (e.g., two samples from a stool on each of 3 days).

Sensitivity, Specificity, and Yield. A six-test guaiac stool sequence has a sensitivity of 30% to 70% for CRC. The lower figure is probably more accurate for early cancers in asymptomatic patients. Sensitivity falls when prepared slides are stored for more than 4 days before being developed. *Rehydration* of the sample before application of developer can increase sensitivity, but at the cost of a loss in specificity. False-positive test results may occur with nonmalignant lesions, aspirin (at doses >325 mg daily) and NSAIDs, rare red meat, or foods with high peroxidase activity. Studies on the ability of iron supplements to cause false-positive guaiac results have been conflicting. A specificity of 97% to 98% can be attained by omitting rare red meat, horseradish, cantaloupe, and uncooked fresh vegetables (especially broccoli, turnip, radish, cauliflower) 2 days before the first sample is collected. High doses of vitamin C increase the false-negative rate. Newer tests and combinations of tests are being evaluated, and clinicians should follow the literature for new developments.

Based on screening results in population studies and randomized trials, the clinician should expect 2% to 4% of persons over the age of 50 to have a positive fecal occult blood test (FOBT) result (Hemoccult II). Of these, about 10% will have CRC and 40% either CRC or polyps. Most of these polyps are too small to cause detectable bleeding but are found serendipitously when follow-up studies are performed after a positive occult blood test result. When rehydration is used, the positivity rate is about 10%. Of these, about 2% will have CRCs and 30% either cancers or adenomas.

A new screening strategy has been proposed that combines a more sensitive guaiac test (HemoccultSENSA) with a more specific immunochemical test (HemeSelect) when the guaiac test result is positive. This strategy may increase the sensitivity of screening for occult blood without as great a loss of specificity as occurs with rehydration of older guaiac cards, but it adds complexity to the testing process.

Individuals with a positive FOBT result require a thorough evaluation for colorectal neoplasia. Smaller polyps produce guaiac positivity only on occasion, but their high prevalence makes them the most common lesions found during the evaluation of patients with occult bleeding. *Colonoscopy* or the combination of *sigmoidoscopy* and *air-contrast barium enema* are acceptable alternatives for follow-up evaluation of the patient with a test positive for occult blood. Colonoscopy offers the advantage of allowing a biopsy or polypectomy to be performed during the same examination and is the more sensitive for detecting smaller polyps. However, given the uncertain natural history of small polyps and the cost of polypectomy (both initially and for any necessary future colonoscopic surveillance), it is not clear whether this higher sensitivity is an advantage or disadvantage.

Outcomes. The best outcome measure of screening efficacy is *reduced CRC mortality*, as judged by prospective, randomized, controlled clinical trials with a long period of follow-up. One such study, The Minnesota Colon Cancer Study, demonstrated a 33% reduction in cumulative CRC mortality (from 8.3 in 1,000 to 5.9 in 1,000 over 13 years) as a result of annual occult blood screening. This trial used a six-sample annual testing protocol, followed by colonoscopy for persons with positive test results. The guaiac cards were rehydrated, which increased the true-positive rate of testing from 81% to 92% but increased the false-positive rate from 2% to 10%. As a result of this decrease in specificity, 38% of screenees underwent colonoscopy during the study. The cumulative incidence of CRC was almost identical in the screened and control groups, which suggests that most of the benefit came from early detection of established cancers rather than from prevention of future cancers by resecting polyps. Compared with the control group, screened patients demonstrated a shift to detection of earlier cancers. Despite the large relative benefit in terms of mortality, the absolute risk that any one man or woman will die of CRC is quite low. As a result, data from this trial indicate that about 300 men would need to be screened annually for 13 years to prevent one CRC death. In a subsequent publication, reporting 18 years of follow-up, the Minnesota investigators reported that even biennial screening reduced CRC mortality by 21%.

As seen from the Minnesota study, rehydration of the guaiac card increases its sensitivity, but it also increases the number of colonoscopies needed, the cost of screening, and the false-positive rate. Two other trials, conducted in Denmark and the United Kingdom, used guaiac cards without hydration and conducted screening biennially rather than annually. Population-based samples of patients were randomized without their knowledge, so it is likely that the persons screened were representative of actual practice. Only 4% of persons screened in the studies underwent colonoscopy. Even under these circumstances, the trials demonstrated 18% and 15% reductions in CRC mortality, respectively.

Sigmoidoscopy

About 25% of colon cancers are within the range of the *rigid sigmoidoscope*, whereas the longer (65 cm) *flexible sigmoidoscope* can potentially detect about 50% of cancers. The risk for a bowel perforation—the major complication of sigmoidoscopy—is low (about 1 to 2 in 10,000 rigid sigmoidoscopic examinations). The risk with flexible scopes has been less well studied. The number of cancers found per 1,000 examinations ranges from 1.5 for the rigid scope to 4 for the 65-cm flexible scope. Adenomatous polyps are found in up to 20% of persons screened. When adenomatous polyps are detected and removed at sigmoidoscopy, the patient then usually undergoes colonoscopy for examination of the rest of the colon.

Outcomes. Sigmoidoscopy can clearly find localized cancers and polyps for removal, but the key question is the effect of the procedure on CRC mortality rates when used for periodic screening. Data from prospective studies are pending, but a retrospective, case–control study of periodic rigid sigmoidoscopy for CRC screening suggested a 60% to 70% reduction in CRC mortality risk. As would be expected, the protective association appeared specific for cancers within reach of the sigmoidoscope; the exposure odds were not reduced for more proximal cancers. The marginal value, in terms of mortality reduction, of adding sigmoidoscopic screening to regular guaiac testing is undefined.

Ongoing long-term controlled trials of sigmoidoscopic screening for colorectal cancer should help define and refine best approaches to its utilization, including optimum screening interval and the expected added value of combining with other screening modalities. Some argue for shortening the screening interval, based on data showing a 0.8% incidence of new significant lesions at 3 years. The reader is urged to watch the literature closely as data from these ongoing studies become available.
Updated: 07/09/03

Colonoscopy

Primary colonoscopic screening is growing in popularity, because all colorectal cancers are theoretically within the reach of the colonoscope (incomplete insertion or suboptimal preparation will limit sensitivity to some degree). The risk of perforation is about 1 in 500 exams. In a major VA study comparing colonoscopy to sigmoidoscopy and one-time fecal occult blood testing, colonoscopic screening of men ages 50 to 75 revealed large or dysplastic polyps in 10% and cancer in 1%. Approximately 70% of these lesions would have been discovered by a sigmoidoscopic exam (with follow-up colonoscopy for any distal polyps). The one-time set of six stool cards detected 24% of the neoplastic lesions, but because of poor sensitivity of the stool blood tests for proximal neoplasia, the combined sensitivity of sigmoidoscopy and one-time fecal occult blood testing was only 76% relative to colonoscopy. Presumably, though, serial annual fecal occult blood testing combined with sigmoidoscopy would have an even better combined sensitivity.
Updated: 11/14/02

Outcomes

There is no direct evidence to date of the magnitude of reduction in colorectal cancer mortality that can be expected from a strategy of periodic colonoscopy.
Updated: 11/14/02

Overall Screening Strategy

The American Cancer Society favors annual FOBT and flexible sigmoidoscopy every 5 years, beginning at age 50 for patients at average risk; colonoscopy every 10 years; or double-contrast barium enema every 5 to 10 years. The U.S. Preventive Services Task Force (USPSTF) has recently recommended that men and women age 50 and older be screened for colorectal cancer but did not endorse a particular screening strategy because of insufficient evidence. In particular, the USPSTF felt it was unclear if the higher sensitivity and specificity of colonoscopy for detection of neoplasia warranted the procedure's additional complications, inconvenience, and costs.

Updated: 11/14/02

CONCLUSIONS AND RECOMMENDATIONS

Conclusions

- The relatively high prevalence of CRC, its slow evolution from adenomatous polyp to cancer, and the accumulating evidence that screening reduces mortality from this disease suggest that an aggressive approach to screening is reasonable and appropriate. Although the impact of annual FOBT plus periodic sigmoidoscopy or periodic colonoscopy on CRC mortality has not been measured, it is likely to be higher than the significant impact of annual fecal occult blood testing alone.

Updated: 11/14/02

Recommendations: Test Selection and Frequency of Screening

- All patients at normal risk should be offered some form of colorectal cancer screening beginning at age 50. Two practical strategies with the highest sensitivity are annual FOBT plus flexible sigmoidoscopy every 5 years, or colonoscopy alone every 10 years. However, fecal occult blood testing and sigmoidoscopy alone are also effective screening strategies. Patient preference, local availability of high-quality endoscopy, and the patient's insurance coverage need to be considered in developing an optimal screening program with an individual patient.

Updated: 11/14/02

- Patients at higher risk for CRC, such as persons with a family history for CRC and larger (>1 cm) adenomas in first-degree relatives before age 60, may especially benefit from the higher-sensitivity screening strategies. Screening might be started at age 40 or 10 years before the youngest affected relative was diagnosed.

Updated: 11/14/02

- Patients at the highest risk, such as persons with a past personal history of CRC or larger adenomas, long-standing ulcerative colitis with pancolonic involvement, familial adenomatous polyposis, or nonpolyposis colon cancer should have a strategy of periodic colonoscopy worked out with a gastroenterologist.

Updated: 11/14/02

Recommendations: Test Performance

- Perform *FOBT* by instructing the patient to obtain two samples on each of 3 days, restricting dietary peroxidases and rare red meat according to the test instructions.
- Follow any positive FOBT result with colonoscopy.
- Order colonoscopy in any patient with adenomatous polyps found on screening sigmoidoscopy.
- For normal-risk, asymptomatic persons being screened with periodic colonoscopy, interim fecal occult blood tests are not necessary. **Updated: 11/14/02**

CHAPTER 57 PREVENTION OF VIRAL HEPATITIS

JULES L. DIENSTAG

Viral hepatitis is an infectious disease of the liver estimated to afflict more than 500,000 people in the United States each year. Although the majority of those infected are either asymptomatic or minimally symptomatic, chronic viral hepatitis is associated with substantial morbidity, and fulminant hepatitis, often fatal, may develop in a small proportion of acutely infected patients. Several thousand deaths per year are related to the disease.

Prevention of infection and prophylaxis against clinical disease are prime objectives in the management of viral hepatitis. The primary physician has the major responsibility for these tasks because patients and their contacts often present at a time when infectivity is high. Prevention of viral hepatitis requires a knowledge of the common modes of viral transmission, the periods of maximal communicability, and the efficacy of globulin preparations and vaccines.

EPIDEMIOLOGY AND RISK FACTORS

Viral Types. Five distinct types of viral hepatitis are recognized: A, B, C (formerly labeled non-A, non-B), D, and E (formerly labeled the enteric form of non-A, non-B). Although other types of hepatitis viruses (e.g., "hepatitis G") have been described, none have proved to be true hepatitis viruses or to account for the small proportion of cases that cannot be linked serologically to hepatitis viruses A through E.

Sources of Outbreaks. In general, outbreaks of hepatitis are often traced to a source of hepatitis A virus (HAV) or, in developing countries, to hepatitis E virus (HEV). Occasionally, clusters of hepatitis B follow exposure of several persons to contaminated needles or blood products. Among urban adults presenting to a primary care physician with sporadic cases of hepatitis, hepatitis B accounts for approximately 50% of cases, hepatitis C for 15% to 30%, and hepatitis A for the remainder. More than 95% of transfusion-associated cases were attributable to hepatitis C; however, the frequency of transfusion-related cases has been reduced dramatically to negligible levels by the use of sensitive screening tests for hepatitis C (see below). Hepatitis D is caused by a defective virus that infects only in the presence of infection with hepatitis B virus. Chronic infection with hepatitis B virus (HBV) is prevalent in 0.1% to 0.5% (1 million persons) and chronic infection with hepatitis C virus (HCV) is prevalent in 1.8% (4 million persons) of the U.S. population.

Hepatitis A. HAV is shed in the feces, and transmission occurs predominantly by the *fecal–oral* route (e.g., ingestion of contaminated food, water, shellfish). Prior exposure to hepatitis A is manifested by the presence of antibody to HAV (anti-HAV), which confers lifelong immunity. Many patients over the age of 60 years test positive for anti-HAV, but acute infection is rare in this age group. Because children and adolescents are least likely to have had previous exposure to the virus, they are the most susceptible to infection. Spread of infection is greatest where poor sanitary conditions and crowding exist, with prevalences as high as 75% among low-income people, compared with 20% to 30% for residents in middle- to upper-income neighborhoods. In developed countries, the prevalence of anti-HAV and of immunity to the virus has fallen by approximately 10% per decade since the 1970s. The down side of this declining prevalence of anti-HAV is the growing prevalence of susceptibility to infection in population subgroups that heretofore had been immune. The resulting shift in acute cases from the very young, in whom the disease tends to be subclinical, to adults, in whom the disease tends to be associated with jaundice and relatively severe, has translated into an increased frequency of clinically apparent, severe hepatitis A. There is no carrier state.

Hepatitis B can be transmitted both by *percutaneous* and *nonpercutaneous* modes of spread. The application of sensitive screening methods for the detection of HBV has essentially eliminated posttransfusion hepatitis type B. Reliance on blood obtained from volunteer donors, which is less likely to contain the virus, in addition to blood donor exclusion practices and screening tests to prevent transfusion-transmitted AIDS and hepatitis C, has also contributed to reducing the frequency of hepatitis B after transfusion. Injection drug use remains a common route of exposure. Perinatal transmission from mother to offspring accounts for most HBV infections in developing nations, whereas sexual transmission is an important and efficient mode of spread in the United States and other Western countries. About 0.1% of healthy blood donors are infected; the percentages increase markedly for injection drug users and patients exposed to blood, such as hemophiliacs and those in hemodialysis units. Surgeons, laboratory technicians, oral surgeons, and other medical personnel exposed to blood and body fluids are at increased risk for contracting hepatitis B. Spread of infection from health personnel who are hepatitis B carriers is a rare event.

Hepatitis C, initially labeled "non-A, non-B hepatitis," was first recognized in *transfusion* recipients and found to be the predominant type of hepatitis after transfusion. In the 1970s, it occurred in up to 10% of transfusion recipients, usually within 1 to 3 months after they had received volunteer-donated blood. The frequency of infection fell with the exclusion of blood donors at risk for HIV infection and was further reduced by the use of screening tests for HIV (see Chapter 7), surrogate tests for hepatitis C (e.g., alanine aminotransferase, antibodies to hepatitis B core antigen), and finally direct testing for antibodies to HCV. Currently, the risk for hepatitis C after transfusion is barely measurable. Hepatitis C can be spread by *any percutaneous route*, such as needlestick inoculation (3% to 10% risk of infection) or self-injection among drug users. The risk for hepatitis C resulting from sexual or perinatal transmission is felt to be extraordinarily low, on the order of 5%. In about 40% of patients with acute hepatitis C and in almost all volunteer blood donors with hepatitis C, risk factors are not readily apparent; however, in most such cases, remote or less obvious percutaneous exposures can be identified or inferred. One such route of HCV infection is nasal cocaine inhalation, often associated with mucosal bleeding and practiced with shared inhalation equipment.

Hepatitis D, or Delta Hepatitis, is caused by a defective RNA virus that requires *coinfection with HBV* (a DNA virus) to support its replication. Infection with this agent occurs either simultaneously with acute hepatitis B infection or is superimposed on chronic hepatitis B. Like hepatitis B, hepatitis D is transmitted by *percutaneous inoculation* and *intimate contact*. In nonendemic areas, such as the United States and western Europe, hepatitis D has been confined primarily to populations with frequent percutaneous exposures, such as injection drug users and hemophiliacs. In endemic areas, such as the Mediterranean countries, hepatitis D is transmitted primarily through intimate contact. Hepatitis D remains rare in the United States.

Hepatitis E, prevalent in India, Asia, Central America, and developing countries, is transmitted by the *fecal–oral* route. Rarely encountered in the United States except for imported cases from endemic countries, hepatitis E does not cause chronic infection.

NATURAL HISTORY

Both hepatitis A and E are self-limited and do not lead to chronic liver disease; however, hepatitis B, C, and D can cause chronic hepatitis and cirrhosis; long-standing chronic hepatitis B and C can be complicated by hepatocellular carcinoma.

Hepatitis A has an average incubation period of 30 days (range, 15 to 45 days) from the time of exposure to the onset of symptoms. An early manifestation of disease is elevation of the serum aminotransferase level, which occurs about a week before the onset of flulike symptoms. Fecal shedding of HAV occurs well before the rise in aminotransferase levels and up to 2 weeks before the development of symptoms. HAV can be detected in serum for no more than a few days, and the virus disappears from stool within 2 to 3 weeks, usually at the same time as the onset of jaundice and resolution of prodromal symptoms. A fall in viral titer parallels a rise in the titer of anti-HAV, which persists indefinitely. Initially, the *anti-HAV* is of the *immunoglobulin M (IgM)* class; during convalescence, anti-HAV of the *immunoglobulin G (IgG)* class becomes predominant. Therefore, a diagnosis of acute hepatitis A can be made by demonstrating IgM anti-HAV in a single serum sample. No episodes of chronic hepatitis or a carrier state have been found to result from hepatitis A infection. Fatalities are rare; fewer than 5% of cases of fulminant hepatitis result from HAV infection, but clinically more severe cases are becoming more common (see above).

Hepatitis B is a much more variable disease. The incubation period averages 12 weeks, with a range of 4 weeks to 6 months.

Acute Infection. About 2 to 4 weeks before the onset of symptoms, the viral envelope protein, *hepatitis B surface antigen* (HBsAg), appears in the serum, followed by a rise in aminotransferase levels and symptoms. This antigen usually is cleared from the serum by 4 to 6 months; persistence of antigenemia beyond 6 months is considered chronic infection. Symptoms of acute hepatitis B typically last 4 to 6 weeks, but the clinical expression of acute hepatitis B is very variable, ranging from clinically inapparent disease to fulminant hepatitis with hepatocellular failure and death. Determinants of disease severity include age, immunologic competence,

undefined host factors, and virulence of the virus.

Chronic Infection. Approximately 1% to 2% of patients with clinically apparent disease acquire *chronic infection* and continue to have circulating HBsAg. A much larger number of cases of chronic hepatitis B do not originate as clinically apparent acute illness, so that the number of chronic cases is much larger than anticipated based on the number of recorded acute cases. Among patients with chronic hepatitis B, some have detectable serologic markers of high-level virus replication and some remain *asymptomatic carriers*. Those with high-level replication tend to have chronic hepatitis that is progressive and of at least moderate severity, whereas asymptomatic carriers lack evidence of high-level virus replication, infectivity, and liver injury (see below). The fatality rate for acute hepatitis B is about 0.1%; however, among those requiring hospitalization, the mortality rate is 1%. Although hepatocellular carcinoma is rare in immunocompetent patients who become chronically infected following adulthood acute infection, this dreaded complication of chronic HBV infection is common among those who become chronically infected after perinatally acquired acute infection. In Asia, where perinatal infection is the most common route of exposure, the lifetime risk for death from cirrhosis and hepatocellular carcinoma may be as high as 40%.

Serology. Antibody to HBs Ag (anti-HBs) is produced early during infection but becomes detectable with commercially available serologic assays only as HBsAg disappears. More than 95% of patients with self-limited acute hepatitis B acquire detectable levels of anti-HBs, which persist indefinitely.

Antibody to the nucleocapsid core of HBV (anti-HBc) appears in the circulation within a week or so after HBsAg becomes detectable and persists indefinitely. Occasionally, during late acute infection, an interval occurs in which HBsAg has already disappeared and anti-HBs has not yet become detectable. This so-called window period can be identified by the presence of isolated anti-HBc; however, now that tests for HBsAg and anti-HBs are so sensitive, this window period is rarely encountered among patients with acute hepatitis B. Most cases in which anti-HBc occurs in the absence of HBsAg and anti-HBs represent HBV infection in the remote past. In rare instances, isolated anti-HBc represents a false-positive test result, whereas in patients at high risk for blood-borne infections (e.g., injection drug users), isolated anti-HBc may represent low-level HBV infection in which the level of HBsAg does not exceed the detection threshold.

A test for anti-HBc of the IgM class (*IgM anti-HBc*) can distinguish between acute or relatively recent acute hepatitis B (IgM-positive) and infection in the remote past or current chronic infection (IgM-negative, anti-HBc of the IgG class). In a small proportion of cases of acute hepatitis B, HBsAg does not reach the threshold for detection; in such cases, a diagnosis of acute hepatitis B can be established by detecting IgM anti-HBc.

Hepatitis B early antigen (*HBeAg*) is a product of the gene that codes for the nucleocapsid core; its presence signifies *high-level virus replication*. As such, patients with HBeAg have a high level of circulating virions and infectivity and substantial liver injury. HBeAg becomes detectable in *all* patients early during acute hepatitis B, and therefore this test has no clinical utility during early acute hepatitis B; however, if circulating HBeAg persists beyond the first 3 months of acute hepatitis, the likelihood of chronic infection is increased.

Testing for HBeAg is more important during chronic infection because the presence of HBeAg denotes a more highly replicative chronic infection, associated with increased infectivity (e.g., 20% to 30% infectivity of a needlestick) and liver injury (chronic hepatitis). When *anti-HBe* can be detected in the absence of HBeAg during chronic infection, the patient can be classified as having a less replicative infection, with *limited infectivity* (e.g., 0.1% infectivity of a needlestick) and liver injury (chronic carrier).

Complicating this simple distinction between highly replicative and relatively nonreplicative chronic hepatitis B are patients with "*pre-core*" *HBV mutations*. For HBeAg to be produced, the pre-core region of the gene encoding the nucleocapsid core protein must be operative; one of a number of mutations in the pre-core gene precludes elaboration of HBeAg, but this mutation does not prevent production of complete virions or high-level HBV replication. Common in Mediterranean and Asian countries and still rare in the United States but growing in frequency, patients with pre-core mutant HBV have all the virologic (i.e., detectable HBV DNA; see below) and clinical hallmarks of highly replicative HBV infection with the exception of HBeAg.

Quantitative Markers of Hepatitis B Viral Replication. *HBV DNA* is a quantitative marker of HBV replication and is helpful in following patients with chronic disease and in monitoring the success of antiviral therapy (see Chapter 70). Insensitive hybridization assays identify circulating HBV DNA down to a threshold of approximately 105 to 106 virions per milliliter, below which infectivity and liver injury are less common. Clinical assays for HBV DNA are shifting to ultrasensitive amplification techniques such as *polymerase chain reaction*, which can detect HBV DNA in serum down to thresholds of 100 to 1,000 virions per milliliter, well below the level associated with infectivity and liver injury. The presence of a pre-core variant of HBV infection can be inferred in a patient with chronic hepatitis B, high levels of HBV DNA ($>10^5$ or 10^6 virions per milliliter), and anti-HBe in the absence of HBeAg.

Hepatitis C has a mean incubation period of 7 weeks (range, 2 to 15 weeks), with most cases occurring after 5 to 10 weeks of incubation. Only a fourth of patients with acute, transfusion-associated hepatitis C become icteric, compared with two thirds of those with transfusion-induced hepatitis B. However, more than 50% of patients with acute hepatitis C have a chronic elevation of aminotransferase levels, and *chronic infection* (with or without liver injury) occurs in 85% of all acutely infected patients. Contributing to this high rate of chronic infection is the common failure to mount an effective, neutralizing immunologic response.

Progression to Cirrhosis and Hepatocellular Carcinoma. Among those with chronic hepatitis following acute hepatitis C, 20% may progress to cirrhosis during the first decade of illness, even patients with mild liver disease. On the other hand, morbidity within the first 20 years after acute hepatitis C is limited. Although certain hepatitis C genotypes (e.g., *genotype 1*, occurring in 70% to 80% of U.S. patients) are associated with more severe liver disease, perhaps the best predictor of progression to cirrhosis is *liver histology*. Patients with moderate to severe necrosis, inflammation, or fibrosis almost always progress to cirrhosis during the following 10 to 20 years, whereas those with negligible or mild histologic features usually do not progress to cirrhosis during this interval. After approximately 30 years of infection, patients with chronic hepatitis C have an increased risk for hepatocellular carcinoma. Almost all such patients are already cirrhotic, and the risk for hepatocellular carcinoma in cirrhotic patients with chronic hepatitis C ranges from 1% to 4% annually.

Serology and Markers of Viral Replication. Improved assays for *antibody to hepatitis C* (*anti-HCV*) yield positive results during acute infection, and results remain positive indefinitely in most patients. They can be used for routine diagnostic purposes during acute hepatitis C. Because of occasional nonspecificity of immunoassays for anti-HCV, a supplemental confirmatory test is needed when a positive result is encountered in a patient at very low risk for blood-borne infection (e.g., the asymptomatic blood donor with no risk factors). In such instances, a *recombinant immunoblot assay* (*RIBA*) can be performed to identify the viral or nonviral proteins responsible for the positive test result.

Such RIBA tests, still used to supplement anti-HCV–reactive assays among blood donors, are likely to be supplanted by testing for HCV RNA, the most sensitive test for hepatitis C infection. Tests for HCV RNA include a *branched-chain complementary DNA* (*bDNA*) test, in which the detection molecule is amplified, with a sensitivity threshold of 2×10^5 virion equivalents per milliliter, and a *polymerase chain reaction assay*, with a sensitivity threshold of 100 to 1,000 virion equivalents per milliliter. Both *qualitative* and *quantitative polymerase chain reaction assays* for HCV RNA are available. The qualitative assay is less expensive and can be used to confirm active infection in persons who are antibody-positive.

Hepatitis D (Delta Hepatitis) has an incubation period similar to that for hepatitis B; when both hepatitis B and hepatitis D infections are acquired simultaneously, a single clinically apparent episode of hepatitis may ensue. When the two infections occur simultaneously, the risk for *fulminant hepatitis* is increased slightly, but in general the outcome of simultaneous acute hepatitis B and D is no different from the outcome of hepatitis B alone. In contrast, among patients with chronic hepatitis B infection, superimposed hepatitis D may lead to severe, fulminant hepatitis, convert mild or asymptomatic chronic hepatitis into severe chronic hepatitis, or accelerate the course of chronic hepatitis. A diagnosis of delta hepatitis is made by demonstrating the appearance of *antibody to hepatitis D* (*anti-HDV*).

Hepatitis E has a mean incubation period of about 40 days, slightly longer than that for hepatitis A. Its clinical course is similar to that of hepatitis A, except that more patients experience a *cholestatic illness* and the likelihood of fulminant disease is higher (1% to 2%, and 10% to 20% in pregnant women). The disease is *self-limited* and does not progress to chronic infection. The virus is excreted in stool early, and antibodies to HEV become detectable during acute illness. Serologic tests are not available routinely.

PRINCIPLES OF PROPHYLAXIS

The principal means of prophylaxis, *minimizing exposure* to hepatitis viruses and use of *immunoglobulin* preparations (passive immunoprophylaxis) and *vaccines* (active immunoprophylaxis), vary for each of the hepatitis viruses.

Hepatitis A. Precautions against contact with a patient who has hepatitis A are most appropriate during the prodromal stage of illness, when the patient sheds virus

most heavily.

Minimizing Exposure. During the early phase of clinical hepatitis, when jaundice first appears, there may still be some shedding of virus; precautions such as avoiding intimate contact and careful washing of hands after contact are probably reasonable for a week or two longer. The patient should not serve food to others and can minimize transmission of virus by using disposable dishes and utensils.

Passive Immunoprophylaxis for hepatitis A can be accomplished by the use of standard *immune globulin* (IG) or formalin-inactivated hepatitis A vaccine. IG preparations contains high titers of anti-HAV and are about 80% effective in preventing clinical disease. IG was thought to protect by passive–active immunization (passively administered antibody acts to minimize clinical illness but does not prevent infection and the durable immunity that follows natural infection). Newer analyses suggest that IG more often prevents infection entirely. IG is currently used exclusively for *postexposure prophylaxis* and must be administered within 1 to 2 weeks of exposure to be most effective. Patients with a prior history of serologically documented hepatitis A need not receive IG because they are already protected by their own anti-HAV. Household contacts and small groups experiencing a common source outbreak should be given IG prophylaxis if the outbreak is identified early enough. Routine immunoprophylaxis is not necessary for casual contacts at work or school.

Active Immunoprophylaxis. For *preexposure prophylaxis*, *hepatitis A vaccine* has supplanted IG. Two "killed" hepatitis A vaccines are available, and both are safe, immunogenic, and highly effective in preventing hepatitis A. Doses of the two vaccines vary slightly, and regimens for the two vaccines vary with age of the vaccinee, but both require at least two injections spaced 6 to 12 months apart. Vaccination is recommended for those who travel to areas of the world where hepatitis A is endemic. (In cases of imminent travel to endemic areas, when inadequate time remains (<4) weeks before travel to achieve vaccine-induced protection, IG should be given along with the first dose of hepatitis A vaccine.) Other candidates for hepatitis A vaccine include military personnel, populations and communities with cyclical outbreaks or high frequencies of hepatitis A, laboratory workers exposed to fecal specimens, day care center employees, primate handlers, patients with chronic hepatitis C, homosexual men, injection drug users, and patients with clotting disorders who require frequent clotting factor concentrates. Vaccine-induced immunity is projected to last 20 years or longer.

Hepatitis B. *Reducing the spread* of hepatitis B has been aided by screening *blood donors* for HBsAg. People discovered to be *asymptomatic carriers* require attention. If such persons are health care workers, they need not be removed from work unless proven to be a source of infection; however, health care workers and professionals with HBeAg who perform "exposure-prone" invasive procedures are advised to have their privileges evaluated by an expert review panel. *Food handlers* have not been implicated in the transmission of hepatitis B, and when HBsAg-positive, they need not be restricted.

Minimizing Exposure is facilitated by having the patient use a separate razor, toothbrush, and other personal items. Avoidance of intimate contact should be recommended, but confinement to home is unnecessary. Ensure that any materials containing HBsAg are handled carefully, particularly blood samples and other body fluids; use of gloves is required. If universal precautions are followed in the handling of clinical materials, additional precautions are unnecessary. Hands should be washed thoroughly after direct contact with the patient or with the patient's blood or body fluids.

Passive Immunoprophylaxis of hepatitis B is achieved by providing the susceptible person with protective antibody, anti-HBs. This can be accomplished by passive immunization with IGs containing anti-HBs. *Hepatitis B immune globulin* (*HBIG*) is prepared from the plasma of persons with high-titer anti-HBs and contains anti-HBs at titers in the range of 1:100,000 or higher. HBIG, which appears to attenuate clinical illness rather than prevent infection, is recommended in conjunction with vaccine for *postexposure prophylaxis* (see below).

Active Immunization with recombinant *hepatitis B vaccines*, derived from recombinant yeast into which the gene for HBsAg has been inserted, have replaced earlier-generation, plasma-derived vaccines in the United States. Hepatitis B vaccine has been recommended as *preexposure prophylaxis*, primarily for population subgroups considered to be at high risk for exposure to HBV (e.g., health and laboratory workers exposed to blood, hemodialysis staff and patients, residents and staff of custodial institutions, sexually promiscuous persons, injection drug users, patients requiring repeated administration of blood products or clotting factors, and household and sexual contacts of chronic HBsAg carriers).

Universal Vaccination. Although these groups remain targets for vaccination, the attempt to vaccinate them has not been successful in limiting the spread of HBV within the general population of developed countries. Therefore, the U.S. Public Health Service has recommended *universal vaccination in childhood* and also vaccination of adolescents born before universal vaccination was implemented and who were not vaccinated at birth. Three deltoid injections of the vaccine are recommended, the first two given 1 month apart and the third given at 6 months. Doses vary according to age group and vaccine manufacturer.

Postexposure Prophylaxis in susceptible persons is best provided by a combination of *HBIG* and *hepatitis B vaccine*. Babies born to mothers with chronic hepatitis B (or acute hepatitis B during the third trimester of pregnancy), sexual contacts of patients with acute hepatitis B, and those who sustain HBsAg-positive needlesticks should receive HBIG plus hepatitis B vaccine. The HBIG provides immediate, high-level, passively acquired anti-HBs, and the vaccine adds long-lasting immunity and probably attenuation of clinical illness in the postexposure setting. HBIG should be administered as soon as possible after exposure (e.g., no later than 48 hours after a needlestick, in the delivery room for babies). The first dose of vaccine can be given simultaneously or within a few hours in newborns, within a week in those sustaining needlestick exposures, or within 2 weeks in those with sexual exposure. Becauseearly prophylaxis is paramount after an HBsAg needlestick, HBIG should be administered immediately and without a delay to wait for the results of antibody testing. There is no interference between hepatitis B vaccine and HBIG, even when administered simultaneously. Although determination of the HBeAg status of the contact case or inoculum source may provide information about relative infectivity, HBeAg status should not be a criterion for providing prophylaxis to contacts. The delay necessitated by waiting for HBeAg testing may invalidate efforts at prophylaxis, and infectivity can occur in the absence of HBeAg, although the likelihood is reduced. Nonintimate household contacts do not require prophylaxis, nor do casual contacts at work.

Durability of Protection. The duration of protection after hepatitis B vaccination is not definitively known but appears to be at least 10 years. Even after anti-HBs falls below detectable levels, new exposures in nature are likely to be accompanied by an anamnestic immune response, and adequate immunity against clinically apparent infection and chronic infection appear to be maintained. Based on these observations, authorities have not recommended routine booster vaccination in immunocompetent persons. Booster doses are recommended for hemodialysis patients who lose protective levels of anti-HBs after vaccination.

Differentiating between Infection and Immunization. Hepatitis B vaccine consists entirely of HBsAg protein (no core proteins are included); making the distinction between immunization and infection is therefore possible by assaying for the presence of antibody to core protein (anti-HBc).

Hepatitis D (Delta Hepatitis). Prevention of delta hepatitis in persons susceptible to HBV infection can be achieved by administering *hepatitis B vaccine*. Once immune to HBV, a person is immune to hepatitis D also. For those with chronic hepatitis B, immunoprophylaxis against hepatitis D is not available, and prevention of delta hepatitis requires limitation of percutaneous and intimate contacts with patients known to be infected with hepatitis D virus.

Hepatitis C. The incidence of posttransfusion hepatitis C has been dramatically reduced by excluding commercially donated blood and persons highly likely to transmit blood-borne disease, and also by screening prospective donors for anti-HCV. Barrier sexual precautions with latex condoms are recommended for persons with multiple sexual partners or with sexually transmitted diseases; however, no such precautions are recommended for stable, monogamous sexual partners. Persons with hepatitis C, however, should avoid sharing of razors, toothbrushes, and other such implements with sexual partners and family members. Special precautions are not recommended for babies born to mothers with chronic hepatitis C; breast-feeding is not restricted.

Immune globulin and HBIG are of no proven benefit in preventing hepatitis C, and IG is no longer recommended for needlestick, sexual, or perinatal exposure to hepatitis C. There is no vaccine for hepatitis C, and the acquisition of durable immunity after naturally acquired hepatitis C is considered rare. Still, efforts to develop a protective vaccine based on immunization with envelope proteins is being pursued.

Hepatitis E. Immunoprophylaxis for hepatitis E is not available. Whether globulins prepared in developed countries, where hepatitis E is rare, protect against HEV infection in Asia and other parts of the world where hepatitis E is common is not known. Experimental vaccines have been effective in animal models but have yet to be developed for routine use.

RECOMMENDATIONS AND PATIENT EDUCATION

Hepatitis A Precautions (To Be Continued until a Week after Onset of Jaundice)

- Advise the patient to wash hands thoroughly after toilet use.
- The patient need not be confined to home, but intimate contact should be avoided.
- Prohibit the patient from handling and serving food to others.
- Advise others to avoid contact with the patient's fecal material and to wash hands thoroughly if contact is made.

Hepatitis A Prophylaxis

- For postexposure prophylaxis, administer IG to household contacts within 2 weeks of exposure; the dose is 0.02 mL/kg, with an average adult dose of 2 mL IM.
- For preexposure prophylaxis, administer two IM injections of hepatitis A vaccine at least 6 months apart (dose recommendations vary between the two vaccine manufacturers). For imminent travel to endemic areas, when time is too short to achieve vaccine-induced immunization, IG should be administered, at the same dose as for household contacts, along with the first dose of vaccine.

Hepatitis B Precautions (To Be Continued until HBsAg Clears from the Serum)

- All blood donors should be screened for HBsAg.
- Use volunteer blood rather than blood from commercial donors.
- Use disposable syringes and needles.
- Have the patient use a separate razor, toothbrush, and other personal items.
- Have any materials containing HBsAg handled carefully, particularly blood samples and other body fluids; use of gloves is required. Following universal precautions when handling clinical materials makes additional precautions unnecessary.
- Recommend avoidance of intimate contact, but confinement to home is unnecessary.
- Hands should be washed thoroughly after direct contact with the patient or with the patient's blood or body fluids.

Hepatitis B Prophylaxis:

Preexposure.

- Administer three 1-mL IM injections of hepatitis B vaccine at 0, 1, and 6 months to persons in high-risk groups. (Doses for specific age groups may vary according to manufacturer.) High-risk groups include health workers exposed to blood, residents and staff of custodial institutions, household and sexual contacts of chronic HBsAg carriers, promiscuous male homosexuals and promiscuous heterosexuals, patients with hereditary hemoglobinopathies and clotting disorders who require long-term therapy with blood products, and hemodialysis patients.

Postexposure.

- Administer 0.06 mL of HBIG IM per kilogram of body weight (approximately 5 mL) to those who sustain an accidental percutaneous or transmucosal exposure to HBsAg-positive blood or body secretions or needles and instruments contaminated with HBsAg-positive material. This globulin injection should be administered as soon after exposure as possible; although globulin injections are recommended up to 7 days after inoculation, their efficacy is nil beyond 2 days. Passive immunoprophylaxis with HBIG should be followed by a complete, three-injection course of hepatitis B vaccine; these injections can be started at the same time as HBIG or within the first few days to a week after exposure.
- Administer HBIG, at the dose cited above, to sexual contacts of patients with acute hepatitis B as soon after exposure as is practical. Because recognition of hepatitis in a sexual contact is often delayed, early prophylaxis is usually impossible. In one study, prophylaxis within 30 days of recognized exposure was effective, but current recommendations call for prophylaxis within 14 days of exposure. HBIG should be followed by a complete three-injection course of hepatitis B vaccine in all sexual contacts of patients with acute hepatitis B.
- Administer 0.5 mL of HBIG IM to newborns of HBsAg-positive mothers immediately after birth, preferably in the delivery room. This should be followed by a complete three-injection course of hepatitis B vaccine, 0.5 mL per dose, preferably to be started within 7 days of birth (dose may vary according to manufacturer).
- No prophylaxis is necessary for casual contacts or nonintimate household contacts.
- Universal vaccination of all children, in conjunction with routine vaccinations of childhood, is recommended. For children born after the implementation of universal hepatitis B vaccination, vaccination during adolescence is recommended.

Hepatitis D Prophylaxis

- Vaccination against hepatitis B prevents hepatitis D in those susceptible to hepatitis B.
- For those already infected with hepatitis B, prevention of hepatitis D relies on limiting percutaneous and intimate contact with persons known to harbor hepatitis D virus (HDV) infection.

Hepatitis C Precautions and Prophylaxis

- Precautions are the same as those for hepatitis B (i.e., limitation of exposure to the blood and body fluids of infected patients).
- The best means of limiting transfusion-associated hepatitis C is to rely exclusively on volunteer rather than commercial blood donors and to screen donors for anti-HCV.
- IG, which has not been shown to be effective in preventing hepatitis C, is not recommended for those who sustain a needlestick injury, sexual contacts of acute cases of hepatitis C, or babies born to mothers with hepatitis C.
- An effective hepatitis C vaccine has not been developed.

Hepatitis E Prophylaxis

- Approaches to preventing exposure to enteric agents apply to the prevention of hepatitis E (see hepatitis A, above).
- Neither an IG nor a vaccine is available for the prevention of hepatitis E.

CHAPTER 58 EVALUATION OF ABDOMINAL PAIN

JAMES M. RICHTER

INTRODUCTION

One of the most challenging problems faced by the primary care physician is the outpatient assessment of the patient with abdominal pain. When the pain is acute in onset, triage decisions have to be made regarding the need for hospital admission and surgical intervention. If the pain is chronic or recurrent, the physician must design a safe, cost-effective plan for workup that will efficiently distinguish among a myriad of possible etiologies. In many instances, the exact cause of pain is not immediately evident, so that a few basic studies are necessary to define the underlying pathophysiology, narrow the differential diagnosis, and effectively guide further assessment and treatment. Also important is the need to decide on the proper speed and extent of evaluation. Etiologies of pelvic pain often overlap with those of abdominal pain (see Chapter 116).

PATHOPHYSIOLOGY AND CLINICAL PRESENTATION

The major mechanisms include obstruction of a hollow viscus, peritoneal irritation, vascular insufficiency, mucosal ulceration, altered bowel motility, capsular distention, metabolic disorder, nerve injury, abdominal wall injury, and referral from an extraabdominal site.

Obstruction. Pain receptors in the bowel, biliary tree, and ureters respond to distention and increased wall tension. The severity of the pain is a function of the speed of onset as well as the degree of distention. Obstruction that develops slowly during weeks to months may be relatively subtle in presentation in comparison with acute obstruction, which produces a more dramatic picture. In acute obstruction, the pain is severe and "colicky" or wavelike in nature; it makes the patient restless.

Small Bowel. The pain of acute *small-bowel* obstruction is greatest when the obstruction is jejunal. The patient is often comfortable between bouts of pain. Severity decreases with time as bowel motility diminishes. Complete strangulation of small bowel is associated with steady pain from secondary vascular insufficiency or peritoneal irritation. Vomiting is common, particularly in proximal obstruction; when the problem is distal, vomiting is less frequent. Flatus and passage of small amounts of stool may occur at the outset, but they soon cease if the obstruction is complete. Diarrhea is noted in some cases of partial obstruction. On examination, the patient appears restless during bouts of pain. The temperature is typically normal or only mildly elevated. The abdomen may be distended, especially when the obstruction is distal. High-pitched, hyperactive bowel sounds are characteristic but not always present. Tenderness to palpation is not impressive unless ischemia or leakage of bowel contents has occurred and caused peritoneal soilage. The stool is usually negative for occult blood.

Large Bowel. Obstruction of the large bowel is, in most instances, less painful and associated with less vomiting than is obstruction of the small intestine. Constipation or a change in bowel habits often precedes complete obstruction. Diarrhea may occur with partial obstruction. Distention is greater than that seen in small-bowel obstruction. Stools are frequently positive for occult blood.

In cases of bowel obstruction, the white blood cell count may be normal, even in association with a strangulating obstruction (i.e., with compromise of the intestinal blood supply in addition to blockage of the lumen). A plain *radiograph of the abdomen* (supine and upright) in patients with small-bowel obstruction often shows distention of loops of small bowel with high air–fluid levels. This, together with an absence of gas in the large bowel (distal to the obstruction), is characteristic of small-bowel obstruction. The radiographic appearance of colonic obstruction varies with the competency (or incompetency) of the ileocecal valve. If the valve is competent, less small-bowel dilation ensues.

Cystic Duct. Sudden obstruction of the cystic duct by a stone produces acute pain, sometimes referred to as *biliary "colic."* Unlike the cramping pain of acute intestinal obstruction, the pain of acute cystic duct obstruction is mostly steady, lasting over an hour after sudden onset. *Acute cholecystitis* is associated with localized peritonitis in addition to obstruction. Pain is typically maximal in the right upper quadrant or epigastrium, radiates to the scapular region, and is accompanied by nausea, vomiting, and fever without jaundice; at times only mild epigastric discomfort is present (see Chapter 69). *Murphy's sign* (inspiratory arrest in response to right upper quadrant palpation) may be seen, and right upper quadrant tenderness to percussion or pressure over the gallbladder is also a suggestive finding. Laboratory investigation usually reveals a leukocytosis and sometimes a modest alkaline phosphatase elevation. In an occasional case, slight hyperbilirubinemia may occur, usually after the initial onset of symptoms. *Gallstones* in the absence of ductal obstruction or gallbladder inflammation produce no characteristic pain (see Chapter 69).

Common Duct. The pain is more likely to be epigastric and less severe than in cystic duct obstruction. Jaundice is noted soon after onset. Emesis may be prominent. Obstruction and dilation that occur gradually are often painless. Physical examination may reveal a tender right upper quadrant, but in comparison with that of acute cholecystitis, tenderness is less focal and deeper. A palpable gallbladder suggests gradual progressive development of ductal obstruction, typically caused by malignancy. Alkaline phosphatase is markedly elevated, as is the serum bilirubin.

Urinary Tract. Obstruction within the urinary tract can present as abdominal pain. Acute ureteral blockade by a stone is extremely uncomfortable. Onset is sudden and the pain is cramping, beginning in the back and flank and radiating into the lower abdomen and groin. If acute pyelonephritis develops, upper abdominal pain, fever, and chills may ensue. Acute bladder outflow obstruction presents as lower abdominal distention and suprapubic pain. Symptoms of prostatism (see Chapter 134) may precede the episode.

Peritoneal Irritation. Peritoneal irritation may cause severe pain because of the rich innervation of the parietal peritoneum. Focal injury results in well-localized discomfort that is described as sharp, aching, or burning. Spread of the irritant process leads to more generalized abdominal pain. Severity is related to the nature of the irritant and the speed with which the noxious exposure occurs. Reflex spasm of the overlying abdominal wall musculature can produce involuntary guarding. Rebound tenderness is prominent on physical examination. Most important, the pain is accentuated by pressure changes in the peritoneum; thus, palpation, coughing, or movement may increase the pain, leading the patient to lie still, in contrast to the restlessness of patients with "colicky" pain.

Focal Peritonitis. *Focal peritonitis* of the retroperitoneum, which is characteristic of *early appendicitis*, may be tested by having the patient lie on the left side and extend the right hip (*psoas sign*). Bowel sounds are often reduced or absent, especially when the irritation is generalized. The origin of the peritoneal irritant need not be intraabdominal.

Familial Mediterranean Fever. *Familial Mediterranean fever* is an autosomal recessive disorder that causes recurrent, severe attacks of peritoneal irritation. The condition occurs among Armenians and Sephardic Jews and presents in childhood or early adulthood. It is characterized by brief but severe attacks of fever, peritoneal irritation, pleuritis, and synovitis. Patients complain of abdominal swelling and severe pain. Marked elevations in the sedimentation rate and acute-phase reactants accompany attacks. Amyloidosis is a serious consequence, sometimes resulting in renal impairment. Colchicine provides dramatic relief from the pain of an acute attack and also prevents amyloid deposition and renal impairment.

Vascular Disease. Vascular disease of the abdomen can result in a host of presentations of abdominal pain, many of which simulate those of other etiologies.

Acute Arterial Insufficiency. *Acute arterial insufficiency* (resulting from atherosclerosis or embolus) may present with severe abdominal pain, but often the early presentation is more subtle, with mild constant pain the only symptom for several days in the absence of tenderness and rigidity. The diagnosis may not become apparent until signs of peritonitis and shock ensue as a consequence of peritoneal soilage resulting from bowel perforation associated with ischemic necrotic injury.

Chronic Mesenteric Insufficiency. *Chronic mesenteric insufficiency* characteristically produces dull or cramping postprandial pain ("abdominal angina") localized to

the epigastrium or mid-abdomen. Onset is usually within an hour after eating; severity is proportional to the size and fat composition of the meal. Pain is greatest at times of maximal demand for blood supply to the bowel. Symptoms can persist for 2 to 3 hours. The timing, location, and duration reflect meal-triggered ischemia in the territory of the celiac or superior mesenteric artery. Some patients lose considerable amounts of weight because of the fear that eating will induce pain. Symptoms may precede an acute episode of infarction, especially in cases of progressive atherosclerotic disease. Ischemia in the celiac territory may be accompanied by nausea, vomiting, and bloating. In ischemia to the midgut, the predominant complaints are pain and weight loss. Constipation accompanied by occult blood loss characterizes chronic inferior mesenteric artery insufficiency. Abdominal bruits are reported in 20% to 60% of cases. Other signs of vascular insufficiency (e.g., carotid or femoral bruit) are often detectable. Ischemic abdominal pain also results from vascular occlusive crises of sickle cell anemia.

Aortic Dissection

Aortic dissection or rupture of an *abdominal aortic aneurysm* produces severe acute abdominal pain that often radiates to the back or genitalia. Before dissection, aneurysms are usually silent, but physical examination may reveal an increase in aortic diameter (>3.0 cm). The greater the increase in aortic diameter on examination, the more likely an aneurysm is present. Clinically silent abdominal aneurysms are often discovered serendipitously during workup for other causes of abdominal pain. Risk of catastrophic rupture is minimal as long as aneurysm diameter remains <5.0 cm. However, the probability over time of continued growth in diameter is substantial, necessitating careful followup (see below).

Updated: 5/20/02

Mesenteric Venous Thrombosis. *Mesenteric venous thrombosis* is a less common cause of intestinal ischemia than is arterial occlusion. It may present similarly, although it often has a more slowly progressive course. Both aortic dissection and mesenteric thrombosis typically result in pain complaints that are in excess of those elicited by physical examination.

Mucosal Injury. Ulceration or inflammation of the gastrointestinal tract is often accompanied by pain.

Peptic Ulcer Disease. Although the exact mechanism of pain in peptic ulcer disease remains incompletely understood, it is believed that acid plays a major role. This hypothesis is supported by the observation that neutralization of acid often provides immediate relief. The pain pattern of duodenal ulcer disease usually parallels the acid–peptic cycle (see Chapter 68). Unless perforation or penetration into the pancreas is present, the pain is mostly confined to the epigastrium. Patients use such terms as "gnawing," "aching," and "burning" to describe their discomfort. Radiation of pain into the back in patients with duodenal ulcer suggests perforation into the pancreas.

Inflammation. *Inflammation* of the middle or lower intestine, as seen with acute *gastroenteritis* and acute flares of *inflammatory bowel disease* (see Chapter 73), can disturb motility and absorption. In most instances, the pain is diffuse, but occasionally it is focal and can simulate appendicitis or other surgical conditions. Fever, nausea, and vomiting are often prominent in the early stages of gastroenteritis; bowel sounds are usually hyperactive.

Altered Bowel Motility. This mechanism predominates in functional bowel disturbances, of which irritable bowel syndrome and psychophysiologic disturbances are the best examples.

Irritable Bowel Syndrome. Spasmodic, nonpropulsive, segmental contractions of large bowel result in high intraluminal pressures, manifested by cramping lower abdominal pain and bloating. Constipation alternating with diarrhea and mucous stools are typical findings, as are pain relieved by defecation, more frequent and loose stools with the onset of pain, and a feeling of incomplete evacuation (see Chapter 74). Altered motility and chronically increased intraluminal pressures may lead to *diverticular disease* (see Chapter 75).

Functional Dyspepsia. This condition is characterized by chronic or recurrent upper abdominal discomfort or pain, often in conjunction with food-related dysmotility symptoms (e.g., bloating, fullness, nausea, early satiety). Many patients have concurrent esophageal reflux and irritable bowel syndrome, supporting the concept of "irritable gut syndrome" (see Chapter 74).

Psychiatric Disturbances. *Psychiatric disturbances*, especially *anxiety* and *mood disorders*, are common in persons with irritable bowel syndrome who seek medical attention. Symptoms may arise from any area of the intestinal tract—esophagus, stomach, small intestine, and biliary tree as well as the colon. The result is a broad spectrum of presentations that includes nausea, vomiting, dyspepsia, and flatulence in addition to cramping abdominal pain.

Acute Ileus. Causes include *peritonitis* (resulting from a variety of causes), systemic infections, bowel *ischemia*, abdominal *surgery* (a common etiology), abdominal *trauma*, pharmacologic agents (especially *anticholinergics* and *narcotics*), and metabolic disturbances (particularly *hypokalemia*).

Intestinal Pseudoobstruction. Clinical features mimic those of intestinal obstruction. Symptoms may be chronic (recurrent or persistent) or occur acutely (so-called acute ileus). Symptoms can include vomiting and abdominal distention; diarrhea or constipation may also be seen. Plain films of the abdomen demonstrate intestinal dilation, suggestive of partial obstruction. It is noteworthy that the syndrome of chronic pseudoobstruction may precede the recognition of associated systemic diseases by many years (see below). *Chronic intestinal pseudoobstruction* is often idiopathic, although it may occur in the setting of scleroderma, Parkinson's disease, drug use (opiates, phenothiazines, tricyclic antidepressants, or antiparkinsonian medications), hypercalcemia, diabetes, myxedema, amyloidosis, radiation enteritis, and chronic laxative abuse.

Capsular Distention. Distention of the well-innervated capsule surrounding an organ can be another source of constant, *aching* abdominal pain. *Hepatic* capsular distention may result from hepatic swelling secondary to hepatitis, congestive heart failure, fatty infiltration, or subcapsular hematoma and cause right upper quadrant pain. The pain of *splenic* capsular distention, as may occur secondary to blunt trauma (e.g., in an auto accident), is located in the left upper quadrant. With subdiaphragmatic peritoneal irritation, the patient may experience pain radiating to the ipsilateral shoulder. With splenic trauma, a deceptive period of many hours can pass before peritoneal signs develop if a subcapsular hematoma temporarily retards the spilling of blood into the peritoneum.

Metabolic Disturbances. Metabolic disturbances may mimic intraabdominal etiologies or sometimes result from them and exacerbate the clinical presentation.

Ketoacidosis. *Ketoacidosis* presents with severe abdominal pain in 8% of instances and may be accompanied by emesis and an elevated white blood cell count. Symptoms are caused, at least in part, by accompanying gastroparesis. An acute intraabdominal event such as cholecystitis in a diabetic may be the precipitant.

Porphyria. *Porphyria* sometimes simulates bowel obstruction because of the cramping abdominal pain and hyperperistalsis that may occur. *Acute intermittent porphyria* presents with moderate to severe colicky abdominal pain, which may be localized or generalized. Abdominal symptoms may be the result of intestinal dysmotility; vomiting and diarrhea are also common complaints. Fever and leukocytosis may be present, but on examination the abdomen is found to be soft. Proximal muscle pain and a range of neuropsychiatric symptoms accompany the abdominal pain. The clinical features of *hereditary coproporphyria* and *variegate porphyria* are similar to those described for acute intermittent porphyria; skin lesions may be prominent.

Lead Poisoning. *Lead poisoning* may also present with abdominal pain. Such pain is typically wandering, poorly localized, colicky, and accompanied by a rigid abdomen. Encephalopathy, peripheral neuropathy, and anemia are associated features. The *urine coproporphyrin* test is a more reliable indicator of this entity than is a serum lead level, which can be normal.

Angioneurotic Edema. *Angioneurotic edema* caused by *C" esterase inhibitor deficiency*, may result in episodic and severe abdominal pain. If this diagnosis is suspected, it is useful to check the serum level of C4, which is low in C" esterase inhibitor deficiency.

Nerve Injury. Nerve injury from encroachment or irritation is an important mechanism of abdominal pain. The source of pain may be intraabdominal, as occurs when a pancreatic cancer invades adjacent splanchnic nerves, or it may be extraabdominal, as occurs when a nerve root supplying an abdominal wall dermatome becomes irritated in herpes zoster. Abdominal pain occurs in about 75% of patients with *cancer of the pancreas*; it is usually epigastric and most common in patients with tumor involving the body or tail of the pancreas. Sometimes, the pain radiates to the back or is confined to it. Pancreatic malignancy also causes pain by other mechanisms, including obstruction of the common or pancreatic duct. Nerve root irritation from *herpes zoster* may be mistaken for an intraabdominal process, especially before the rash appears. Often, the patient complains of a severe, lancinating pain resembling that from an intraabdominal source. An associated rectus muscle spasm may simulate peritonitis, but there is no effect on bowel function, as there is with peritoneal irritation, and palpation may actually alleviate the rectus muscle spasm. The

pain of herpes infection often precedes the rash by several days and may persist after the skin clears, particularly in the elderly (see).

Abdominal Wall Pathology. Abdominal wall pathology can also be mistaken for disease inside the abdominal cavity. Traumatic injury to the musculature of the wall produces pain that is constant, aching, and exacerbated by movement or pressure on the abdomen. The muscles may be in spasm, simulating the involuntary guarding of peritonitis. When a generalized myositis is responsible for the muscle pain, discomfort occurs in the limbs as well as in the abdomen. Occasionally, a tender mass in the wall, such as a rectus sheath hematoma, is found to be the source of difficulty.

Referred Pain. Referred pain from a process originating in the chest is sometimes an etiology of abdominal complaints. *Pulmonary infarction* and *pneumonia* of the lower lobes are among the chest problems that may present as pain in the upper abdomen; at times, reflex muscle spasm accompanies the pain. Upper abdominal pain, nausea, and vomiting may be the principal manifestations of an acute *inferior myocardial infarction.* However, most intrathoracic sources of abdominal pain are accompanied by symptoms and signs of cardiac or pulmonary disease.

DIFFERENTIAL DIAGNOSIS

Because the number of possible causes of abdominal pain is large, it is helpful to consider the differential diagnosis in terms of pathophysiologic mechanisms ( ). Let the nature of the pain suggest a pathophysiology and narrow the differential. Etiologies causing obstruction, peritoneal irritation, and vascular insufficiency are among the most dangerous. In about 70% of cases, mechanical small-bowel obstruction is caused by adhesions or external hernias; 90% of cases of large-bowel obstruction are attributable to diverticular disease and carcinoma. Acute arterial insufficiency results most often from systemic embolization secondary to atrial fibrillation, severe atherosclerotic occlusive disease, and hypoperfusional states. Pelvic pathology is a common extraabdominal source of peritoneal irritation.

Obstruction	Altered Motility
Gastric outlet	Gastroenteritis
Small bowel	Inflammatory bowel disease
Large bowel	Irritable bowel syndrome
Biliary tract	Diverticular disease
Urinary tract	
	Metabolic Disturbance
Peritoneal Irritation	Diabetic ketoacidosis
Infection	Porphyria
Chemical irritation (blood,	Lead poisoning
bile, gastric acid)	
Systemic inflammatory	**Nerve Injury**
process	Herpes zoster
Spread from a local	Root compression
inflammatory process	Nerve invasion
Vascular Insufficiency	**Muscle Wall Disease**
Embolization	Trauma
Atherosclerotic narrowing	Myositis
Hypotension	Hematoma
Aortic aneurysm dissection	
	Referred Pain
Mucosal Ulceration	Pneumonia (lower lobes)
Peptic ulcer disease	Inferior myocardial infarction
Gastric cancer	Pulmonary infarction
	Psychopathology
	Depression
	Anxiety
	Neuroses

Table 58-1. Principal Mechanisms of Abdominal Pain

Other pathophysiologic mechanisms, such as nerve injury, metabolic imbalance, abdominal wall disease, and disordered motility, may produce symptoms that superficially mimic those of a more worrisome etiology; however, conditions associated with these mechanisms are usually more annoying than dangerous (an important exception is diabetic ketoacidosis). Pain referred from an extraabdominal site is more of a problem; significant cardiac disease (e.g., inferior myocardial infarction) or pulmonary pathology (e.g., lower lobe pneumonia) may present as abdominal pain.

WORKUP

The first priority is to determine the likelihood of serious pathophysiology and the pace and extent of workup. Patients with acute pain need to be examined promptly for evidence of obstruction, peritoneal irritation, vascular compromise, and cardiopulmonary disease. The evaluation of chronic pain can be assessed at a more gradual pace, with time allowed to get to know the patient and the problem before extensive testing is undertaken.

History. A complete description of the pain should be obtained, including localization, characterization, area of referral, time course of onset and resolution, and precipitating and alleviating factors. The chronologic sequence of symptom occurrence should be clearly outlined.

Checking for Serious Underlying Pathology. In addition to obtaining a complete description of the patient's pain, one needs to inquire into symptoms and risk factors indicative of pathology requiring urgent attention: prior abdominal surgery; previous episodes of obstruction; known gallbladder or kidney stones; presence and nature of vomitus; presence of rectal bleeding or melanotic stools; passage of flatus; time of last bowel movement; occurrence of diarrhea, constipation, or change in bowel habits; effect of activity on pain; presence of fever and rigors; development of distention; difficulties in urination; presence of atherosclerotic risk factors (especially smoking), any known systemic vascular disease, and any cardiac or pulmonary symptoms. Inquiry into pregnancy and symptoms of pelvic pathology, such as dyspareunia, abnormal vaginal discharge, and irregular menstrual bleeding, should be included in the assessment of every woman with abdominal pain.

Taking into Account Potentially Confounding Variables. The physician must learn to interpret accurately the "true" quality and quantity of the patient's experience, especially in cases of chronic abdominal pain, in which a host of nonmedical factors can alter pain perception and affect daily living. A thorough psychosocial history helps elucidate the psychological and ethnic factors that might contribute. Exploring patient fears, concerns, and expectations is also critical to understanding the patient, designing an effective treatment plan, and communicating a sense of caring and understanding.

Clinical Diagnosis of Functional Disease. The symptoms of functional bowel disease may mimic those of more serious pathology, which makes it necessary first to rule out the latter. Compounding the diagnostic challenge is that the recognition of functional disease relies heavily on the history, as there are no characteristic physical or laboratory findings. Clinical criteria predictive of functional disease have been identified to enable a "positive" diagnosis of functional disease to be made, rather than just an exclusionary one.

Irritable Bowel Syndrome. The widely used *Manning criteria* (visible abdominal distention, pain relief with defecation, more frequent stools with onset of pain, looser stools with onset of pain, passage of mucus per rectum, and feeling of incomplete evacuation) were developed to differentiate irritable bowel syndrome from other gastrointestinal disorders. Predictive value rises with the number of criteria that the patient fulfills and with the exclusion of findings suggestive of underlying bowel pathology. With all six criteria present, the predictive value can be as high as 80% to 90%, although lower in the elderly (70% to 80%) because of the increased risk for colon cancer (which can mimic some of the findings). The *Rome diagnostic criteria* are a refined iteration of the Manning criteria with the following features:

- At least 3 months of continuous or recurrent symptoms of abdominal pain or discomfort associated with any or all of the following:
  a. relief with defecation
  b. change in stool frequency
  c. change in stool consistency plus
- Two or more of the following:
  a. altered stool frequency (more than three bowel movements per day or fewer than three per week)
  b. altered stool form (lumpy and hard or loose and watery)
  c. altered stool passage (straining, urgency, or incomplete evacuation)
  d. passage of mucus
  e. bloating or feeling of abdominal distention

Functional Dyspepsia. The *Rome criteria* for this condition identify two forms: ulcer-like and dysmotility-like. For the ulcer-like variant (in which abdominal pain dominates), the principal criterion is 3 months or more of upper abdominal pain with no evidence of organic disease, plus three or more of the following:

- very well-localized pain
- pain relieved by food (>25% of the time)

- pain relieved by antacids or histamine $_2$ blockers
- pain that awakens patient from sleep
- periods of remission and relapse (at least 2 weeks of remission)

Physical Examination. Particular attention ought to be paid to the patient's *general appearance*. The patient who appears reluctant to change position and keeps still is likely to have peritoneal irritation, whereas the patient with obstruction is often restless. It is important to check the *vital signs* for postural changes in the blood pressure or heart rate because obstruction, peritonitis, and bowel infarction can produce large losses of intravascular volume. Any hypotension, atrial fibrillation, or fever should be noted; however, absence of fever does not rule out serious pathology, especially in the elderly or chronically ill patient. The *skin* is examined for jaundice, other stigmata of chronic liver disease, clubbing or spooning of the fingernails, signs of trauma, excoriations, prior surgical scars, and evidence of dehydration, edema, or dermatomal rash. In addition, the sclerae are noted for icterus. The *chest* is checked for splinting, a pleural friction rub, and signs of consolidation (particularly in the lower lobes), and the *heart* is checked for murmurs, chamber enlargement, and signs of heart failure (see Chapter 32).

The *abdominal examination* should be performed with care to avoid unnecessary discomfort. A sharp increase in pain with coughing demonstrates rebound tenderness without the need for palpation and release. Examination of the abdomen includes checking for distention, ascites, altered bowel sounds (increased or absent), hepatic rub, vascular bruit, tenderness, guarding, rebound, hepatosplenomegaly, inguinal hernia, and masses (including a dilated aorta, loops of bowel, stool, distended bladder or uterus). An increased abdominal venous pattern suggests portal hypertension; periumbilical adenopathy suggests pancreatic or ovarian cancer. In a person with risk factors for vascular disease, the abdominal aorta should be palpated to determine its diameter. The index fingers are placed along the lateral margins of the aorta a few centimeters above the umbilicus and the distance between them measured, with the estimated thickness of the skin subtracted. Any diameter larger than 3 to 4 cm raises the possibility of aneurysm and necessitates proceeding to imaging (ultrasonography or computed tomography).

Pelvic and rectal examinations are essential parts of the evaluation, with checks for masses and tenderness. These examinations are certainly more revealing if done gently. The fecal occult blood test is also mandatory.

Examining for *nerve* and *muscle wall* injury is often overlooked in the urgency of searching for more worrisome pathology. Two important signs of nerve involvement are pain in a dermatomal distribution and hyperesthesia. Both occur with nerve injury from herpes zoster or nerve root impingement; however, hyperesthesia is also seen with focal peritoneal irritation. Testing is performed by gentle stroking of the skin overlying the area of pain. The rash of herpes may not appear until the time of the follow-up assessment. Abdominal wall pathology may be discovered by careful palpation of the wall for masses and muscle tenderness and by noting any exacerbation of pain when the muscles are contracted, as occurs with sitting up. Any pain on sitting up should not be confused with that secondary to involuntary muscle spasm associated with peritoneal irritation. The limbs should also be checked for muscle tenderness, which is suggestive of a generalized muscle disorder.

Physical Findings in the Elderly. The usual physical findings of acute peritoneal irritation may be absent in the elderly, especially at the outset. The only manifestations may be unexplained mild fever, tachycardia, reduction in bowel sounds, and vague abdominal discomfort without frank rebound or guarding. A high index of suspicion is required. Acute abdominal pain out of proportion to tenderness on physical examination in a person with known atherosclerotic disease should raise suspicion of vascular compromise.

Suspected Psychogenic Pain. Use of deep palpation while the patient is distracted can provide helpful evidence when a psychogenic etiology or a major degree of psychocultural overlay is suspected. A lack of tenderness is characteristic. A widely used approach is to push down slowly, firmly, and deeply with a stethoscope, distracting the patient by appearing to auscultate. Such a maneuver should be performed only after more serious pathology has been ruled out by history and physical examination.

Laboratory Studies: Initial Office Testing for Serious Acute Etiologies. Relatively few laboratory tests are needed for an initial assessment in the office setting. Studies are aimed at determining the likelihood of obstruction, peritonitis, acute vascular insufficiency, metabolic abnormality, and cardiac or pulmonary disease.

Complete Blood Cell Count and Differential. Although very nonspecific, the complete blood cell count and differential are reasonably sensitive for confirming the presence of an acute inflammatory process. Unfortunately, the complete blood cell count may show little change in the elderly or chronically ill patient, even in an acute intraabdominal emergency. The differential ought to be ordered even if the white cell count is "normal," particularly in the elderly, because a shift to immature forms sometimes occurs without a significant elevation in the white cell count. At times, a relatively benign condition such as viral gastroenteritis may produce an impressive elevation in the white cell count (as high as 20,000 cells per milliliter) accompanied by a marked shift to immature forms, which simulates the peripheral blood picture of a patient with more worrisome disease. The complete blood cell count and differential must be carefully interpreted in the context of the entire clinical picture and not used alone to decide whether to admit the patient. For patients with diarrhea, a microscopic *examination of the stool* for white blood cells is indicated (see Chapter 64).

Pregnancy Testing. Because of the seriousness of an ectopic pregnancy, every woman of reproductive age who presents with lower abdominal pain in the office setting should have pregnancy ruled out early in the assessment and usually before a radiologic study is performed. A *serum human chorionic gonadotropin b-subunit* is the most sensitive test; kit-based urine testing is less sensitive (see Chapter 112).

Plain Films of the Abdomen. Supine and upright films are essential if one suspects bowel obstruction or perforation. Multiple (i.e., 3) air–fluid levels, distention of the small bowel, and absence of gas in the large bowel are characteristic of complete small-bowel obstruction; however, such findings are present in fewer than 50% of cases of bowel strangulation, especially in the early stages of obstruction. Partial mechanical obstruction may produce some loops of bowel with air–fluid levels, but there is also gas in the colon; the same findings are found in patients with adynamic ileus. In colonic obstruction with a competent ileocecal valve, only the large bowel appears distended, but if the valve is not competent, both the large and small bowel demonstrate distention and gas, mimicking the findings of adynamic ileus. Distinguishing partial small-bowel obstruction from ileus requires repeated films or a barium study. Suspected obstruction of the large bowel is an indication for a barium enema and is usually a contraindication to performing an upper gastrointestinal series.

On the plain film, *free air* under the diaphragm indicates perforation of a viscus; *absent psoas shadows* suggest retro-peritoneal bleeding, abscess, or mass; and displaced stomach or bowel (determined by gas patterns) may be caused by compression from a tumor. Plain films detect *calcifications*, such as those representing a biliary or renal stone, abdominal aortic disease, or pancreatitis. Calcification of the aortic wall has been found on plain films of the abdomen in more than 60% of abdominal aneurysms; a cross-table lateral view best demonstrates the finding.

Plain films of the abdomen are commonly overused in evaluating abdominal pain. Limiting the study to patients who have moderate to severe tenderness or who are strongly suspected of having bowel obstruction, urinary tract calculi, trauma, ischemia, or gallbladder disease (regardless of degree of tenderness) can reduce utilization by more than 50% without compromising the detection of clinically important pathology. Plain films reveal little unsuspected pathology, especially in patients with mild tenderness on examination. Using plain films to "rule out" serious pathology is possible only with bowel obstruction and perforation, for which the sensitivity of the plain film approaches 100%. Its sensitivity for the detection of other conditions is much lower.

Urinalysis and Chemistries. A *urine specimen* should be checked for pyuria, hematuria, bacteria, sugar, and ketones. Mild to moderate ketonuria is common when the patient has not eaten and is unrelated to diabetes; the diagnosis of ketoacidosis requires urine ketones in large concentrations (see Chapter 102). Red cells in the urine of a patient with flank pain suggest a stone in the ureter (see Chapter 135).

The *blood urea nitrogen*, *glucose*, *electrolyte*, and *amylase* levels should be measured. Elevation of the serum amylase occurs not only in pancreatitis but also in intestinal obstruction, perforated ulcer, and biliary tract disease; additional information is needed to identify the source of the elevation (see Chapter 72). Although not especially specific, the serum amylase is sensitive. Serum electrolytes can be helpful in cases of vomiting, diarrhea, or adynamic ileus; tests of renal and liver function should also be performed and blood sugar determined when clinical findings are suggestive.

Chest Film and Electrocardiogram. The initial investigation of acute upper abdominal pain should also include a *chest film* and *electrocardiogram* to look for pleuropulmonary disease in the lower lobes and acute ischemic changes in the inferior myocardium.

Laboratory Studies: Emergent Setting. Patients with evidence of acute obstruction, peritonitis, bowel ischemia, or worrisome metabolic or cardiopulmonary disease need immediate hospitalization and urgent testing. Although testing in the emergency department/urgent care setting is beyond the scope of this book, a few tests in addition to those noted above are worth mentioning for their contributions to initial decision making.

Paracentesis. In the subset of patients with acute pain who have ascites or abdominal trauma, an abdominal paracentesis performed with a small needle inserted into the lower abdomen (where there is less chance of perforating a viscus or a large blood vessel; see Chapter 71) helps to detect peritonitis by providing fluid for detection of blood and white cells. The best sites are nontympanitic areas of the right lower quadrant, left lower quadrant, and linea alba (midline).

Computed Tomography of the Abdomen. Abdominal computed tomography (CT) with Gastrografin oral contrast is the test of choice in patients with suspected *diverticulitis*, especially if there is concern on clinical grounds for abscess formation. CT with IV contrast is indicated for suspected *dissecting aortic aneurysm*. When *appendicitis* is the concern, *helical CT of the appendix* (with Gastrografin contrast) should be performed in the emergency department. This variation of CT technology maximizes diagnostic accuracy (95% to 98%) and, in doing so, shortens time to surgery for those with a positive test result and spares hospitalization and unnecessary surgery in persons with a negative result. The net impact is an improvement in outcomes and a reduction in costs.

Abdominal Ultrasonography. Ultrasonographic examination of the biliary tree is the test of choice for suspected *acute cholecystitis* and *choledocholithiasis*. The test can also detect *aortic aneurysm*. Ultrasonographic examination of the kidneys is needed when *hydronephrosis* from urinary tract obstruction secondary to *ureterolithiasis* is suspected.

Testing for Familial Mediterranean Fever. For Sephardic, Turkish, Arabic, or Armenian patients who present with peritoneal signs and fever, familial Mediterranean fever must be considered before they are subjected to surgery. A high index of suspicion for the diagnosis is warranted in such patients, especially those who have a positive family history or who describe self-limited attacks that may also involve the joints and pleurae. Detecting C5a inhibitor deficiency in serosal or synovial fluid is diagnostic, but not practical. Use of a DNA amplification assay for rapid detection of the responsible genetic mutation is now available in centers where the condition is common.

Laboratory Studies: Subsequent Outpatient Testing. The workup of patients without sufficient evidence of serious acute pathology necessitating immediate hospitalization can be continued on an outpatient basis. Any patient sent home with undiagnosed acute abdominal pain requires careful follow-up and reexamination because several serious etiologies (e.g., bowel ischemia, cholecystitis) may initially present with an indolent picture, particularly in the elderly. Despite the abundance of tests available, a repeated history and physical examination remain among the most productive of diagnostic measures. Additional testing is most productive when directed at working hypotheses suggested by the clinical findings and initial testing. Test selection ought to be judicious and based on the need to confirm or rule out specific diagnoses. Blind searches that involve "running the bowel" in the absence of suggestive clinical evidence are not only wasteful but also potentially misleading and may subject the patient to unnecessary risk. Test selection can be considered in terms of location of pain.

Epigastric Pain. Epigastric pain that parallels the acid–peptic cycle or responds to food or antacids suggests peptic ulcer disease. If the patient is under the age of 40 and little clinical evidence for malignancy is present (e.g., no dysphagia, weight loss, melena, hematemesis), then *serologic testing* for *Helicobacter pylori* and symptomatic treatment for presumed ulcer disease (see Chapter 68) can be started without first documenting the lesion. However, failure to respond to a 4- to 8-week course of empiric therapy or the development of worrisome symptoms, especially in older patients (who are at increased risk for esophageal and gastric cancers), necessitates direct visualization of the upper gastrointestinal tract by an *upper gastrointestinal series* or *esophagogastroduodenoscopy* (EGD). Endoscopy provides an opportunity for biopsy and should be considered if there is serious concern for cancer.

Recurrent bouts of epigastric or right upper quadrant pain are an indication for *abdominal ultrasonography*, which provides an important noninvasive approach to the detection of intraabdominal and retroperitoneal conditions presenting as abdominal pain. It is the test of choice for suspected cholecystitis (see Chapter 69) and useful for the detection of biliary and ureteral obstructions (see Chapter 62 and Chapter 135, respectively). It can help identify ascites and aortic aneurysm and sometimes localize an intraabdominal abscess. *Duplex scanning* (the combination of *Doppler* with *B-mode ultrasonography*) provides a sensitive, noninvasive approach to screening for mesenteric insufficiency. When performed by skilled operators, sensitivity for celiac and superior mesenteric artery disease is 87% and 96%, respectively. The test deserves consideration when abdominal pain is postprandial in a person with systemic vascular disease or its risk factors (especially smoking).

Periumbilical Pain. Periumbilical pain suggests small-bowel pathology and is an indication for an *upper gastrointestinal series* with *small-bowel follow-through*. A lymphoma or carcinoid tumor may cause an intermittent partial obstruction. When the pain is postprandial, mesenteric ischemia requires consideration; duplex scanning by *Doppler ultrasonography* can provide noninvasive screening (see above).

Lower Abdominal Pain. All patients with lower abdominal pain accompanied by signs of rectal bleeding (be it gross or occult) should be evaluated by *colonoscopy* or the combination of *barium enema* and *sigmoidoscopy* to identify the source (see Chapter 63). However, the young patient (<40 years) with constipation, obvious hemorrhoidal bleeding, and no risk factors for colorectal cancer need undergo only a sigmoidoscopy to rule out associated rectosigmoid pathology, such as that of inflammatory bowel disease. Sigmoidoscopy is ideal for the assessment of suspected rectosigmoid masses or mucosal abnormalities. A full colonoscopy is needed when the source of lower gastrointestinal bleeding is unknown, as in cases of hematochezia or guaiac-positive stools. Barium enema is a reasonable alternative to colonoscopy, although not as sensitive for the detection of some sources of bleeding, such as angiodysplasia. Endoscopic study makes possible not only direct visualization but also biopsy of suspected lesions, polypectomy, and an assessment of the extent of disease in patients with inflammatory bowel disease.

Patients with lower abdominal pain in the absence of bleeding, weight loss, or a change in bowel habits are less likely to benefit from radiologic or endoscopic evaluation unless their symptoms are particularly severe or chronic. At times, the patient insists on having a study for reassurance purposes. The contribution of a normal test result to the patient's peace of mind has to be taken into account in any decision regarding whether or not to test. Carrying out age-appropriate screening for colorectal cancer (see Chapter 56) helps provide appropriate reassurance without excessive testing.

Flank and Adnexal Pains. The patient with flank pain, hematuria, or pyuria may have a renal source of abdominal pain. An *IV pyelogram* may help in detecting disease in the kidneys or ureters or displacement of a ureter by an abdominal or retroperitoneal mass. *Renal ultrasonography* can reveal a stone, tumor, or ureteral dilatation. *Pelvic ultrasonography* is indicated when the patient with adnexal pain has tenderness or a mass noted on bimanual examination.

Suspected Pancreatic Cancer. *Ultrasonography* is the test of choice for screening. Sensitivity ranges from 65% to 85%; specificity is a bit lower but can be greatly enhanced by adding *needle biopsy* of any suspected lesion. A proportion of studies are technically inadequate or indeterminate because of bowel gas or fat, which limits overall sensitivity. Nonetheless, the relatively high sensitivity, low cost, noninvasiveness, and absence of radiation exposure make this the preferred screening test for pancreatic cancer and other forms of pancreatic pathology.

The sensitivity and specificity of *abdominal CT* for the detection of pancreatic cancer parallel those of ultrasonography, but the frequency of indeterminate readings is lower (e.g., 4% vs. 23%). CT is less dependent on the skill of the operator, but it is more expensive and involves radiation exposure, a particularly important consideration in children. In addition to imaging the pancreas, it provides excellent views of the liver, retroperitoneum, and spine. Both ultrasonography and CT visualize the common bile duct, portal vein, and hepatic artery and detect any displacement, encroachment, or encasement of the major intraabdominal vessels and organs.

Endoscopic retrograde cholangiopancreatography (ERCP) is more sensitive and more specific for detecting pancreatic cancer than is ultrasonography, but success is very dependent on the skill of the endoscopist. If ultrasonography is not technically adequate, then CT or ERCP should be ordered. If a mass is found, needle aspiration biopsy is usually needed to confirm a diagnosis of malignancy. Although much progress has been made in identifying pancreatic masses in symptomatic patients, early detection in the asymptomatic period remains an elusive goal.

Suspected Functional Disease. The diagnosis of functional bowel disease is a clinical one, facilitated by careful attention to the history and physical examination. In the absence of history or physical examination evidence (e.g., significant weight loss, positive stool test for occult blood) suggesting a more serious medical condition, the diagnostic screening evaluation can be relatively limited.

For irritable bowel syndrome, the most useful test is *flexible sigmoidoscopy*, because of the considerable overlap between the symptoms of this disease and those of inflammatory bowel disease in younger persons and colorectal cancer in older patients. The routine ordering of chemistry profiles, blood counts, thyroid indices, urinalyses, and tests for ova and parasites appears to add little to the assessment or to decision making in the absence of clinical evidence of the conditions these tests screen for.

For functional dyspepsia, an empiric trial of treatment for peptic ulcer disease is one approach to screening for conditions that may resemble this functional illness.

Another is to consider *serologic testing* for *H. pylori* infection, which is etiologic in peptic ulcer disease but not associated with functional dyspepsia. The decision to order upper gastrointestinal endoscopy is more difficult. The rationale is early detection of gastroesophageal malignancy. Because of the expense, discomfort, and potential morbidity associated with the procedure, in addition to a lack of evidence for any significant alteration in outcomes, the controversy regarding the usefulness of upper gastrointestinal endoscopy is considerable. Suggested criteria for its use include onset of symptoms after the age of 40, especially in persons whose symptoms persist without remission for longer than 8 weeks.

Evaluation of Undiagnosed Abdominal Pain. A most vexing problem arises when the cause of abdominal pain remains undetermined despite a careful initial medical evaluation. There may be pressure from patient and family to look still harder for a serious cause and a tendency, from frustration, to order progressively more invasive studies in search of such an etiology. Certainly, further anatomic study is indicated in patients with a strongly positive family history of bowel malignancy (see Chapter 56), significant weight loss, presence of a mass, unexplained iron-deficiency anemia, or a stool test that is positive for occult blood. However, the cause of undiagnosed abdominal pain is often an underlying psychological disturbance or sometimes a condition that can mimic it (e.g., lead poisoning or porphyria) and requires positive identification to facilitate treatment. At other times, no cause can be uncovered, and a plan for observation and follow-up is required.

Identification of Contributory Psychopathology. Abnormal illness behaviors characterize patients with psychosocial problems that present as a bodily complaint such as abdominal pain (see Chapter 230). Such behaviors include an exaggerated presentation with disability out of proportion to the degree of detectable disease, chronic complaints that defy precise diagnosis, persistent attempts to validate suffering, excessive dependence on the physician and others for care, avoidance of health-promoting behaviors, and attempts to maintain the sick role.

Include a history of *multiple bodily complaints*, a *chronic nonprogressive* clinical course that may span many years, *lack of relation* between symptoms and physiologic stimuli, inconsistent or *distractible* physical findings, and presence of the *somatic symptoms of depression* (e.g., early morning awakening, fatigue, decreased libido, altered appetite). Such behaviors and presentations of pain divert attention from the patient's psychosocial suffering and root causes unless they are recognized, understood, and responded to appropriately (see Chapter 226, Chapter 227, and Chapter 230). In the absence of worrisome objective findings, one can avoid exhaustive testing of these patients and concentrate more on their underlying psychosocial problems.

The Patient's Perspective. Of particular importance is eliciting the patient's concerns, beliefs, and expectations. Also pertinent are the patient's daily functioning at work and at home, social supports, and psychological state. If elicited early on, these elements can speed recognition of psychosocial distress. The abdominal pain may be only a symptom of psychosocial suffering. Although the patient, family, or friends may be pressing for a medical diagnosis, the real need is for care rather than a diagnostic label. The risk of a missed anatomic diagnosis is less than 3% when the initial evaluation findings are normal and evidence of abnormal illness behavior and clinical features of psychological disturbance are present.

Patients with a clinical picture suggestive of functional disease may also benefit from inquiry into psychosocial issues, such as concurrent stresses, losses, and the effect of the pain on the patient's life and daily activities. However, a suggestion at the outset that the problem is probably psychogenic is inaccurate (about half of patients with functional disease have no etiologic psychopathology), and it also invites resistance and hostility if proclaimed before a careful evaluation is completed.

Avoiding an Adversarial Stance. Care must be taken neither to deny the reality of the patient's pain and suffering nor to emphasize the psychosocial nature of the problem any more than the patient is willing to accept. A detailed and pertinent history and physical examination that address patient concerns along with simple screening laboratory tests should suffice. Any requests for aggressive testing can be postponed as long as a plan for careful longitudinal follow-up is in place and available data show no evidence for dangerous underlying pathology. A caring response and an open-minded attitude help forge a working partnership and avoid triggering an adversarial relationship. In patients with neurotic complaints presenting with irritable bowel syndrome, thorough reassurance that specifically addresses patient concerns can be most effective, especially when delivered in sympathetic and respectful fashion.

Testing for Lead Poisoning and Porphyria. The patient with acute colicky pain but no signs of obstruction or inflammation may have lead poisoning and should have urine samples checked for *coproporphyrin*. Serum lead levels are unreliable. The person with acute intermittent porphyria may also present with colicky pain. Often, such persons are thought to be psychiatrically disturbed because of abnormal behavior during an attack. The diagnosis is suggested by periodic attacks of cramping pain, constipation, nausea and vomiting, and neuromuscular symptoms in conjunction with the altered psychological state. The *Watson-Schwartz test* for *urinary porphobilinogen* is a reliable screening test for acute intermittent porphyria in patients who are symptomatic.

Observation and Follow-Up. When the diagnosis remains unclear, close follow-up is essential to proper management.

Acute Pain. If urgent admission does not seem warranted, assiduous, close follow-up is mandatory. Repeated histories and examinations may yield the diagnosis and hence allow proper treatment. Such factors as the degree of distress manifested by the patient, any elevation in temperature or white blood cell count, other laboratory abnormalities, and the ability of the patient to eat and drink all need to be reassessed continually. Judgment also must be made as to whether a patient with undiagnosed abdominal pain should undergo more invasive testing. In general, patients with unexplained abdominal pain in conjunction with recurrent nausea and vomiting, jaundice, fever, weight loss of more than 10% of body weight, or blood in the stool require more extensive evaluation.

Chronic Pain. The patient with chronic or recurrent abdominal pain that defies explanation poses one of the most difficult problems in clinical medicine. In a study of 64 patients with abdominal pain of unknown etiology despite extensive assessment, the younger the age and shorter the duration of the symptoms, the better the chances were for improvement. Older women with pain for more than 3 months were less likely to improve or be given a diagnosis. Of those subjected to *exploratory laparotomy*, a diagnosis was obtained in only 10%; the rate of improvement was the same as for those who did not undergo exploration. In 15% of the total study population, a cause for the patient's abdominal pain was found, but in only 6% did the condition require surgery. Thus, very few patients with abdominal pain of unknown etiology are endangered by continued observation, as long as signs of serious pathophysiology are absent. The morbidity of exploratory laparotomy in such patients greatly exceeds the benefit. Unexplained pain that is present for less than 2 weeks is likely to resolve spontaneously, but such improvement is unlikely when pain has persisted for more than 3 months.

Clinically Silent Abdominal Aortic Aneurysm

Patients with a clinically silent abdominal aortic aneurysm found serendipitously during work-up for abdominal pain require close attention and follow-up. Those with aneurysm diameters <5.0 cm are at little risk for rupture and can be followed expectantly; however, careful monitoring of aneurysm diameter is essential, as is achievement of smoking cessation. Obtaining an abdominal ultrasound at 6-month intervals provides a convenient noninvasive approach to monitoring. Consideration of elective surgical repair is indicated once diameter exceeds 5.0-5.5 cm. **Updated: 5/20/02**

INDICATIONS FOR ADMISSION AND REFERRAL

Admission. Any evidence suggestive of peritoneal irritation, obstruction, or acute vascular compromise is an indication for immediate hospitalization and surgical consultation. Sometimes, further observations made in the hospital can save the patient a surgical procedure, but no patient with the possibility of a condition that might require urgent surgery should be sent home from the office. Elderly patients are especially prone to subtle presentations. The patient with unexplained pain that has defied outpatient diagnostic attempts may benefit from further assessment in the hospital, especially if a need for large amounts of pain medication has developed. Admission provides an opportunity for 24-hour observation, specialty consultation, and assessment of the need for further study.

Referral. Consideration of invasive study is an indication for consultation with the gastroenterologist or surgeon before plans are made to proceed. Conversely, the internist can feel comfortable following the patient who appears well and has an otherwise normal history, physical examination findings, and screening laboratory results. For the overly anxious patient, a session with the gastroenterologist to talk over concerns and review the workup to date can be useful and may obviate need for further testing. Psychiatric consultation is indicated for patients with evidence of serious depression (see Chapter 227) or excessive somatization (see Chapter 230).

SYMPTOMATIC THERAPY

Symptomatic relief may be a high priority in some instances, even before a definitive diagnosis is achieved. Analgesics and therapeutic trials are the principal means utilized, but selective use is essential to ensure patient safety. Behavioral methods can be useful in persons with suspected psychopathology whose symptoms

appear refractory.

Analgesics. Although analgesics are inappropriate for most patients with acute abdominal pain of unknown etiology (important diagnostic findings may be obscured), in certain instances their use should not be overlooked. Most important are patients with terminal cancer, for whom the compassionate use of narcotics must not be denied, even if the cause of abdominal pain is not fully defined (see Chapter 90). Patients with undiagnosed chronic pain who request pain medication represent the opposite situation. Many such patients have underlying psychopathology and a strong potential for narcotic abuse. Narcotic analgesics are to be avoided in such instances, even if the request is for "just a few pills."

Therapeutic Trials. Thoughtfully applied empiric therapy can provide relief as well as diagnostically useful information. Patients with suspected *peptic ulcer disease* and no evidence of malignancy are reasonable candidates for a 4-week course of *antacids*, *histamine$_2$ blockers*, or *proton pump inhibitors* (see Chapter 68); they may begin to feel better within days. Those with probable *irritable bowel syndrome* can be tried on a *high-fiber* program, such as a tablespoon of psyllium in 8 oz of water two to three times daily. (Psyllium is preferred to high-fiber cereal because of the need for milk intake with the latter and the associated risk for lactose intolerance in susceptible persons, which can simulate irritable bowel syndrome and confuse the diagnosis; see Chapter 64). As noted earlier, a trial of *antidepressant therapy* (with an agent low in anticholinergic activity) may be useful for patients with abdominal pain who manifest symptoms of major depression (see Chapter 227).

Behavioral Methods. Patients with refractory functional disease linked to underlying psychosocial distress are among the hardest to help, especially when illness behavior is greatly distorted. Although formal psychiatric care may be necessary, the primary physician can help to modify illness behavior by a series of simple actions. One is to provide the patient with techniques to increase control over the illness. Useful approaches include *participating* in treatment decisions, learning relaxation techniques, and beginning an *exercise* program. Even keeping a *symptom diary* can help provide a sense of control.

Equally important for such patients is the reinforcement of positive behaviors and removal of rewards for symptoms. Follow-up should be scheduled at regular intervals rather than as needed for symptoms. However, *setting limits* to time and availability is appropriate, with no more than 20 minutes necessary for a visit and unscheduled visits discouraged. During the visit, the focus should be on *accomplishments* ("What have you been able to do?") rather than on symptoms ("How do you feel?"). Reports of accomplishments are best received with positive reinforcement and requests for elaboration, whereas complaints of suffering and symptoms should be accorded a neutral stance and no request for elaboration unless worrisome new symptoms are reported. Finally, setting *realistic treatment goals* is critical. The emphasis needs to be on improving the quality of life and not on removing symptoms, which may not be possible.

CHAPTER 59 EVALUATION OF NAUSEA AND VOMITING

Nausea and vomiting are extremely common presenting complaints, ranking in one study of primary care practice second only to symptoms of upper respiratory tract infection. Although in most instances the symptoms are caused by self-limited disease, they may be a manifestation of a more serious underlying illness. The primary care physician needs to recognize the more worrisome causes of nausea and vomiting, provide relief from these debilitating symptoms, and correct any important fluid and electrolyte disturbances.

PATHOPHYSIOLOGY AND CLINICAL PRESENTATION

Mechanisms. Two major central nervous system centers are involved in the vomiting reflex—the vomiting center and the chemoreceptor trigger zone. Irritation of vagal and sympathetic afferents in the pharynx, heart, peritoneum, mesentery, bile ducts, stomach, and bowel triggers impulses to the vomiting center in the medullary reticular formation. Gastric irritation, distention of a hollow viscus, myocardial ischemia, increasedintracranial pressure, metabolic disturbances, drugs, pharyngeal stimulation, and emotional upset are important noxious stimuli that act through this pathway. Vestibular disturbances, centrally acting drugs, and metabolic derangements stimulate the chemoreceptor trigger zone in the floor of the fourth ventricle, which in turn activates the vomiting center. A cortical pathway to the vomiting center has been postulated to account for some forms of psychogenic vomiting.

Clinical Presentations. The act of vomiting is a stereotyped response that varies little regardless of cause. Even so-called *projectile vomiting* (which is characterized by forceful emesis without prior nausea or retching), supposedly limited to cases of increased intracranial pressure, occurs in other conditions. Moreover, nausea, retching, and nonprojectile vomiting are seen with increased intracranial pressure.

Nausea and vomiting may be only one part of a symptom complex or may dominate the clinical picture (as in psychogenic vomiting, early pregnancy, digitalis toxicity, and metabolic disturbances). Considerable overlap exists among presentations nevertheless. With some causes of nausea and vomiting, symptoms are more likely to occur independently of meals, whereas in others, they are characteristically associated with food intake.

Metabolic Etiologies. Early morning nausea and vomiting are typical of *metabolic causes*. Up to 75% of cases of diabetic ketoacidosis are accompanied by nausea and vomiting. Emesis and nausea are found among as many as 90% of patients in addisonian crisis. Uremia may be heralded by similar symptoms; nausea often improves with correction of any associated hyponatremia, but it can be refractory. *Binge drinkers* experience early morning nausea and dry heaves from excessive alcohol intake.

Early Pregnancy. Early morning nausea and vomiting are characteristic of early pregnancy, occurring in more than 50% of instances. The problem is severe in fewer than 1% of cases but can lead to electrolyte abnormalities, dehydration, and weight loss. Most cases are mild; symptoms begin after the first missed period and terminate by the fourth month. Women with severe cases often have a history of vomiting in response to psychosocial stress. Disturbed motility is also noted in many cases. The diagnosis of pregnancy is sometimes overlooked.

Psychogenic Disease. In contrast to the causes of early morning vomiting, conditions such as psychoneurotic illness, acid or bile reflux, peptic ulcer disease, and gastritis can trigger symptoms shortly after food is ingested. Psychogenic vomiting is characterized by years of recurrent emesis. It can often be traced back to childhood and is more common when a family history of vomiting is present. Patients report that symptoms appear just after intake of food and can be sufficiently controlled voluntarily to avoid vomiting in public. Some patients admit to inducing emesis; most are surprisingly untroubled by the problem. Nausea accompanies almost all episodes. A study of 20 patients with psychogenic vomiting revealed a marked predominance of women engaged in hostile relationships; abdominal pain and depression were uncommon.

Bulimia is a form of psychogenic emesis in which vomiting is self-induced, often after a period of binge eating. A preoccupation with being thin and a poor self-image in a young woman are characteristic. Laxative abuse frequently complicates the clinical picture (see Chapter 234).

Peptic Ulcer Disease and Gastritis. A pyloric channel ulcer or acute gastritis may be associated with marked postprandial emesis. The vomiting in ulcer disease is believed to be in part a consequence of irritation, edema, and spasm of the pyloric sphincter mechanism. Concurrent bleeding can lead to vomiting of "coffee grounds." Patients who undergo surgery for peptic ulcer may be troubled by recurrent *bilious vomiting*, which is believed to be caused by reflux of bile into the stomach or gastric remnant. Patients vomit bile within 15 minutes of eating; little food is present. Nausea and a bad taste in the mouth are present on awakening in the morning.

Gastric Retention results in vomiting of food eaten more than 6 hours previously. A succussion splash is detectable on examination, and food is seen in the stomach on upper gastrointestinal series. In chronic cases, gastric outflow obstruction or atony may be secondary to diabetic neuropathy, anticholinergic use, or gastric malignancy. Transient gastric dilation is a frequent concomitant of pancreatitis, peritonitis, gallbladder disease, and hypokalemia. A *cyclic idiopathic* form of nausea and vomiting has been described with gastric hypomotility demonstrated.

Gastroesophageal Reflux Disease usually does not present with nausea as the predominant symptom (see Chapter 61), but a subset of patients with otherwise unexplained intractable nausea may suffer from reflux. Treatment of their reflux results in resolution of the nausea.

Acute Gastroenteritis. Acute episodes of vomiting accompany a host of conditions that range from the self-limited to life-threatening. The most common is *viral gastroenteritis*. After many years of attributing this illness to viral infection, investigators have finally isolated and identified the responsible viruses. Explosive bouts of nausea and vomiting in conjunction with watery diarrhea, cramping abdominal pain, myalgias, headache, and fever are typical. Recovery is rapid in most instances, but symptoms may linger for 7 to 10 days. Similarly, anorexia, nausea, and vomiting often dominate the prodromal stage of *acute viral hepatitis* (see Chapter 70).

Acute gastroenteritis that results from *food poisoning* secondary to *Salmonella* or *Shigella* infection has a similar clinical presentation and course; onset is 24 to 48 hours after exposure to the contaminated food. Domestic fowl and their eggs represent the largest single reservoir of *Salmonella* infection. Inadequate cooking is often responsible for human infection. Intake of pastries and similar items containing *staphylococcal enterotoxin* causes symptoms indistinguishable from those of viral gastroenteritis, except that onset is within 1 to 6 hours after ingestion of the spoiled food, fever is rare, and complete clearing takes place by 24 to 48 hours. *Clostridial* food poisoning rarely produces prominent nausea and vomiting.

Cholera. Persons who travel to an epidemic area are at risk for contracting *cholera*, especially if they have eaten raw or undercooked seafood or have had drinks chilled with contaminated ice. South America is the latest area to experience an epidemic. High U.S. sanitary standards for the handling of sewage, water, and food have so far prevented outbreaks from spreading to this country. The causative organism is a toxigenic strain of *Vibrio cholerae*, which elaborates an enterotoxin that induces secretion of water and electrolytes from the intestinal mucosa. Mild infection is characterized by a nonspecific diarrheal illness. In 3% to 5% of cases, the disease is much more severe (*cholera gravis*) and presents as profuse watery diarrhea withflecks of whitish mucus ("rice water stools"), vomiting, and dehydration. Vomiting is exacerbated by the acidosis that results from bowel bicarbonate loss. Circulatory collapse, altered consciousness, renal failure, and death are possible outcomes.

Peritoneal Irritation and Acute Obstruction may precipitate acute emesis, usually in the context of severe abdominal pain (see Chapter 58). *Intestinal obstruction*, especially of the proximal small bowel, produces marked nausea and vomiting of bilious material. Distention may be lacking, but intermittent cramping abdominal pain is characteristic. Feculent emesis is found in distal small-bowel obstruction. In *acute pancreatitis*, emesis is seen in 85% of patients; however, upper abdominal pain radiating into the back is the cardinal symptom, occurring in 95% of patients (see Chapter 72). Anorexia, nausea, and vomiting are early symptoms in more than 90% of patients with *acute appendicitis*; usually emesis clears early. As with pancreatitis, pain typically precedes other symptoms. *Acute pyelonephritis* may mimic a gastrointestinal etiology by causing nausea, vomiting, and abdominal pain. *Acute cholecystitis* sometimes triggers acute emesis, but less regularly than does *acute*

cholangitis resulting from sudden obstruction of the common duct.

Myocardial Infarction may activate vagal afferents and produce nausea, vomiting, and epigastric discomfort, simulating intraabdominal disease. A prospective series of 62 patients with acute infarction revealed nausea and vomiting at the outset in 69% of those with inferior infarctions and 27% of those with anterior infarctions.

Neurologic Emergencies can provoke severe bouts of acute emesis. In *midline cerebellar hemorrhage*, nausea and vomiting are profuse, in association with severe gait ataxia; meningeal signs and headache are also seen. Within a few hours, the patient may become comatose and die unless the condition is promptly diagnosed and treated (see Chapter 165). One third of patients with *increased intracranial pressure* experience vomiting. When it is sudden, forceful, and not preceded by nausea, it is described as *projectile*, but this presentation is not specific. Concurrent bilateral frontal or occipital headache is the rule. *Migraine headaches* and *vestibular disease* are less worrisome neurologic causes of acute emesis (see Chapter 165 and Chapter 166). The former is suggested by photophobia and throbbing unilateral headache, the latter by vertigo.

Drugs. Of the many causes of *drug-induced* vomiting, *digitalis intoxication* is among the most serious. Anorexia is an early sign, followed by nausea and vomiting resulting from stimulation of the chemoreceptor trigger zone. Visual disturbances, such as seeing colored haloes, are suggestive of the diagnosis (see Chapter 32). Hypokalemia and dehydration induced by vomiting may precipitate or worsen digitalis toxicity.

Cancer Chemotherapies and Radiation Therapy produce substantial nausea and vomiting, with cisplatin being among the most problematic of chemotherapy agents. The mechanism of nausea and vomiting is believed to involve drug-induced release of serotonin from enterochromaffin cells, which leads to activation of serotonin receptors on visceral afferent fibers and stimulation of the vomiting center and chemoreceptor trigger zone. Drugs that block such serotonin receptors have proved uniquely effective (see below and Chapter 90).

Drug Withdrawal and Substance Abuse may trigger emesis. Nausea, dry heaves, and retching beginning at about 36 hours are characteristic features of opiate withdrawal syndrome. Sweats, chills, and restlessness precede other symptoms; the vomiting peaks by 72 hours and then subsides (see Chapter 235).

DIFFERENTIAL DIAGNOSIS

Table 59.1 lists some of the more common and important conditions associated with prominent nausea and vomiting. Causes of simple regurgitation are omitted from the list because they are usually manifestations of esophageal difficulties (see Chapter 61) and unaccompanied by emesis. For convenience, the etiologies are listed according to clinical presentation; however, it is important to keep in mind that overlap and variation in the clinical picture can be considerable. For example, some causes listed as being accompanied by abdominal pain may present with just isolated emesis.

Table 59.1. Some Important Causes of Nausea and Vomiting

WORKUP

The history and physical examination, supplemented by a few well-chosen laboratory studies, are sufficient for diagnosis in most cases.

History should focus on such details as timing of symptoms, their relation to meals, characteristics of the vomitus, and associated complaints.

Timing and Relation to Meals. An early morning onset points to metabolic disturbances, alcoholic binge, and early pregnancy. Emesis precipitated by meals suggests psychogenic vomiting, pyloric channel ulcer, and gastritis. Onset a few hours after eating raises the possibility of obstruction of the gastric outflow tract, gastric atony, or bowel obstruction. Emesis of food that was ingested more than 12 hours earlier strongly suggests gastric stasis and an organic etiology, as does vomiting of large volumes (>1,500 mL daily). However, absence of such features hardly rules out organic disease.

Nature of the Vomitus. Vomiting blood or coffee ground material is indicative of gastritis and ulcer disease. Bilious vomitus means that the pyloric channel is open. When the material vomited is pure gastric juice, peptic ulcer disease and Zollinger-Ellison syndrome are suggested. Lack of acid suggests gastric cancer. Feculent material is a sign of distal small-bowel obstruction and blind-loop syndrome.

Associated Symptoms, Past Medical History, Psychosocial History. The history needs to include inquiry into abdominal pain, fever, jaundice, weight loss, abdominal surgery, external hernias, family history of emesis, symptoms of diabetes, prior renal disease, ischemic heart disease, drug use (e.g., digitalis, narcotics), visual disturbances, headache, ataxia, vertigo, last menstrual period, and concurrent emotional stresses and conflicts. Gentle questioning about self-image, binge eating, and self-induced emesis is indicated when the patient is a young woman suspected of bulimia.

Epidemiologic Data need to be obtained, particularly any exposure to commonly contaminated foods (e.g., raw shellfish, pastries, poultry) or hepatitis and any travel to an area with poor sanitation and outbreaks of cholera. Vomiting in conjunction with diarrhea sufficient to cause severe dehydration in an adult suggests cholera, especially if there are supportive epidemiologic data.

Physical Examination requires a check for *postural hypotension* (indicative of marked volume depletion or circulatory collapse). Other findings to check for include blood pressure elevation, irregularities of rate and rhythm, Kussmaul's respiration, pallor, hyperpigmentation, jaundice, papilledema, retinopathy, nystagmus, stiff neck, abdominal distention, visible peristalsis, abnormal bowel sounds, succussion splash, peritoneal signs, focal tenderness, organomegaly, masses, flank tenderness, muscle weakness, ataxia of gait, and asterixis. If there is a history of vertigo in conjunction with nausea, then Báranáy's maneuver (see Chapter 166) might reproduce symptoms and confirm the diagnosis of a vestibular etiology.

Patients suspected of having a "functional" disorder should be checked carefully for signs of autonomic insufficiency. A finding of postural hypotension, lack of sweat, or blunted pulse and blood pressure responses to Valsalva's maneuver suggests autonomic dysfunction and a bowel motility problem as the underlying etiology of the nausea and vomiting.

Laboratory Studies. Ordering tests is a function of the clinical presentation and is best conducted as a means of testing clinically generated hypotheses, rather than as a routine request for "nausea and vomiting studies."

Acute Emesis with Concurrent Abdominal Pain. In patients with emesis accompanied by acute abdominal pain, the first priority is to rule out an acute surgical cause such as bowel obstruction, peritonitis, or blockage of a hollow viscus. *Plain and upright films of the abdomen* are indicated when such causes are suspected (see Chapter 58). The onset of pancreatitis may be dominated by emesis in addition to abdominal pain, and if pancreatitis is suspected, a serum *amylase* determination is indicated. For suspected acute cholecystitis and choledocholithiasis, liver function studies (e.g., *alkaline phosphatase, aspartate aminotransferase*)

and prompt consideration of *abdominal ultrasonography* are required.

Acute Nausea and Vomiting without Associated Abdominal Pain may also be a clue to serious illness. The acute onset of nausea and vomiting in conjunction with ataxia of gait and a stiff neck is very suggestive of a midline cerebellar hemorrhage; emergency *computed tomography* of the posterior fossa is needed (see Chapter 165). If the patient is a known diabetic, ketoacidosis should be suspected and *urine* and *serum ketones* and blood *glucose* should be checked (see Chapter 102). In a patient with risk factors for coronary artery disease, an *electrocardiogram* should be obtained; inferior ischemia may present as gastrointestinal upset (see Chapter 20). Hepatitis may present like acute gastroenteritis, with anorexia, nausea, and vomiting; a *transaminase* determination can be diagnostic. If the patient is taking a medication that potentially causes nausea and vomiting, a *serum drug level* might be informative. If a *digitalis* preparation is being taken, the drug should be withheld, an electrocardiogram obtained, a serum level ordered, and a potassium supplement prescribed if the potassium level is below 4.0 mg/100 mL (see Chapter 32).

Recurrent Vomiting raises the question of a psychogenic cause, but before leaping to such a conclusion, the physician should consider pregnancy, metabolic derangements, and chronic gastroesophageal disease. Metabolic disease and pregnancy are suggested by vomiting that occurs in the early morning. A *urinalysis* and determinations of the serum *blood urea nitrogen, creatinine, electrolytes, glucose,* and, in a woman of childbearing age, *human chorionic gonadotropin* b-*subunit* ought to be obtained (see Chapter 112).

Gastroesophageal causes are suggested by postprandial symptoms and best investigated by *upper gastrointestinal series* if there is concern about gastric outlet obstruction or retention, and by *endoscopy* if mucosal injury is a possibility (see Chapter 62 and Chapter 68).

Psychogenic vomiting is suggested by the characteristic history of chronic emesis, with vomiting around mealtime, partial suppressibility, and a conflict-ridden social situation. The need for additional studies in such cases is best individualized; some patients may insist on further testing, whereas others will be comforted by knowing that extensive studies are not necessary.

Therapeutic Trials. A therapeutic trial may have diagnostic utility and provide symptomatic relief. When a gastroesophageal motility disorder is suspected, a short course of a prokinetic agent such as *metoclopramide* or *cisapride* (e.g., 10 mg half an hour before meals) supplemented by a *proton pump inhibitor* (e.g., 20 mg of omeprazole daily) can be useful. Patients suspected of having an underlying affective disorder sometimes respond to a 4- to 8-week trial of *antidepressant medication*; an agent with minimal anticholinergic activity (e.g., trazodone, desipramine, or fluoxetine) is preferred to minimize the chances of gastrointestinal side effects.

INDICATIONS FOR REFERRAL AND ADMISSION

Hospital admission for parenteral fluid and electrolyte replacement and additional workup is indicated if postural hypotension is present, especially if the patient is elderly. Prompt hospitalization also is needed for a patient with evidence of bowel obstruction, increased intracranial pressure, or any other gastrointestinal, neurologic, or metabolic emergency.

In the case of a patient whose condition remains undiagnosed after extensive evaluation and is unresponsive to therapeutic trials, and for whom evidence of an underlying psychiatric disturbance is lacking, gastric emptying and motility studies should be considered. These studies are performed at only a few specialty centers; referral should be made in consultation with a gastroenterologist. Patients suspected of psychogenic vomiting require psychiatric consultation because they may be seriously disturbed. Suicidal attempts are not uncommon among bulimic patients and others with psychogenic emesis. Referral to a mental health professional skilled and experienced in the treatment of patients with eating disorders is optimal for those suffering from bulimia (see Chapter 234).

SYMPTOMATIC RELIEF

When a cause has been identified but treatment of the underlying condition does not adequately control the symptoms, antiemetic drug therapy may help provide symptomatic relief. The available agents work by suppressing the vomiting center, the chemoreceptor trigger zone, or peripheral receptors. Symptomatic therapy must not be used in lieu of making a diagnosis.

Phenothiazines and other centrally acting agents are indicated for initial symptomatic treatment of vomiting caused by drugs, metabolic disorders, and gastroenteritis. They suppress the chemoreceptor trigger zone and probably the vomiting center and peripheral receptors also. *Prochlorperazine* (*Compazine*) and *promethazine* (*Phenergan*) are the phenothiazines used most often for vomiting. Prochlorperazine can be given orally in doses of 5 to 10 mg every 6 hours, or rectally in a dose of 25 mg three times daily. The oral dose of promethazine is 12.5 to 25.0 mg every 6-8 hours; the rectal dose is 25 mg three times daily. This class of drugs is not effective for motion sickness or vestibular disease. *Trimethobenzamide* (*Tigan*) is a centrally acting non-phenothiazine antiemetic useful for emesis of central causes. The oral dose is 250 mg three times daily. Rectal suppositories are given three times daily. Like all centrally acting agents, it can cause drowsiness, especially in the elderly. In *hepatitis*, nausea and vomiting may respond to very cautious use of phenothiazines. However, because they are metabolized by the liver and in rare instances can cause cholestasis, they should be used only in limited doses for short periods of time (see Chapter 70).

Antihistamines. For symptomatic relief from the nausea and vomiting of *vestibular disturbances*, the antihistamine *meclizine* (*Antivert*) has proved useful; it acts on the vestibular system and the chemoreceptor trigger zone and helps to control the nausea and vomiting associated with vestibular dysfunction. Because meclizine can suppress or blunt important clues of vestibular disease, it should not be used unless a diagnosis has been established. Other antihistamines are quite popular for the treatment or prevention of motion sickness because, in comparison with meclizine, they provide either a more rapid onset of action [e.g., *dimenhydrinate* (Dramamine)] or a more prolonged effect (e.g., *transdermal scopolamine*). The average dose of meclizine is 25 mg four times daily for vestibular disease. A single transdermal scopolamine patch applied behind the ear several hours before a trip will provide prophylaxis for up to 3 days. Anticholinergic side effects (constipation, dry mouth, giddiness) are common. Meclizine is teratogenic in animals and is not indicated for vomiting resulting from pregnancy. All antihistamines can cause drowsiness and should not be used before driving or use of machinery.

Prokinetic Agents. For patients with emesis resulting from gastroparesis, the prokinetic agents *metoclopramide* (10 mg after meals and at bedtime) and *cisapride* (10 mg after meals and at bedtime) can help. The latter does not act centrally and thus causes few central nervous system side effects, which makes it more tolerable for long-term use, particularly in the elderly; however, its association with ventricular irritability needs to be taken into account (see Chapter 61).

Antiemetics for Cancer Chemotherapy. The nausea and vomiting associated with *cancer chemotherapy* can be especially uncomfortable and demoralizing. A wide variety of agents have been tried empirically, ranging from phenothiazines to tetrahydrocannabinol (as found in marijuana). Few provide truly satisfactory control, particularly when cisplatin is required. The selective serotonin S $_3$ receptor antagonist *ondansetron* has proved remarkably effective and safe, probably by virtue of its ability to block the effects of cisplatin-induced serotonin release from enterochromaffin cells. Anticholinergic therapy with high-dose *metoclopramide* has also been used, but cisplatin was superior and better tolerated in double-blinded crossover study (see Chapter 91).

Drugs for Morning Sickness. Morning sickness is best treated with small morning feedings and support; the goal is to try to avoid the use of antiemetics. No antiemetic is approved for use in pregnancy. The more prolonged, severe form of nausea and vomiting in pregnancy (hyperemesis gravidarum) may remit with hypnosis or supportive psychotherapy, but drug therapy is sometimes necessary. *Vitamin B$_6$* (25 mg/d) has proved useful in controlled trials and appears safe. *Metoclopramide* has also been used for years in severe cases without reports of fetal injury. Approval for *Bendectin* has been withdrawn because of concern for teratogenic effects.

Treatment of Psychogenic Vomiting. The best approach involves attention to the conflicts troubling the patient. No controlled studies have been performed of the effectiveness of antiemetics; fortunately, patients often do not request medication for symptomatic relief.

CHAPTER 60 EVALUATION OF DYSPHAGIA AND SUSPECTED ESOPHAGEAL CHEST PAIN

Dysphagia is the unpleasant sensation of difficulty in swallowing as a consequence of neuromuscular or anatomic pathology involving the esophagus (and sometimes the oropharynx). Such pathology may also trigger substernal chest pain and simulate angina (see Chapter 20). *Odynophagia* refers to painful swallowing, which usually results from serious mucosal inflammation. Because esophageal dysfunction and pain may be a manifestation of or mimic important pathology, it deserves to be assessed fully and not dismissed as a trivial problem or glibly invoked to account for symptoms.

PATHOPHYSIOLOGY AND CLINICAL PRESENTATION

Dysphagia implies an abnormality in swallowing and arises from either a loss of coordinated motor activity or mechanical obstruction, be it intrinsic narrowing or extrinsic compression of the esophagus.

Transfer Dysphagia (also referred to as *oropharyngeal dysphagia*) usually occurs as a consequence of neurologic or neuromuscular disease and presents as choking or difficulty in initiating swallowing. In many instances, other neurologic symptoms dominate the clinical picture, but at times, difficulty in swallowing is the major complaint, with aspiration and regurgitation of fluid into the nose. The problem is particularly common among the very old. Cortical and brainstem lesions resulting from stroke, tumor, and degenerative disease are important causes. In addition, medications with central effects (e.g., benzodiazepines, L-dopa, phenothiazines) may blunt the swallowing mechanism. Unlike esophageal disease, oropharyngeal dysphagia is accurately localized to the suprasternal area. Those with neuromuscular etiologies report more difficulty in swallowing liquids than solids, nasal regurgitation, coughing, and aspiration. Patients with anatomic narrowing and mechanical obstruction of the pharynx or upper esophagus have more difficulty with solids than liquids.

Achalasia, the most common cause of motor dysphagia, is a slowly progressive motility disorder with a chronic course. The pathologic hallmark is a loss of cells in the myenteric ganglia. Lesions in the dorsal vagal nucleus and vagal trunks have also been described. It has been speculated that these changes represent damage caused by a neurotropic virus. As a consequence of a loss of smooth-muscle ganglion cells, the esophagus functions poorly, exhibits episodes of aperistalsis, and demonstrates exquisite sensitivity to gastrin and cholinergic agents. The gastroesophageal sphincter fails to relax properly, leading to functional obstruction at the gastroesophageal junction. In addition, a *loss of peristaltic activity* occurs in the distal esophagus. Dysphagia and substernal chest pain ensue. The resting pressure at the lower esophageal sphincter (LES) rises, and barium study shows an absence of peristalsis and delay in esophageal emptying. Paradoxically, vigorous nonpropulsive (tertiary) esophageal contractions resulting in chest pain may be observed early in the disease in young patients. Swallowing liquids and solids is equally difficult, yet by eating slowly and drinking small amounts, the patient may be able to consume a full meal. Pain is reported by 70% to 80% of patients, especially if they eat or drink rapidly, but pain is not an invariable accompaniment, and only 2% of patients with chest pain caused by esophageal disease have achalasia. Very cold liquids or emotion may provoke symptoms. Patients find that repeated swallowing or performing a rapid Valsalva's maneuver can help pass material into the stomach. Regurgitation is common and can be provoked by changes in position or physical exercise; pulmonary aspiration sometimes results. Patients may have foul breath because of retained esophageal material. Squamous cell carcinoma of the esophagus is sometimes a complication of achalasia; it occurs in 5% to 10% of patients.

Carcinoma-induced achalasia is seen with tumors at the gastroesophageal junction. Adenocarcinoma of the stomach is the most common of these neoplasms. The mechanism by which tumor induces achalasia is unclear, but manometric findings are identical to those of primary achalasia. Patients are typically over the age of 50 and complain of marked weight loss and symptoms of dysphagia of less than a year's duration.

Scleroderma can impair neuromuscular function and result in a decrease in LES tone in addition to a lack of propulsive motor activity. *Reflux* is more of a problem than is dysphagia (helping to distinguish scleroderma from other motility disorders), but as many as 20% of patients may have some difficulty in swallowing. About 75% of patients with scleroderma have esophageal involvement as part of the CREST syndrome (calcinosis, Raynaud's phenomenon, esophageal dysmotility, sclerodactyly, and telangiectasia).

Diffuse Esophageal Spasm is characterized clinically by nonprogressive dysphagia and substernal chest pain that may mimic angina (see below and Chapter 20). Radiologically and manometrically, patients manifest nonpropulsive *simultaneous contractions* (tertiary contractions) throughout the entire esophagus (especially the distal portion) in more than 10% of wet swallows. Such contractions are also observed in normal persons under conditions of emotional stress and dry swallows, which leads some to view this condition as little more than a transient abnormality in motor function induced by stress. However, as noted above, the condition may also be an early manifestation of neuromuscular disease that progresses to achalasia. Unlike achalasia, diffuse esophageal spasm is intermixed with periods of normal peristaltic activity. Dysphagia is noted with both liquids and solids. Diffuse esophageal spasm accounts for about 10% of cases of noncardiac chest pain caused by abnormal esophageal motility. Some asymptomatic patients manifest the radiologic and manometric criteria for esophageal spasm but rarely experience discomfort.

"Nutcracker" Esophagus is a picturesque radiologic description applied to the condition of patients experiencing *very high-amplitude contractions* in the distal esophagus. The resultant pressures exceed the mean by more than two standard deviations. These peristaltic contractions are not only of exceptionally high amplitude but also of long duration. There are no simultaneous contractions, as there are in diffuse esophageal spasm, and only occasionally does impairment of esophageal function lead to dysphagia. The principal symptom is *chest pain* (see below), with nutcracker esophagus accounting for about half of all cases of noncardiac chest pain associated with an esophageal motility disturbance. Occasionally, reflux precipitates the contractile abnormalities. Achalasia develops in about 3% to 5% of patients, and degenerative changes are noted in ganglia and nerves, suggesting to some a possible link to achalasia. Supersensitivity to gastrin and cholinergic agents can be demonstrated.

Hypertensive Lower Esophageal Sphincter is characterized by increased resting LES pressure but normal relaxation and peristalsis, with no impediment to bolus passage. About half of the patients have high-amplitude contractions, consistent with nutcracker esophagus.

Mechanical Obstruction differs clinically from motor dysfunction in that the patient has more difficulty with solids than with liquids. The duration of symptoms is shorter (<1 year) for patients with malignancy than it is for those with benign causes of obstruction; progression is often rapid. Most patients with tumor are over the age of 50 and report marked weight loss. The location of discomfort does not necessarily correlate with the site of obstruction because the pain may be referred. Spontaneous pain is not a common feature of neoplasm involving the esophagus. Patients with stricture caused by severe esophagitis usually have a long history of reflux.

Inflammatory Lesions of the pharynx or esophagus may cause *odynophagia* (pain on swallowing). Esophageal motility is not disturbed, but swallowing is made difficult by the pain. Even saliva may be irritating. *Radiation therapy*, *tablet ingestion*, and *infection* are important causes of this severe esophageal irritation. Tetracycline, quinidine, potassium tablets, NSAIDs, and iron preparations have been implicated. The elderly are at greatest risk because they are likely to consume more tablets with less water, and saliva production decreases with age. The discomfort is often associated with ingestion of the tablets and generally decreases during a period of a few days.

Infectious esophagitis caused by *Candida, herpes simplex virus*, or *cytomegalovirus* is being increasingly recognized in immunocompromised patients, including the growing number with AIDS, and in patients taking broad-spectrum antibiotics on a long-term basis. Onset may be rapid and accompanied by fever, chills, nausea, vomiting, and epigastric pain. Viral or fungal esophagitis rarely occurs in immunologically intact persons; when it does, it is usually short-lived and self-limited.

Esophageal Chest Pain is most often associated with prolonged or severe contractile waves, although distention of stretch receptors and stimulation of chemoreceptors may also contribute. Certain investigators have suggested that some patients subject to attacks of esophageal chest pain may have an esophageal version of irritable bowel syndrome, with motor dysfunction and increased sensitivity to distention and chemical stimuli. They wonder whether there might be an "irritable gut syndrome," with a common pathophysiology extending from the esophagus to the rectosigmoid. They note that many patients with esophageal chest pain

also report symptoms of irritable bowel syndrome.

Chest pain is particularly prevalent in patients with nutcracker esophagus. The chest pain associated with esophageal motor disorders can mimic that of angina in terms of location (substernal), quality (tightness), radiation (into the arm or back), and response to nitroglycerine (prompt relief). Adding to the confusion with coronary pain is the fact that esophageal chestpain need not be accompanied by dysphagia, although sometimes heartburn is reported as a preceding symptom. The pain is frequently nocturnal, awakening the patient from sleep. Chest discomfort need not occur in relation to swallowing, but sometimes it is triggered by drinking very hot or very cold liquids.

Conditions Confused with Dysphagia. Sometimes, *globus hystericus*, a condition seen in anxiety disorders, is confused with dysphagia. The patient complains of a constant "lump in the throat" and has a perception of obstruction, although no actual difficulty in swallowing food. An involuntary tightening of the cricopharyngeal muscle has been observed in some patients with this condition and may account for the symptoms. Symptoms are unrelated to swallowing, and esophageal function is normal.

DIFFERENTIAL DIAGNOSIS

The causes of dysphagia can be divided into motor and obstructive categories, and these are often subdivided according to whether they affect the upper or lower esophagus (Table 60.1). Most esophageal cancers are of the squamous cell variety, although half of those in the distal half of the esophagus are adenocarcinomas, which suggests that they arise in the cardia of the stomach. True dysphagia must be distinguished from conditions that may produce esophageal pain without interfering with the mechanics of swallowing, such as most forms of esophagitis and motor disorders with propulsive but high-amplitude contractions (e.g., nutcracker esophagus). The patient with globus hystericus reports a constant sensation of having something in the throat but swallows normally.

Motor Disease
Pharyngeal (transfer dysphagia)
  Pseudobulbar palsy
  Myasthenia gravis
  Multiple sclerosis
  Amyotrophic lateral sclerosis
  Parkinson's disease
Transesophageal
  Achalasia
  Scleroderma
  Diffuse esophageal spasm
Distal
  "Nutcracker" esophagus
  Hypertensive lower esophageal sphincter
Obstructing Lesions
Upper esophageal
  Tumor
  Zenker's webs (Plummer-Vinson syndrome)
  Goiter
  Enlarged lymph nodes
  Cervical spine osteophytes
Lower esophageal
  Carcinoma
  Stricture (chronic reflux, corrosive agents, intubation)
  Webs and rings
  Foreign bodies
  Food impaction
  Mediastinal tumors
  Aortic aneurysm
Odynophagia
  Opportunistic esophageal infection (cytomegalovirus, herpesvirus,
  Candida)
  Tablet-induced irritation
  Severe reflux esophagitis

Table 60.1. Differential Diagnosis of Dysphagia

No detailed population studies have been performed on the prevalence of dysphagia and the relative frequencies of its causes. However, in a study of 910 patients with noncardiac chest pain, 28% were found to have abnormal esophageal motility. Of these 28%, 48% had nutcracker disease, 36% had nonspecific esophageal motility dysfunction, 10% had diffuse esophageal spasm, and 2% had achalasia.

WORKUP

History

A tentative diagnosis can often be made by history. A British study found that history alone could provide an accurate diagnosis in about 80% of cases. The most important features of the history include the duration and progression of symptoms, relation of symptoms to ingestion of solids and liquids, effect of cold on swallowing, and response to swallowing a bolus. Inquiry into these aspects of the problem help in the important task of differentiating a motor disorder from mechanical obstruction. Motor disease is suggested by gradual onset, slow progression, chronic course, equal difficulty with liquids and solids, aggravation of symptoms on swallowing cold substances, and passage of a bolus by repeated swallowing, forceful drinking, Valsalva's maneuver, or throwing back the head and shoulders. Mechanical obstruction is characterized by more rapid onset and progressive course, more difficulty with solids than with liquids, no aggravation with cold foods, and regurgitation on trying to swallow a bolus. As noted above, the location of discomfort helps to locate the lesion only if it is very high or very low in the esophagus; with a distal lesion, pain may be referred to the neck. Hiccups point to difficulty in the terminal portion of the esophagus. Intermittent dysphagia that occurs only with solid food is indicative of a lower esophageal (Schatzki's) ring.

Other features of the history also have some discriminative value, including the presence of pain, reflux, and neurologic defects. Pain in conjunction with dysphagia suggests spasm or achalasia, although pain may occur in these conditions without concurrent difficulty in swallowing. Pain on swallowing saliva alone is characteristic of mucosal inflammation. A history of heartburn in conjunction with difficulty in swallowing solids argues strongly for a stricture secondary to chronic reflux esophagitis, especially if the problem is chronic. Scleroderma also is suggested when symptoms of reflux occur with dysphagia (together with skin changes and cold extremities). Dysphagia that comes on only after activity and is associated with motor aphasia, diplopia, or dysphonia is indicative of myasthenia. Tremor or difficulty in initiating movement suggests Parkinson's disease (see Chapter 174). Other historical facts to note are recent use of topical upper respiratory or inhaled steroid aerosols or broad-spectrum antibiotics, and concurrent immunodeficiency (e.g., AIDS).

The pace of illness is important to note. Very acute dysphagia suggests infection, irritation, or food impaction. Rapid progression is caused by tumor until proved otherwise, whereas slow progression is most consistent with a motor disorder. Weight loss may occur with any etiology, but in a Mayo Clinic study, it was more predictive of obstruction.

Physical Examination

The skin is noted for pallor, signs of scleroderma (sclerodactyly, telangiectasia, calcinosis), and hyperkeratotic palms and soles (a rare finding suggestive of esophageal carcinoma). The mouth should be examined carefully for inflammatory lesions, ill-fitting dentures, and pharyngeal masses. The HIV-positive patient with oral candidiasis is at increased risk for esophageal involvement. Lymph nodes are palpated in the neck and elsewhere to detect enlargement suggestive of neoplasm or infection (see Chapter 12), and the thyroid is palpated for a goiter that might extrinsically compress the esophagus. The abdomen is checked for masses, tenderness, and organomegaly, and the stool for occult blood (suggestive of neoplasm and esophagitis). The neurologic examination should be thorough and include testing for motor dysfunction, with a search for tremor, rigidity, and fatigability in addition to cranial nerve deficits, abnormal Babinski's response, and abnormal gag reflex.

Laboratory Studies

The history and physical examination usually provide sufficient evidence to distinguish oropharyngeal from esophageal dysphagia, and a mechanical form of esophageal dysphagia from a neuromuscular one. Making such a determination before laboratory testing helps focus the laboratory workup, interpret the results, and avoid unnecessary studies.

Barium Swallow is usually the first step in the diagnostic evaluation of the dysphagic patient and is especially important if a structural impediment to swallowing is suspected. Its sensitivity is excellent for determining the location and severity of an obstructing mass lesion or stenosis, but it often lacks precision in identifying the nature of the lesion, particularly in distinguishing cancer from postinflammatory scarring and stenosis. For example, some gastric carcinomas may show little more than intrinsic narrowing. Endoscopic biopsy (see below) may be necessary, especially when the history suggests malignancy (e.g., rapid progression, marked weight loss).

By providing fluoroscopic evidence of esophageal function, the barium swallow can sometimes help in documenting motor disorders, although test sensitivity is not high. Early achalasia and esophageal spasm may produce few findings on a routine barium swallow, especially when symptoms are infrequent. The characteristic radiologic features of achalasia include dilation of the distal two thirds of the esophagus, segmental contractions, and termination of the distal esophagus into a narrowed segment (often referred to as a "break"), caused by the tonically contracted LES. When the patient is upright, an air–fluid level may be present on the barium esophagram. If diffuse esophageal spasm occurs during barium examination, it produces multiple tertiary contractions and differs from achalasia in that no break is observed. The functional assessment of dysphagia is facilitated by performing all barium studies with the patient in the supine position to cancel the effect of gravity, and by dipping a piece of bread into barium to trace better the movement of solid food. *Video studies of the oropharyngeal phase* of swallowing are essential in the evaluation of suspected oropharyngeal dysphagia, not only for diagnosis but also to determine the risk for aspiration. Radiologic expertise is required for the interpretation of such films.

Upper Gastrointestinal Endoscopy and Biopsy are needed when an intrinsically obstructing lesion is discovered that may be malignant. As noted above, even stenoses can represent early cancer and should be considered for endoscopy and biopsy if the clinical context is suggestive (e.g., age over 50 years, progressive clinical course). On occasion, even the patient with achalasia may require endoscopy, particularly when contraction of the LES is so persistent that stenosis cannot be ruled out by barium study alone. Stretching of the sphincter can be accomplished at the same time. However, endoscopy for truly radiographically negative dysphagia is generally of low yield.

Acute onset of odynophagia suggests severe esophageal inflammation and, in an immunocompromised host, raises the possibility of an infectious etiology. Endoscopic examination is needed to examine for plaques, vesicles, and pseudomembranes. Brushings and biopsy specimens are obtained as needed and prepared appropriately to detect fungi, giant cells, and intranuclear inclusion bodies. All patients with new-onset odynophagia require endoscopic evaluation.

Manometry. Strong clinical suspicion of motor dysfunction or failure of the barium swallow to reveal a probable etiology raises the question of proceeding to manometry. Although potentially diagnostic, manometry often gives indeterminate data. Many patients suspected of achalasia or esophageal spasm fail to show typical manometric findings at the time of testing. Furthermore, others who are symptom-free may demonstrate abnormalities when tested. Still others end up being placed in a category of nonspecific motility disease. Nevertheless, many authorities insist on manometric data before concluding that a patient has esophageal spasm or a related motor disorder. The diagnosis of nutcracker esophagus is especially dependent on manometric data.

Provocative Testing is most useful and worth serious consideration when the physician is confronted with a patient who complains of *atypical chest pain*. Once cardiac disease is ruled out (see Chapter 20), an esophageal problem is high on the list of possible explanations. Provocative testing provides a ready means in the office of identifying an esophageal origin for an atypical pain, although it does not specify a mechanism and it is of less use in the evaluation of dysphagia. The objective of provocative testing is to reproduce the patient's exact symptoms. Two tests have proved most useful: the Bernstein or acid perfusion test and edrophonium (Tensilon) infusion.

The Bernstein test was initially used to confirm symptoms caused by reflux, but a positive test result has also proved specific for esophageal chest pain, even in the absence of documented reflux. In 7% to 27% of cases, noncardiac chest pain has been associated with a positive Bernstein test result and deemed to be of definite esophageal origin, although evidence of acid reflux may not be found on 24-hour pH monitoring. The test consists of instilling a small amount of acid through a nasogastric tube placed in the esophagus.

Edrophonium testing grew out of a desire to find a safe and well-tolerated means of stimulating esophageal contractions. Ergonovine was originally tried, and although it was successful in reproducing symptoms, its risks of serious cardiac side effects negated its usefulness. Edrophonium (a relatively gentle muscarinic agonist) has proved superior to acid perfusion, bethanechol, and pentagastrin in reproducing atypical chest pain, with 24% to 34% of patients having a positive test result (reproduction of pain during wet swallows). Like the Bernstein test, edrophonium identifies an esophageal origin for the pain but does not specify the mechanism (correlation between response to edrophonium and manometric findings is poor). Side effects of a rapid bolus of IV edrophonium (80 μg/kg of body weight) include mild degrees of light-headedness, nausea, and abdominal cramps, but not the tachycardia, hypertension, or coronary vasoconstriction seen with ergonovine.

Ambulatory Monitoring of both *intraesophageal pH* and *pressures* for 24 hours is becoming increasingly available and may prove useful, especially in cases that defy explanation despite comprehensive testing. Monitoring of esophageal pH during 24 hours has emerged as a useful tool in the evaluation of noncardiac chest pain, as it provides an opportunity to correlate acid reflux with occurrence of symptoms. In a study comparing traditional esophageal tests (manometry, Bernstein test, and edrophonium) with 24-hour pH monitoring, the latter led the field in providing an explanatory correlation in 46% of instances of chest pain, versus 19% for both edrophonium and the Bernstein test, the next-best studies. A single manometric study was of little use. Because no gold standard is available, determinations of sensitivity and specificity are not possible.

As just noted, abnormal motor activity may be difficult to detect at the time of a particular study or may be induced by the study and have little to do with the patient's problem. Round-the-clock pressure monitoring opens up new avenues of evaluation. The precise indications for such testing remain to be defined; studies are ongoing.

SYMPTOMATIC RELIEF AND PATIENT EDUCATION

Motility Disorders. A conservative approach sometimes suffices for patients with mild motor disease. The dysphagic person with achalasia is often able to manage reasonably well by *eating slowly, drinking small quantities* at a time, and *avoiding cold foods*. A trial of *sublingual nitrates* or *calcium channel blockers* before eating may sufficiently relax spastic smooth muscle in patients with mild to moderate dysfunction to provide relief.

Patients with *atypical chest pain* caused by esophageal disease benefit greatly from knowing definitively that their pain is not indicative of heart disease. A thorough explanation after a careful evaluation can greatly reduce morbidity and even the frequency of symptoms. Given the presumed relation of atypical chest pain to esophageal spasm, nitrates and calcium channel blockers have been used. The results have been variable, which is not surprising, as the relation of spasm to pain is variable; however, benefit does accrue for some patients, which makes a trial of these agents worthwhile. *Antireflux therapy* (see Chapter 61) can be an important component of the treatment program when the workup suggests acid reflux as a trigger of symptoms. *Antidepressants* with little anticholinergic activity, such as trazodone, have proved effective in patients suspected of having a psychiatric precipitant of esophageal motor dysfunction. *Relaxation techniques* and other *behavioral methods* are worth a try in those with stress-induced esophageal motor dysfunction (see Chapter 226). *Anticholinergic therapy* has been disappointing. When *odynophagia* is present and an inflammatory lesion is suspected as the precipitant, especially when opportunistic infection might be the cause (e.g., patients with HIV disease), then antifungal or antiviral therapy may be needed (see Chapter 13).

Patients with severe achalasia get little relief from dietary or drug manipulations; *esophageal dilation* or *myotomy* is needed. Myotomy is more effective but requires major surgery and often produces severe reflux that does not respond to antireflux surgery. Consequently, pneumatic esophageal dilation is usually the most effective invasive procedure for treatment of severe motor disease. Dysphagia is relieved immediately, and sufficient LES pressure remains to prevent bothersome reflux.

Obstructing Lesions. Regardless of etiology and pending definitive diagnosis, all patients suspected of having obstruction should be advised to take predominantly liquids or soft solids. The goal is to provide an adequate caloric intake that can be swallowed with a minimum of discomfort. Patients with mechanical obstruction often require dilation or surgery, but there are many exceptions. The best management for a person with a lower esophageal ring is to advise slow intake of small amounts; dilation does not work very well. Restoration of adequate iron intake will reverse the pathologic changes of sideropenic dysphagia unless a carcinoma has developed in the pharynx. Carcinoma of the upper or middle third of the esophagus is often unresectable and best treated by radiation therapy; considerable palliation is sometimes achieved. Oropharyngeal dysphagia caused by obstruction is treated surgically (e.g., removal of a Zenker's diverticulum or large goiter), whereas attention to the underlying neurologic deficit is necessary in cases caused by motor dysfunction, although myotomy may help as well. The patient with globus hystericus can be given thorough reassurance, although symptoms are not likely to resolve easily.

INDICATIONS FOR REFERRAL

Patients with oropharyngeal dysphagia who aspirate more than 10% of a barium test bolus and show barium residue in the oropharynx with subsequent swallows are at great risk for aspiration and should be referred for consideration of a non-oral means of nutrition. In addition, those with evidence of neuromuscular disease severe enough to cause oropharyngeal dysphagia might benefit from a neurologic consultation. The patient with an obstructing lesion requires endoscopic evaluation and referral to a gastroenterologist or surgeon for consideration of endoscopic biopsy. The patient who is referred for further evaluation and therapy should still be

followed closely by the primary care physician, especially to monitor nutritional status.

CHAPTER 61 APPROACH TO THE PATIENT WITH HEARTBURN AND REFLUX (GASTROESOPHAGEAL REFLUX DISEASE)

JAMES M. RICHTER

INTRODUCTION

Heartburn is a nearly universal experience. In one survey of presumably normal hospital staff, 7% reported current daily heartburn and 36% experienced heartburn at least once a month. The term *heartburn* typically refers to retrosternal burning that radiates upward, as a consequence of reflux of gastric acid up into the esophagus. It is characteristically exacerbated by large meals, supine posture, or bending over, and it is alleviated, at least temporarily, by antacids. Heartburn ranges in severity from an occasional episode of postprandial discomfort without sequel to a syndrome of severe esophageal inflammation that can lead to bleeding, stricture, and malignant transformation. Symptoms may be transient or a manifestation of chronic gastroesophageal reflux disease (GERD). Key tasks include deciding who requires endoscopic assessment and selecting the most cost-effective approach to controlling symptoms and preventing serious sequelae.

PATHOPHYSIOLOGY AND CLINICAL PRESENTATION

Normal Esophageal Physiology. The physiologic action of the *lower esophageal sphincter* (LES) is critical to maintaining a pressure barrier between the stomach and the esophagus. The LES is a complicated region of smooth muscle modulated by the interaction of hormonal, neural, and dietary factors. The hormone gastrin increases its resting tone, whereas estrogens, progesterone, glucagon, secretin, and cholecystokinin all decrease sphincter pressure. Vagus nerve input helps maintain resting tone, as does a-adrenergic stimulation. Pharmacologic agents that increase sphincter tone include bethanechol, metoclopramide, pentobarbital, histamine, edrophonium, and antacids. Anticholinergics, theophylline, meperidine, and the calcium channel blockers all decrease the resting tone. Saliva may be an important protective mechanism, inducing peristalsis in addition to aiding in washout, dilution, and neutralization of acid refluxed into the esophagus.

Mechanisms of Reflux. GERD is a multifactorial problem, involving reduction in resting LES tone, transient episodes of inappropriate relaxation of the LES, irritant action of gastric acid and digestive enzymes, decreased secondary peristalsis, and defective mucosal resistance to caustic liquids. Also implicated are impaired esophageal clearance of acid from the esophagus and delayed gastric emptying.

LES pressures vary and overlap enormously between those with and without symptomatic reflux. Normal pressure ranges from 12 to 30 mm Hg. LES pressures below 6 mm Hg are apt to allow reflux, and those above 20 mm Hg usually prevent it. Pressures between 6 and 20 mm Hg are found in both patients and controls. In many patients, reflux occurs as a result of transient episodes of inappropriate sphincter relaxation rather than low basal tone.

Anatomic factors, such as the presence of a *hiatus hernia*, are not as important as they once were believed to be, but patients with hiatus hernia may be modestly predisposed to reflux disease. A certain portion of the esophagus must be situated intraabdominally for optimal esophageal function and sphincter competence; moreover, peristaltic clearing of acid is impaired in patients with a hiatus hernia.

Contributing factors include *tobacco*, *ethanol*, *chocolate*, and foods with high concentrations of *fat* or *carbohydrate*, all of which decrease LES pressure and increase heartburn. *Citrus fruits* and fruit juices often exacerbate symptoms; the mechanism by which they cause heartburn is not clear. Although *pregnancy* may cause reflux because of increased intraabdominal pressure, the primary reason for heartburn in pregnancy is reduced sphincter pressure as a consequence of increased circulating levels of progesterone and estrogen. Reflux can be precipitated in normal persons by *exercise*, with jogging after meals the most common cause.

Clinical Features. *Heartburn* predictably accompanies gastroesophageal reflux. The patient characteristically complains of retrosternal ache or burning within 30 to 60 minutes of eating, especially after large meals. Symptoms are made worse by lying down or bending over; many patients learn to avoid lying down after meals. Reflux may trigger *chest pain* than can mimic cardiac angina, with some patients describing chest heaviness or pressure that, like angina, may radiate to the neck, jaw, or shoulders (see Chapter 20 and Chapter 60).

Regurgitation of fluid or food particles may occur, particularly at night. The patient may describe soiling of the pillow with gastric contents or may awake because of coughing or a strangling sensation. *Nocturnal aspiration* is occasionally associated with gastroesophageal reflux and can cause recurrent pneumonias, bronchospasm, and chronic cough. A *reflex salivary hypersecretion* or *"water brash"* is sometimes described by patients with reflux. Water brash is especially common in children, but direct questioning is often required to determine its occurrence. Hoarseness, sore throat, and the feeling of a lump in the throat are other common otolaryngologic manifestations of reflux.

Painful or difficult swallowing (odynophagia, dysphagia) usually suggests long-standing reflux disease with *either* active inflammation, stricture, or both. Solid food may stick in the distal esophagus (with or without stricture formation), although food usually passes into the stomach after repeated swallowing or drinking liquids unless a fairly tight obstruction is present (see Chapter 60). Odynophagia is seen in cases complicated by severe erosion and may be a symptom of malignancy or infection.

Barrett's Esophagus and Adenocarcinoma. A strong, dose-related, independent risk for *adenocarcinoma of the esophagus* is conferred by symptomatic reflux. In a substantial number of patients with long-standing severe reflux, a premalignant change develops that is referred to as *Barrett's esophagus*, which denotes metaplastic columnar epithelialization of the distal esophagus. Barrett's esophagus is believed to represent a reparative response to tissue injury from chronic exposure to gastric acid, pepsin, and bile (annual incidence, 0.6% per year; prevalence, 10% among those with reflux lasting longer than 20 years). Histologically, the normal stratified squamous epithelium of the mucosa is replaced by columnar epithelium. Dysplastic transformation may ensue and eventually lead to adenocarcinoma. The risk for the development of adenocarcinoma with onset of Barrett's esophagus is less than 1% annually but rises fivefold with the onset of low-grade dysplasia and 10-fold in persons with high-grade dysplasia. Symptoms are those of reflux and its complications.

Esophageal ulcers, strictures, and hemorrhage may also develop as a consequence of chronic severe esophagitis. *Bleeding* may be slow and chronic, resulting in iron-deficiency anemia, or brisk, resulting in hematemesis.

Dental erosions occur in a substantial proportion of patients with marked reflux as a consequence of the effects of acid and bile on tooth enamel. Patients with teeth erosions of unknown etiology are often found to have reflux on evaluation.

Reflux-induced asthma and laryngitis are among the airway consequences of chronic GERD. Unexplained wheezing, voice change, chronic cough, and lump in the throat are among the symptoms reported; reflux must be considered when such complaints develop in the absence of a known cause.

DIFFERENTIAL DIAGNOSIS

The diagnosis of gastroesophageal reflux disease is secure when the patient describes heartburn and experiences regurgitation of stomach contents. However, many patients report only a dull substernal discomfort or ache, and in such circumstances the physician must consider *myocardial ischemia*, esophageal *spasm* or high-amplitude esophageal peristalsis, *cholelithiasis*, and mediastinal inflammation. Gastroesophageal reflux may accompany *peptic ulcer disease* (particularly in gastric hypersecretory conditions) and *cancer* of the gastroesophageal junction. Esophageal *infections* with opportunistic organisms such as cytomegalovirus, herpesvirus, and *Candida albicans* can cause heartburn in the immunocompromised host. Reflux esophagitis may also accompany intestinal dysmotility syndromes, including idiopathic intestinal pseudoobstruction or secondary pseudoobstruction associated with *scleroderma*. *Diabetic gastroparesis* may predispose a patient to

reflux and heartburn because of retarded emptying of gastric contents.

WORKUP

History. The characteristic history of a retrosternal burning sensation radiating upward, associated with large meals and supine posture, is virtually diagnostic of reflux disease. An attempt should be made to identify any aggravating factors, such as intake of fatty foods, concentrated sweets, alcohol, peppermint, coffee, tea, anticholinergics, calcium channel blockers, and theophylline compounds. The use of drugs capable of causing esophageal injury (NSAIDs, quinidine, wax matrix potassium chloride tablets, tetracycline) should also be elicited. Inquiry should be made regarding response to antacids. Surgery near the gastroesophageal junction (e.g., antireflux surgery or vagotomy) may predispose the patient to reflux disease. A history of Raynaud's phenomenon raises the possibility of scleroderma. Consideration of achalasia, malignancy, esophagitis, and stricture is indicated if dysphagia is part of the clinical presentation (see Chapter 60).

Physical Examination. The physical examination is generally unrevealing, but several points are worth special attention. Sclerodactyly, calcinosis, and telangiectasia suggest underlying scleroderma (see Chapter 146). The epigastrium should be carefully examined for the presence of a mass lesion, and the stool should be examined for occult blood.

Laboratory Studies. No single test is accepted as the standard for the diagnosis of reflux disease. Fortunately, a careful history is sufficient to establish the diagnosis in the majority of patients, and laboratory tests are needed only in atypical or severe cases. When a classic reflux story is elicited, initial therapy can be instituted on the basis of history alone for simple heartburn in a young patient.

Esophageal pH monitoring for 24 hours is the most sensitive and specific test for reflux, but it is also very expensive, not universally available, and usually unnecessary. However, it does allow correlation of activity with symptoms and reflux of acid and can be of help in confusing situations, such as atypical chest pain (see Chapter 60).

Barium swallow; esophagoscopy. If dysphagia, painful swallowing, significant weight loss, or occult blood loss is present, the patient should undergo additional study to rule out a neoplasm or a complication of reflux. Suspected damage to the esophageal mucosa from reflux disease is best assessed by *endoscopy* in conjunction with *biopsy*. The barium swallow may show inflammation, ulceration, or stricture, but findings are normal in most cases of reflux. Although it remains widely used for the diagnosis of reflux, its sensitivity may be as low as 25%, and it is far less accurate than a careful history. Its main utility is in searching for major stricture and tumor in persons with severe or long-standing disease.

In atypical cases, the *Bernstein acid perfusion test* is often employed to see if symptoms are caused by reflux; however, the Bernstein test is rarely needed when the patient gives a classic description of heartburn, and the test requires careful interpretation because false-positives are common. It is of more use in determining whether chest pain is a consequence of acid reflux (see Chapter 60).

SYMPTOMATIC MANAGEMENT

A stepwise approach is recommended by most authorities. Otherwise, healthy patients with a classic history of uncomplicated reflux can be treated empirically, first with simple *nonpharmacologic measures* and then the addition of *pharmacologic intervention* as needed (Table 61-1). In many instances, these measures will suffice. If the patient fails to respond, if heartburn is complicated by dysphagia, weight loss, or anemia, or if a stool test is positive for occult bleeding, then, as noted earlier, a more comprehensive diagnostic investigation is indicated. A detailed evaluation is especially important in older patients, in whom the risk for malignancy is increased.

Table 61-1. Treatment of Esophageal Reflux

Nonpharmacologic Measures (Step 1). The first and most important steps are *dietary intervention*, *life-style modification*, and *antacids* (Table 61-1, step 1, and Table 68-1 and Table 68-2). Attention to these measures is essential to a good outcome; they will often suffice. Even if additional therapy is needed, these conservative measures constitute the foundation of all treatment programs and must not be omitted. They represent the most cost-effective approach to therapy for the majority of patients.

Suppression of Gastric Acid Production (Steps 2 and 3). A major objective of symptomatic therapy is a reduction in esophageal exposure to gastric acid. When step 1 measures fail to suffice, pharmacologic measures can be implemented.

Histamine$_2$ blocker (H$_2$-blocker) treatment (Table 61-1, step 2) can be used in place of or in combination with antacid therapy (antacid contributing immediate neutralizing of postprandial acid and H$_2$-blocker providing more sustained acid suppression). Because H$_2$-blocker absorption may by reduced by up to 20% when an H$_2$-blocker is taken with antacids, the two agents should not be taken at the same time. H$_2$-blockers are more convenient to use than a high-dose antacid program and provide better round-the-clock symptom relief and esophageal healing. A twice-daily, full-dose regimen achieves best results (e.g., 800 mg of cimetidine twice daily, 150 mg of ranitidine twice daily, or 20 mg of famotidine twice daily). In milder cases of reflux, a once-daily dose at the time of maximal symptoms often suffices, supplemented when necessary by an antacid for prompt relief of any breakthrough heartburn.

Proton pump inhibitor (PPI) therapy is indicated for patients with symptoms refractory to the full implementation of step 1 and step 2 measures and for those with erosive esophagitis (see Table 61-1, step 3). A single daily dose of a PPI achieves nearly complete suppression of gastric acid production. It has demonstrated efficacy in the healing of erosive lesions and controlling refractory symptoms. However, relapses after completion of therapy are common, so that long-term maintenance therapy must be considered, especially in persons with erosive esophagitis (see below).

The *choice of PPI* should be based on cost and interactions with other medications; side effects are similar (see Chapter 68). At present, lansoprazole is the least expensive PPI, but omeprazole is likely to drop in price as it comes off patent.

Prokinetic Therapy (Step 4). A few patients will report persistent symptoms despite the above measures. In such situations, prokinetic drugs have been used in an attempt to increase LES pressure and halt reflux (Table 61-1, step 4).

Metoclopramide, a dopamine receptor antagonist, is the leading choice for prokinetic therapy. The drug augments gastric emptying and raises LES tone. It is most useful for patients who have reflux without severe heartburn and those with gastroparesis. However, up to a third of patients may not tolerate the drug because of its central nervous system side effects.

Cisapride, a dopamine antagonist that does not cross the blood—brain barrier, represents an advance in prokinetic therapy in that central nervous system side effects are minimal. However, reports of serious cardiac arrhythmias (ventricular tachycardia, ventricular fibrillation, torsades de pointes, and QT prolongation) have emerged, most often in the context of concurrent use of drugs that inhibit hepatic cytochrome P-450 metabolism. These reports have resulted in a warning by the

Food and Drug Administration that cisapride is contraindicated when such drugs are being taken. In addition, the agent should not be used in persons with a cardiac rhythm disorder, underlying heart disease, renal failure, electrolyte disturbances, or drugs that may be proarrhythmic. An electrocardiogram should be obtained before cisapride is given and checked for arrhythmias and any prolongation of the QT interval.

Bethanechol, a potent cholinergic agonist, raises LES pressure, increases salivary flow, and improves acid clearance by the esophagus. However, because of its cholinergic side effects, it is not particularly well tolerated. The drug is contraindicated in those with asthma and other conditions in which cholinergic therapy may aggravate symptoms.

Antireflux Surgery (Step 5). Antireflux surgery (step 5) includes fundoplication, crural tightening, and return of the esophagogastric junction to below the diaphragm. This represents a more aggressive approach to treatment that is best reserved for patients who experience disablingly refractory symptoms or such complications as stricture, bleeding, Barrett's esophagus, or pulmonary aspiration. Results are best in younger patients and those with preserved function of the esophageal body. A major complication of surgery is difficulty with gastric emptying, which can lead to chronic bloating. Normal gastric emptying should be demonstrated before a patient is subjected to surgery. It appears that a substantial percentage of surgical repairs break down after 5 years, so that reoperation must be considered. Symptoms do not necessarily return.

Long-Term Management. Management of gastroesophageal reflux disease can be a challenge because relapse rates are high, so that dietary, postural, behavioral, and even pharmacologic measures must be continued indefinitely. Moreover, severe disease may require long-term pharmacologic intervention.

Treatment of Erosive Esophagitis. Persons with endoscopically documented erosive esophagitis should be considered candidates for long-term maintenance *PPI therapy* (e.g., 15 mg of lansoprazole every morning), but only *after* a symptomatic recurrence has been experienced and only if that recurrence has taken place in the context of full implementation of dietary and other nonpharmacologic measures. Immediate implementation of PPI maintenance therapy *before* a symptomatic recurrence should be reserved for those with a severe erosion (grade 4) and those in whom symptoms cause a reduction in quality of life (>25%). The ability of PPI therapy to reduce the risk for development of Barrett's esophagus remains to be determined.

Initial concerns about the *safety* of long-term PPI therapy (e.g., risk for gastrin-stimulated carcinoid stomach tumors, noted in mice) have not materialized to date, so that most authorities prescribe long-term PPI treatment when necessary. However, the possibility of the development of atrophic gastritis (a risk factor for gastric carcinoma) as a consequence of long-term PPI therapy in persons with concurrent *Helicobacter pylori* infection should be kept in mind, and any *Helicobacter* infection should be eradicated (see Chapter 68).

If prolonged PPI use is a concern, then one can consider a maintenance program of long-term H_2-blocker therapy. Sometimes, reduced doses will suffice (e.g., 150 mg of ranitidine daily at bedtime). Although H_2-blockers are not as effective as PPIs in healing and preventing recurrences of erosive esophagitis, they may suffice and can control symptoms. *Antireflux surgery* represents a final option for patients with a serious complication or refractory disease, but durability of the repair is a concern.

Screening for and Management of Barrett's Esophagus. Because of the significant malignant potential associated with chronic GERD, *screening* for Barrett's esophagus is recommended in persons who have had symptomatic GERD for at least 5 years and are sufficiently fit and willing to undergo surgery should severe dysplasia or early cancer be found. The cancer risk appears greatest in older white men with long-standing symptomatic GERD. Endoscopic assessment with biopsy is required because mucosal changes may not be visible. Whether persons who become asymptomatic with therapy and have no evidence of Barrett's esophagus on initial screening benefit from continued screening is unknown.

For those found to have changes of Barrett's esophagus without dysplastic transformation, *surveillance* endoscopy is recommended every 3 years thereafter, based on cost-effectiveness data from retrospective series. The finding of low-grade dysplasia requires more frequent surveillance (e.g., every 6 months); the finding of high-grade dysplasia is an indication for consideration of *surgery*. Improved means for detecting dysplasia are under investigation.

Medical therapy for Barrett's esophagus is similar to that for erosive disease (e.g., long-term *PPI* therapy; see above). The immediate goal is to eliminate symptoms of heartburn and regurgitation. Although Barrett's esophagus is not known to be reversible by medical therapy, it is hoped that long-term PPI therapy will reduce the risk for progression to dysplasia and cancer by minimizing further esophageal injury. The risks associated with long-term PPI treatment are not well known but appear to be modest (see above).

Attempts to reverse the histologic changes associated with Barrett's esophagus are under study and include a variety of ablative approaches based on laser and other techniques in combination with PPI therapy. The hope is that by removing the metaplastic epithelial tissue and providing a reduced acid environment, the esophagus will heal by laying down normal squamous mucosa.

Chronic Cough. In some patients, chronic reflux has resulted in respiratory problems, particularly chronic cough, believed to be caused by nocturnal reflux and subsequent aspiration (see Chapter 41). Pharyngitis, nocturnal coughing and choking spells, and wheezing have also been described. A trial of antireflux therapy is indicated when a patient with chronic pulmonary complaints reports symptoms of reflux. Several weeks of treatment may be needed to allow for airway healing before symptom resolution is noted. Any use of theophylline for pulmonary complaints in patients with reflux should be stopped because it can aggravate the problem by reducing LES pressure (see Chapter 48).

PATIENT EDUCATION AND INDICATIONS FOR REFERRAL

Successful management depends heavily on the patient's compliance with medications, diet, and postural measures. A thorough explanation of the mechanisms of reflux and its aggravating factors helps provide a rational basis for the patient's action. Patients need to realize that no single measure will alleviate the discomfort of reflux, but when all are performed together, relief is extremely likely. The lack of direct connection between hiatus hernia and reflux also deserves mention because this is commonly misunderstood, often leading to a belief that surgery is required for treatment.

The chief indication for referral is consideration of endoscopy, indicated in persons with chronic symptomatic disease of at least 5 years' duration, dysphagia, odynophagia, unexplained weight loss, or iron-deficiency anemia. The increased awareness of the association between severe chronic GERD and adenocarcinoma of the esophagus has stimulated interest in early diagnosis, especially in detection of premalignant change such as Barrett's esophagus. A particularly cost-effective approach appears to be one-time endoscopic screening of high-risk persons (e.g., men >50 years of age with years of severe symptomatic GERD) for Barrett's esophagus, followed by repeated endoscopy for surveillance in persons with Barrett's esophagus complicated by dysplasia. Surgical referral is worth considering in persons who remain symptomatic despite maximal medical therapy. Modern laparoscopic techniques provide minimally invasive approaches to surgical correction; however, some question remains regarding the durability of such corrections.

CHAPTER 62 EVALUATION OF JAUNDICE

JAMES M. RICHTER

The onset of jaundice usually prompts the patient or the patient's family to seek medical attention. When associated symptoms are minimal, the patient is likely to present on an ambulatory basis, concerned about hepatitis or cancer. The primary physician needs to distinguish jaundice caused by hepatocellular dysfunction (which can be managed medically) from that caused by biliary tract obstruction (which usually requires an anatomic intervention). More specific determination of etiology is a secondary task that is less important to initial decision making. Effective clinical assessment necessitates familiarity with the mechanisms and clinical presentations of jaundice in addition to the indications for and limitations of the noninvasive diagnostic studies available in the outpatient setting.

PATHOPHYSIOLOGY AND CLINICAL PRESENTATION

The mechanisms responsible for jaundice include excess bilirubin production, decreased hepatic uptake, impaired conjugation, intrahepatic cholestasis, extrahepatic obstruction, and hepatocellular injury. Clinically, jaundice becomes noticeable when the serum bilirubin level reaches 2.0 to 2.5 mg/100 mL. The yellow hue may be mimicked by carotenemia, but in the latter no scleral icterus is present. Deeply jaundiced patients often demonstrate a greenish tinge resulting from the oxidation of bilirubin to biliverdin.

Excess Bilirubin Production results from accelerated red cell destruction. Occasionally, markedly ineffective erythropoiesis may be responsible. The excessive amounts of hemoglobin and resultant bilirubin released into the bloodstream overwhelm the normal hepatic capacity for uptake, and an unconjugated hyperbilirubinemia ensues. Total bilirubin rises as a result of the increased indirect fraction. The results of all tests of hepatocellular function are normal (as are urine and stool appearances). Symptoms, signs, and laboratory test findings point to hemolysis or ineffective erythropoiesis (see Chapter 79).

Decreased Uptake and Conjugation are other mechanisms of unconjugated hyperbilirubinemia. The only evidence of hepatocellular dysfunction is an increase in unconjugated bilirubin. Frequently, a concurrent acquired illness, such as an infection, cardiac disease, or cancer, is present. Hereditary conditions,such as Gilbert's and Crigler-Najjar syndromes, are often responsible. *Gilbert's syndrome* is the most common cause. This is a benign disorder that produces recurrent, self-limited episodes of mild jaundice. Typically, the unconjugated fraction rises to no more than 1.5 to 3.0 mg/100 mL. In Gilbert's syndrome, fasting and minor illness can precipitate jaundice.

Intrahepatic Cholestasis may occur at a number of levels: intracellularly (e.g., hepatitis), at the canalicular level (when estrogen-induced), at the ductule (phenothiazine exposure), at the septal ducts (primary biliary cirrhosis), and at the intralobular ducts (cholangiocarcinoma). Regardless of site, there are similarities in presentation. Jaundice begins gradually; pruritus is common. The liver is large, smooth, and nontender; it may be firm but not rock-hard. Splenomegaly is unlikely except in primary biliary cirrhosis. Stools are pale, and steatorrhea develops in severe cases. A hyperbilirubinemia is present, predominantly of the conjugated fraction, with marked alkaline phosphatase elevation, mild transaminase rise, and normal serum albumin. Urine is dark and positive for bilirubin. The prothrombin time may be prolonged because of malabsorption, but the prolongation is reversible by vitamin K injection.

Extrahepatic Obstruction occurs when stone, stricture, or tumor block the flow of bile within the extrahepatic biliary tree. A history of gallstones, biliary tract surgery, or prior malignancy may be elicited. The gallbladder is sometimes palpable, especially when obstruction develops gradually, allowing time for painless dilation of the biliary tree. Sudden onset with pain results from passage of a stone that becomes wedged into the common duct; fever and sepsis may follow shortly thereafter, indicating cholangitis. Weight loss is a nonspecific finding, but when it is marked and accompanied by jaundice, it suggests carcinoma of the head of the pancreas or metastatic disease obstructing the common duct. Extrahepatic obstruction and intrahepatic cholestasis may be identical in presentation. The liver is usually enlarged; tenderness is minimal unless cholangitis or rapid distention occurs. A rock-hard mass strongly points to malignancy. As in intrahepatic cholestasis, conjugated bilirubin exhibits the greatest rise in association with a high serum alkaline phosphatase level and a mild to moderate increase in the transaminase level. Any prolongation of the prothrombin time is at least partially reversible with parenteral vitamin K. Urine is dark because of the conjugated bilirubinuria. Stools are pale from absence of bile.

Hepatocellular Disease is typified by hepatitis, with prodromal symptoms of anorexia, nausea, abdominal pain, and malaise preceding jaundice (see Chapter 52 and Chapter 70). Hepatic tenderness and some hepatomegaly are common. Ecchymoses may be present. Transaminases may reach dramatic levels, except in cases of hepatitis C and alcoholic hepatitis, in which the rise is no more than five times normal. The alkaline phosphatase rises modestly to two to four times above the baseline. Urine is dark, and stools are pale. There may be evidence of decreased protein synthesis. The prothrombin time is the first measure of synthetic function to become abnormal because the half-lives of the clotting factors made in the liver are less than 7 days. If synthetic function remains depressed beyond 2 weeks, the serum albumin begins to fall. Chronic hepatocellular disease may lead to fibrosis and cirrhosis with portal hypertension, peripheral edema, ascites, gynecomastia, testicular atrophy, bleeding, and encephalopathy (see Chapter 71).

DIFFERENTIAL DIAGNOSIS

The causes of jaundice are extensive but can be grouped according to major pathophysiologic mechanisms and type of hyperbilirubinemia (conjugated or unconjugated; Table 62.1). It is important to recognize that more than one mechanism can be operating in a given case. The vast majority of cases are caused by obstruction, intrahepatic cholestasis, or hepatocellular injury. In young patients, hepatitis predominates. In the elderly, stones and tumor are often responsible. Drugs account for many cases of intrahepatic cholestasis, with symptoms often mimicking those of extrahepatic etiologies.

Unconjugated Hyperbilirubinemias (urine negative for bilirubin)
    Increased bilirubin production
    Decreased hepatic uptake of bilirubin
    Decreased conjugation

Conjugated Hyperbilirubinemias (urine positive for bilirubin)
    Hepatocellular disease
    Intrahepatic cholestasis
    Extrahepatic obstruction

Table 62.1. Differential Diagnosis of Jaundice by Pathophysiologic Mechanisms

WORKUP

The *history and physical examination* often provide a diagnosis or at least indicate whether the underlying pathophysiology is hepatocellular injury or biliary obstruction. In a study of 61 cases of jaundice documented by liver biopsy, history and physical examination alone correctly identified 70% of viral hepatitis cases,

80% of cirrhosis cases, and 77% of those with obstructive jaundice.

History. Key historical items found useful for discriminating among etiologies include the presence of abdominal pain (indicative of obstruction) and a history of alcoholism, exposure to hepatitis, and flulike onset (all suggestive of a hepatocellular etiology). Of little discriminant value are a history of weight loss, pruritus, nausea, vomiting, and distaste for tobacco. Dark urine and pale stools confirm a conjugated hyperbilirubinemia but do not distinguish between hepatic and obstructive disease. Absence of abdominal pain does not rule out obstruction, especially that which develops slowly from tumor growth or primary biliary cirrhosis. The history should also be checked for other hepatocellular disease risk factors (e.g., previous blood transfusion, travel to an area endemic for hepatitis, consumption of raw shellfish, IV drug abuse, high-risk sexual practices, use of potentially hepatotoxic drugs). A history of gallstones, previous biliary tract surgery, and high fever points toward an obstructive cause. A family history of episodic jaundice in the setting of an intercurrent illness is consistent with Gilbert's disease. Intrahepatic cholestasis is a consideration if the patient reports use of estrogens, phenothiazines, and other drugs that can cause cholestasis.

Physical Examination. Findings that favor a diagnosis of advanced hepatocellular disease include a small liver, signs of portal hypertension (ascites, splenomegaly, prominent abdominal venous pattern), asterixis, peripheral edema (from hypoalbuminemia), spider angiomata, gynecomastia, and palmar erythema. Mild to moderate hepatic enlargement and mild tenderness to punch are also consistent with early or mild hepatocellular disease, especially that caused by acute viral hepatitis. A palpable gallbladder (Courvoisier's sign) suggests malignant obstruction of the common bile duct. Marked hepatic enlargement (6 cm or more below the inferior costal margin) occurs in some instances of extrahepatic obstruction and also in advanced hepatic infiltration, severe passive hepatic congestion, and metastatic cancer to the liver. If obstruction is acute in onset, there may be some associated guarding, rebound tenderness, and fever. The finding of ecchymoses is consistent with both obstructive and hepatocellular mechanisms. The same is true for the detection of pale stools and dark urine.

Laboratory Investigation can be used to identify the predominant pathophysiology and to assess severity, especially when the history and physical examination findings are nondiagnostic. Testing begins with a check of the *urine* for *bilirubin*, a simple, inexpensive, yet often overlooked test that can be performed quickly in the office. Because only conjugated bilirubin appears in the urine, its presence indicates a conjugated hyperbilirubinemia and the possibility of cholestasis, obstruction, or hepatocellular injury; its absence argues for excess bilirubin production, decreased uptake, and impaired conjugation. Determinations of *direct* and *indirect serum bilirubin* levels quantitatively confirm urinary findings and indicate disease severity.

Unconjugated Hyperbilirubinemia. An elevation predominantly of the unconjugated bilirubin fraction and urine negative for bilirubin should initiate a search for hemolysis (see Chapter 79), ineffective erythropoiesis, hereditary causes of jaundice, and concurrent systemic illness. Standard "liver function tests" add little to the assessment of unconjugated hyperbilirubinemia; results are normal or very mildly and nonspecifically elevated.

Conjugated Hyperbilirubinemia: Differentiating Hepatocellular Injury from Intrahepatic and Extrahepatic Cholestasis. The finding of bilirubin in the urine should focus attention on the liver and biliary tree. Testing needs to include determinations of serum *transaminases* [serum glutamic–oxaloacetic transaminase (SGOT), serum glutamic–pyruvic transaminase (SGPT)]; the newer nomenclature refers to them as *aminotransferases* [aspartate aminotransferase (AST), alanine aminotransferase (ALT)]. *Alkaline phosphatase, prothrombin time,* and *serum albumin* must also be determined. Mechanical obstruction and intrahepatic cholestasis are characterized by marked rises in *alkaline phosphatase* (four to five times normal) and modest elevations in *transaminases* (two to three times normal). Hepatocellular disease characteristically causes a proportionally far greater rise in serum transaminase levels than in alkaline phosphatase concentrations. As noted earlier, two exceptions are hepatitis C and alcoholic hepatitis, in which transaminases may be only mildly elevated (no more than two to three times the upper limits of normal). SGPT (ALT) elevations are more specific for liver disease; SGOT (AST) also rises with myocardial or skeletal muscle injury.

The differentiation of hepatocellular disease from cholestatic and obstructive conditions can be attempted by studying measures of liver synthetic function and, if need be, their response to vitamin K. A prolonged *prothrombin time* unresponsive to parenteral *vitamin K* (IM or SQ administration is preferred because of reports of anaphylaxis with IV administration) is strongly suggestive of hepatocellular failure. Cholestasis and obstruction may also produce prolongation of the prothrombin time, but it can be reversed by vitamin K. *Serum albumin* levels fall when substantial hepatocellular injury has occurred and synthetic capacity has been suppressed for a few weeks. Interpretation of the albumin level requires consideration of dietary intake and sources of possible protein loss.

Liver biopsy is sometimes needed to determine the cause of hepatocellular injury (see also Chapter 70 and Chapter 71), but is unwise in the setting of possible obstructive jaundice because it can lead to bile peritonitis if obstruction is present. Once obstruction is ruled out or relieved, biopsy is an important consideration, especially when evidence of hepatic failure, portal hypertension, or encephalopathy is present, or when jaundice persists longer than 3 months.

Marked Elevation in Alkaline Phosphatase: Differentiating Extrahepatic Obstruction from Intrahepatic Cholestasis. A marked elevation in alkaline phosphatase occurs in the setting of obstructive pathophysiology as well as intrahepatic cholestasis. The latter occasionally occurs in some cases of hepatocellular injury, such as viral, alcoholic, and drug-induced forms of hepatitis. However, a low alkaline phosphatase level (<50 IU/100 mL) is rarely seen in the presence of extrahepatic obstruction. Elevations in alkaline phosphatase also occur in settings of increased bone metabolism. Bony causes can be distinguished from hepatobiliary causes by measuring the *heat-stable fraction* of the enzyme or the *5'-nucleotidase* (these are of hepatobiliary tract origin).

Although hepatocellular disease can usually be distinguished from cholestasis and extrahepatic obstruction on the basis of clinical data and results of liver function tests (including response to vitamin K), cholestasis and obstruction may be indistinguishable without further testing. Clinical evaluation and liver function tests have a sensitivity of 90% for detection of obstruction, but they have a predictive value of only 75%; 25% of patients suspected on clinical grounds of having obstruction turn out to have intrahepatic cholestasis. The distinction is critical to management because mechanical obstruction requires direct surgical, endoscopic, or radiologic intervention to restore bile flow.

Thus, the clinical impression of obstruction must be confirmed by imaging techniques. Only when the clinical likelihood of obstruction is very low is imaging of the biliary tree unnecessary for differentiating intrahepatic cholestasis from extrahepatic obstruction. Available imaging modalities include the following:

Ultrasonography. This is the noninvasive imaging technique of choice to assess the biliary tree in the evaluation of jaundice. Specificity is better than 90%. Sensitivity ranges from 47% to 90%, depending on the duration and degree of bile duct obstruction. Cases of early, acute, or intermittent obstruction may be missed unless ultrasonographic study is repeated after the ducts have had a few days to dilate. False-positive results may occur when ductal dilation persists after cholecystectomy or relief of obstruction. In about half of cases, ultrasonography cannot indicate the level of obstruction, nor is it particularly good at detecting the cause of the obstruction unless it is a mass in the head of the pancreas. Stones in the common duct are frequently missed (sensitivity of 50% if duct not dilated, 75% if duct dilated). Ultrasonographic studies in patients with overlying bowel gas or marked obesity are often of inadequate technical quality, so that a repeated study or computed tomography is required.

Computed Tomography is similar to ultrasonography in sensitivity, specificity, and predictive value for the diagnosis of obstructive jaundice. It has many of the same shortcomings plus greater expense and radiation exposure. As such, it is a second-choice test after ultrasonography. However, results are not obscured by overlying bowel gas or fat, and the ability to detect the level of obstruction is better than with ultrasonography. Moreover, if surgical intervention is being considered, the test is helpful in providing more definitive anatomic information. Nonetheless, cholangiography is usually still necessary.

Other Imaging Modalities: Percutaneous Transhepatic Cholangiography, Endoscopic Retrograde Cholangiopancreatography, Magnetic Resonance Cholangiopancreatography. If common duct obstruction is strongly suspected on clinical grounds (even if ultrasonography or computed tomography is nondiagnostic), or if additional anatomic detail is required for planning treatment, then percutaneous trans-hepatic cholangiography or endoscopic retrograde cholangiopancreatography with retrograde cannulation of the common bile duct can be performed. Both procedures are relatively safe, have similar complication rates and rates of visualization, and provide equally diagnostic information. The predictive value of a positive test result is very high, but occasionally stones are missed in dilated ductal systems.

Trans-hepatic cholangiography is technically simple in patients with dilated intrahepatic ducts; however, 3% to 10% of patients experience cholangitis, hemorrhage, or bile leakage.

Endoscopic retrograde cholangiopancreatography (ERCP) is more difficult but allows examination of the ampulla and pancreas and has a slightly lower incidence of serious complications. For patients who may have a retained common duct stone after cholecystectomy, the opportunity to perform an endoscopic papillotomy makes the retrograde cholangiogram advantageous. Techniques have been developed for draining an obstructed biliary tract either endoscopically or trans-hepatically. Overall, both procedures are valuable diagnostically and have therapeutic uses also; final selection is based on the clinical circumstance in addition to local

availability and expertise. Selection should be made in consultation with a surgeon, radiologist, or gastroenterologist experienced in evaluating obstructive jaundice.

Magnetic resonance cholangiopancreatography (MRCP) provides a new, noninvasive alternative to these two invasive modalities. Test sensitivity for pathology in the common bile duct, particularly stones, is superior to that of ultrasonography or computed tomography and approaches that of the invasive modalities. The cost is slightly less than that of ERCP, and safety is greater because no dye load or invasive procedure is required. Some have suggested that MRCP be used to screen patients for ERCP candidacy.

Ancillary Testing. Other studies deserve comment, more for their limited usefulness than because they are indicated in evaluation of jaundice. *Plain films* of the abdomen and *upper gastrointestinal series* rarely provide diagnostic information. *Hepatobiliary scintigraphy* is better suited for the diagnosis of cholecystitis; it provides poor anatomic resolution and often cannot aid in distinguishing between intrahepatic cholestasis and extrahepatic obstruction. *Cholescintigraphy* is useful for the diagnosis of acute cholecystitis and cystic duct obstruction (see Chapter 69), but it has no value in the evaluation of jaundice and can be misleading.

INDICATIONS FOR ADMISSION, CONSULTATION, AND REFERRAL

Most patients with jaundice turn out to have acute viral hepatitis and can be managed on an ambulatory basis, unless they are unable to maintain their hydration or begin to show evidence of severe hepatocellular failure (see Chapter 71). Admission is mandatory when jaundice is complicated by fever and peritoneal signs indicative of *cholangitis*. IV antibiotics and prompt surgical consultation are required.

As noted earlier, if extrahepatic obstruction is suspected clinically, consultation with a gastroenterologist, surgeon, or radiologist experienced in the evaluation of jaundice can be very useful, especially when it is difficult to differentiate between intrahepatic cholestasis and extrahepatic obstruction.

When hepatocellular disease is suspected and evidence of hepatic failure, portal hypertension, or encephalopathy is present, or when jaundice persists for longer than 3 months, liver biopsy may be indicated for definitive diagnosis. Consultation should be sought with a gastroenterologist familiar with liver disease and needle biopsy techniques.

SYMPTOMATIC RELIEF

Mild jaundice in itself is innocuous, but more marked elevations in bilirubin may produce considerable pruritus. Presumably, the mechanism involves the deposition of bile salts in the skin, although recent evidence refutes this view. Cholestyramine has been used successfully to treat pruritus and is worth a try in patients who are uncomfortable. One 9-g packet of the powder containing 4 g of cholestyramine resin is mixed in orange juice or apple sauce and taken three times a day. Absorption of fat-soluble vitamins may be impaired by cholestyramine, and oral or parenteral supplements of vitamins A, D, and K can be prescribed. Cholestyramine may also interfere with the absorption of drugs; they should be taken at least 1 hour before cholestyramine. Constipation or diarrhea is a minor common side effect.

CHAPTER 63 EVALUATION OF GASTROINTESTINAL BLEEDING

JAMES M. RICHTER

Ambulatory patients frequently report gastrointestinal bleeding to the primary physician. They may complain of *melena* (tarry black stools), *hematochezia* (bright red or maroon blood per rectum), or *hematemesis* (vomiting fresh or changed blood). Sometimes, gastrointestinal bleeding may be evident only as a *positive result on a screening test for fecal occult blood*. Decisions regarding the nature and pace of the evaluation of gastrointestinal bleeding depend on the characteristics, severity, and acuteness of the problem. Proper decision making requires a knowledge of the probability of a serious underlying lesion and of the sensitivity and specificity of contrast studies, endoscopy, and stool guaiac testing.

PATHOPHYSIOLOGY AND CLINICAL PRESENTATION

Hematemesis usually represents bleeding proximal to the ligament of Treitz, although the site of blood loss may on rare occasions be in the jejunum. The absence of hematemesis does not, however, exclude the possibility of active upper gastrointestinal bleeding. *Melena* is usually seen with blood loss proximal to the ileocecal valve, where hemoglobin is converted into hematin, which gives the stool its tarry appearance. Right-sided colonic bleeding may also cause melena when transit is slow. *Hematochezia* most often originates in the left side of the colon or anorectal region, although very brisk movement of blood from the right side of the colon, small bowel, or even stomach can lead to a similar presentation. *Occult gastrointestinal bleeding* may be indicated by a positive result on a test for fecal occult blood or may be suggested by the presence of iron-deficiency anemia without apparent cause. The source of occult bleeding may be anywhere in the gastrointestinal tract.

Manifestations of blood loss are a function of the rate and duration of bleeding. *Postural hypotension* (an orthostatic fall in blood pressure of <10 mm Hg or an increase in heart rate of >10 beats/min on moving from a supine position to standing) in the setting of known bleeding suggests intravascular volume depletion and serious acute hemorrhage. *Fatigue* and *exertional dyspnea* are typical presenting symptoms of anemia resulting from slow, chronic blood loss. Patient descriptions of the volume of bleeding are frequently unreliable.

DIFFERENTIAL DIAGNOSIS

The chief causes of gastrointestinal bleeding can be conveniently grouped by clinical presentation (Table 63.1). Hematemesis prompts consideration of important upper gastroinintestinal etiologies. Melena requires consideration of upper gastrointestinal causes and of small-intestinal and right-sided colonic sources. Hematochezia raises the question of anorectal or colonic disease and, if brisk, a small-bowel or even upper gastrointestinal lesion. The prevalence of specific disorders varies with the population studied, diagnostic methods employed, and time of investigation in relation to bleeding.

Table 63.1. Differential Diagnosis of Gastrointestinal Bleeding

Melena or Hematemesis. A British series of 277 patients with melena or hematemesis provides representative prevalence figures in a population composed of both outpatients and patients seen in emergency departments. More than 85% of the patients in this study underwent endoscopy; diagnosis was also made by upper gastrointestinal series or at surgery: 20% had duodenal ulcers, 15% had gastric ulcers, 12% had Mallory-Weiss tears, 11% had esophageal varices, 5% had gastritis, and1% had gastric cancer. In 21%, no cause was found (half of these patients did not undergo endoscopy), and in 5%, multiple lesions were detected. Patients with chronic renal failure are at increased risk for bleeding, with angiodysplasia and esophagitis being the most common causes.

Hematochezia. In the setting of severe *hematochezia*, age has a major influence on the differential diagnosis. In young adults, Meckel's diverticulum, inflammatory bowel disease, and polyps lead the list of causes. In adults to age 60, diverticulosis, inflammatory bowel disease, and polyps are the predominant etiologies, followed by malignancy and vascular malformations. In persons over the age of 60, vascular ectasia, diverticulosis, malignancy, and polyps are responsible for most cases.

In a study of 311 patients who reported *mild to moderate anorectal bleeding* and were evaluated by careful physical examination, sigmoidoscopy, and barium enema, 79% had lesions of the anal canal, 15% had rectal and colonic disease, and 7% had perianal skin problems. Leading causes were hemorrhoids in 54%, fissure-in-ano in 18%, neoplasm in 6.5%, and inflammatory bowel disease in 5%. In 8%, no cause was found at the time of the examination. The majority of neoplasms were more than 10 cm above the anus, beyond the reach of digital examination.

In a series of 239 patients with *undiagnosed rectal bleeding* who were subjected to colonoscopy, 40% had significant lesions; 16% were found to have polyps, 10% had inflammatory bowel disease, 9% had carcinomas missed by barium enema, and 3% had diverticular disease, hemangiomata, or other causes. In a large percentage of these patients, no cause was found. In a study of anemic competitive runners, an increase in fecal hemoglobin was detected.

Patients with gastrointestinal bleeding while taking *anticoagulant medication in a therapeutic range* are likely to have an underlying lesion and warrant thorough evaluation. In a study examining 3,800 courses of anticoagulant therapy, gastrointestinal bleeding occurred in 45 patients. In 32 patients, a source was determined; 13 had hemorrhoids, 9 had peptic ulcers, 7 had neoplasms, and 3 had other lesions.

Nosebleeds and *respiratory tract bleeding* must be considered in the differential diagnosis of melena and guaiac-positive stools. A false-positive result on a stool guaiac test can be produced by the use of glycerol guaiacolate (a popular expectorant) or a meal of rare red meat. Black stools may result from bismuth (Pepto-Bismol), iron, charcoal, or spinach intake; red stools can occur after large quantities of beets have been consumed.

WORKUP

The history and physical examination may provide information regarding the location and severity of bleeding, but additional investigations are usually necessary to determine the exact cause. In the previously mentioned series of 311 cases of anorectal bleeding, history and physical examination alone yielded a definite diagnosis in 28%. Nevertheless, history and physical examination have important roles that help in determining the pace of workup and the selection and ordering of tests.

Screening for Major Acute Blood Loss. Whenever active bleeding is suspected in a person presenting to the office, the first priority is to determine the severity and

rate of blood loss. The patient should be asked about any *postural light-headedness.* The precise volume lost is not reliably determined by the history, but reports of very large amounts should be taken seriously. When the patient complains of voluminous blood loss or light-headedness, an immediate check of vital signs for *postural hypotension* is indicated. Immediate hospital admission should be considered if the systolic blood pressure falls more than 10 to 15 mm Hg or the heart rate increases by more than 10 to 15 beats/min when the patient stands up from a supine position. The decline in the hematocrit in the acute phase of blood loss may be deceptively small if sufficient time for the reequilibration of intravascular volume has not elapsed.

History. Once it is clear that the degree of blood loss does not pose an immediate hazard, the office evaluation can proceed. Clarifying the nature of the bleeding (melena, hematemesis, or hematochezia) helps not only to assess severity, but also to identify the approximate site of bleeding. Obtaining an accurate description is essential, as is checking for potentially confounding factors. Dark stools must not be mistaken for genuine melena, and one should check for intake of substances that may turn stool black, such as bismuth (Pepto-Bismol), iron, charcoal, or spinach. Red stools can occur after large quantities of beets have been eaten. Factors that can produce a false-positive result on the stool Hemoccult test should be considered (e.g., use of cough syrup containing glycerol guaiacolate, a recent meal of rare red meat), but a positive test result ought not be dismissed lightly.

When hematemesis is reported, sources of esophageal, gastric, and duodenal bleeding must be sought. A history of cirrhosis, chronic liver disease, or alcoholism raises suspicion of esophageal varices. Use of aspirin, alcohol, and antiinflammatory agents suggests bleeding caused by ulceration or gastritis. A history of peptic ulcer or the presence of epigastric pain responsive to antacids or related to food intake raises the possibility of bleeding from a gastric or duodenal ulcer. It is worth noting, however, that another explanation for bleeding may be present in patients with a history typical of ulcer disease, and that more than one potential site of bleeding may be discovered (e.g., esophageal varices).

Even if no hematemesis is noted, the source may still be above the ligament of Treitz; however, small-bowel and colonic lesions become more likely. Diarrhea, urgency, tenesmus, and lower abdominal cramping suggest inflammatory bowel disease (see Chapter 73). With ulcerative colitis, diverticulosis, and other forms of rectosigmoid disease, some frank rectal bleeding is often present. Brisk rectal bleeding in the absence of abdominal pain is particularly common with diverticular disease. Weight loss or change in bowel habits raises suspicion of colonic cancer. A history of diverticular disease may be a clue to the cause of blood loss, but a coincident carcinoma must be ruled out. Many patients with rectal bleeding admit to past or present hemorrhoidal problems, but in almost half of the cases another lesion is found to be the cause of blood loss.

Physical Examination. As noted above, when evidence of acute bleeding is present, the evaluation should begin with a check for *postural signs* and a cardiopulmonary examination to assess the severity of volume loss and the presence of any hemodynamic compromise. Next, the skin is inspected for pallor, ecchymoses, petechiae, telangiectases, and stigmata of chronic liver disease (e.g., jaundice, palmar erythema, spider angiomata). The nose and pharynx are examined for sources of bleeding. Lymph nodes are palpated for enlargement (e.g., left supraclavicular adenopathy suggests an intraabdominal malignancy), and the abdomen is palpated for organomegaly, ascites, and masses. Anorectal lesions are sought on inspection and digital examination; the stool is checked for color and the presence of occult blood (see Chapter 56). Anoscopy is an essential part of the examination for patients who complain of anal symptoms.

If the patient convincingly describes hematemesis, one may assume that the bleeding is from the upper gastrointestinal tract, but if there is evidence of recent significant bleeding of uncertain origin, a nasogastric tube should be passed to aspirate gastric contents and test for the presence of blood. The guaiac test may be insensitive for heme unless the acidic aspirate is neutralized with a few drops of sodium hydroxide.

Laboratory Studies should be performed to determine the chronicity and magnitude of blood loss and the presence of coincident disease. The hemoglobin concentration should be measured in all patients; however, if blood loss is acute, the hemoglobin concentration may not yet accurately reflect the severity of blood loss. A low mean corpuscular volume suggests the possibility of iron deficiency resulting from chronic gastrointestinal blood loss. Studies of coagulation (platelet count, prothrombin time, and partial thromboplastin time) and tests of liver and renal function are useful in checking for factors that may exacerbate bleeding.

Hematochezia. In stable patients, the main concern is the possibility of colon cancer; risk increases with age. Fewer than 5% of such cancers occur in patients under age 40 and fewer than 1% in those under age 30. Thus, if the physical examination or anoscopy reveals a bleeding hemorrhoid or other cause of local anal pathology in a young patient, it may not be necessary to proceed with further tests. The finding on sigmoidoscopy of guaiac-negative stool from above the point of bleeding also provides reassurance. On the other hand, 80% of colorectal malignancies are found in patients over the age of 50. When a person more than 50 years old presents with rectal bleeding, a thorough search for tumor is required, even if a local lesion such as a hemorrhoid is discovered. Twenty-seven percent of patients with carcinoma of the rectum and 10% of those with carcinoma of the sigmoid have been noted to have coincidental hemorrhoids.

Data describing the yields of diagnostic procedures are increasingly available. In the series of 311 patients with bright red rectal bleeding subjected to history, physical examination, sigmoidoscopy, and barium enema, the diagnosis was made by history alone in 5%; physical examination raised the figure to 28%, and the addition of *sigmoidoscopy* provided an explanation in 90%. *Barium enema* raised the yield in this series only another 3%, probably because of the unusually large number of lesions in this study that were within reach of the sigmoidoscope. However, cumulative data suggest that only 30% of colonic malignancies can be viewed by sigmoidoscopy. Consequently, persons with rectal bleeding in the age group at high risk for large-bowel malignancy should undergo additional study. Barium enema has a sensitivity of 70% to 90% for detecting carcinoma and 70% for polyps larger than 5 mm in diameter. Cancers most often missed are in the cecum or rectosigmoid or are obscured by concurrent diverticulosis or ulcerative colitis. Air-contrast techniques improve the results.

Colonoscopy is emerging as the diagnostic procedure of choice for patients with hematochezia who are at risk for colon cancer and whose bleeding is not entirely explained by documented anorectal pathology. About 40% of patients with frank rectal bleeding or occult blood loss in conjunction with normal sigmoidoscopy and barium enema results are found to have previously undetected lesions when studied by colonoscopy. About 10% have cancers, another 10% have polyps, 10% have inflammatory bowel disease, and 5% have telangiectasia. Furthermore, carcinomas and polyps were detected in 20% of patients in whom only diverticula were seen with barium enema. Although the precise role for colonoscopy is not yet entirely settled, most patients over the age of 50 with bleeding are candidates for colonoscopy, either primarily or if barium enema and sigmoidoscopy findings are normal or show only diverticula.

Hematemesis. *Endoscopy* has proved to be diagnostically superior to barium studies and offers the possibility of tissue biopsy for *Helicobacter pylori*. The sensitivity of the upper gastrointestinal series is around 60%, compared with 95% for endoscopy. Esophagitis, Mallory-Weiss tears, and gastritis, which are often undetectable radiologically, are readily seen by endoscopy. Moreover, barium obscures mucosal detail and interferes with endoscopy for 24 to 48 hours. Thus, for suspected acute brisk upper gastrointestinal bleeding, endoscopy is the procedure of first choice, with barium study reserved as a supplementary procedure for patients with inactive bleeding, unexplained chronic blood loss, or suspected small-bowel disease.

The question of whether early endoscopy results in improved outcome for patients with hematemesis remains unresolved. Several studies have failed to demonstrate a significant improvement in outcome among patients who have undergone diagnostic endoscopy. Patients with small bleeds who are hemodynamically stable and do not have liver disease or a significant risk for gastric cancer may be presumed to have peptic ulcer disease and can be treated for *Helicobacter-* or NSAID-induced peptic ulcer (see Chapter 68). Patients at high risk for recurrent bleeding (such as those with evidence of chronic liver disease or an initial bleed that requires a transfusion) and those with persistent bleeding despite medical therapy should undergo endoscopy. In addition, it may be useful to perform upper gastrointestinal endoscopy to exclude esophageal and gastric mucosal features indicative of a high risk for rebleeding (e.g., a "visible vessel" in an ulcer crater).

Melena. Because melena may have an upper or lower gastrointestinal source, one needs to decide which part of the gastrointestinal tract to evaluate first. The decision must be individualized to the patient at hand, although in general, an upper gastrointestinal source of bleeding is more likely.

Occult Bleeding. The evaluation of occult gastrointestinal bleeding is generally aimed at detecting asymptomatic neoplasms at a curable stage. Because colonic adenomas and carcinomas are the most common gastrointestinal neoplasms, evaluation of the colon has greatest utility in this setting. A cost-effectiveness analysis comparing different strategies for evaluating a positive result on testing for fecal occult blood has suggested that colonoscopy would save more lives at lower cost than the combined use of barium enema and flexible sigmoidoscopy. Of seven strategies evaluated, barium enema (without sigmoidoscopy) had the lowest cost-effectiveness ratio but would save fewer lives than colonoscopy. The use of colonoscopy plus barium enema was the only strategy predicted to save more lives than colonoscopy alone, but it does so at significantly higher cost (see Chapter 56).

If no cause of occult bleeding is identified within the colon, evaluation of the upper gastrointestinal tract and small bowel may be considered, although the yield for detection of cancer is likely to be low. In a study of 26 patients followed for 2 to 8 years after a negative result on colonoscopy or barium enema/sigmoidoscopy, only one patient was later found to have a gastric cancer. In five others, a nonmalignant upper gastrointestinal source emerged as the cause of the occult bleeding. A prospective study of patients with iron-deficiency anemia found that site-specific symptoms were predictive of the location of the source of bleeding. Upper

gastrointestinal sources were common. Synchronous sources of blood loss were rare, so that further evaluation was unnecessary when an obvious source was found.

PROPHYLACTIC AND SYMPTOMATIC MANAGEMENT

Patients at high risk for upper gastrointestinal bleeding (such as those with varices or a prior history of upper gastrointestinal bleeding, especially if exposed to anticoagulants or high doses of NSAIDs) are candidates for prophylactic measures. Propranolol has been used successfully to prevent a first bleed in patients with known varices (see Chapter 71). *Sclerotherapy* or endoscopic ligation is not indicated for primary prophylaxis because it may actually increase mortality in patients with varices, but these procedures are reasonable in those at high risk for recurrent variceal bleeding. *Histamine$_2$ blockers* and *omeprazole* may be helpful in selected patients with a history of bleeding from an ulcer or gastritis (see Chapter 68). Patients taking steroids do not appear to require such prophylaxis unless an additional risk factor for bleeding is present.

Modest falls in hematocrit that accompany chronic low-grade gastrointestinal blood loss can be treated with oral iron (300 mg of ferrous sulfate three times daily) to make up for the resulting iron deficiency (see Chapter 82). Marked but gradual decreases in hematocrit are usually well tolerated unless the patient has cardiopulmonary disease. Most patients do not need transfusion unless they are symptomatic. Oral iron usually produces a prompt reticulocytosis and at least partial correction of the anemia (see Chapter 82). Patients with presumed anal bleeding can be given fiber supplements or stool softeners to decrease mechanical trauma to the lesion (see Chapter 65).

INDICATIONS FOR ADMISSION AND REFERRAL

The patient with a story of recent or ongoing brisk bleeding, especially if it is accompanied by orthostatic hypotension or other symptoms or signs of hemodynamic compromise, requires emergency department evaluation. Prompt hospitalization is indicated for the person with a profound anemia, even in the absence of evidence for dramatic blood loss. Some patients who are hemodynamically stable may be expeditiously evaluated in a short stay with endoscopy if they have a lesion unlikely to rebleed. Hospitalization should be considered for patients with less severe or perhaps even chronic gastrointestinal blood loss if they have a comorbid condition that might be aggravated by anemia (e.g., ischemic heart disease). For most others, evaluation can proceed safely on an ambulatory basis if the patient does not have serious cardiopulmonary disease and is responsible enough to recognize and promptly report signs of worsening blood loss or volume depletion. Referral to a gastroenterologist should be considered for patients who are potential candidates for endoscopy, and also for patients whose source of bleeding remains elusive after initial evaluation.

CHAPTER 64 EVALUATION AND MANAGEMENT OF DIARRHEA

JAMES M. RICHTER

Diarrhea is clinically characterized by the frequent passage of unformed stools. Episodes that are brief, self-limited, and well tolerated do not require medical attention, but when diarrhea becomes severe or chronic, a thoughtful evaluation is needed to ensure proper management. The primary care physician needs to know how to conduct an expeditious assessment of acute severe diarrhea and coordinate a cost-effective approach to the evaluation of chronic diarrhea. Diarrhea in the HIV-infected patient requires special attention (see Chapter 13).

PATHOPHYSIOLOGY AND CLINICAL PRESENTATIONS

The pathophysiologic common denominator is increased stool water content, which may be a consequence of increased fluid secretion, decreased water absorption, or altered bowel motility. At times, several mechanisms are operative. *Increased fluid secretion* can be triggered by inflammation, hormones, or enterotoxins. The resulting secretory diarrhea has a stool volume that remains in excess of 500 mL/24 h despite fasting, a low stool osmolality, and a normal stool electrolyte concentration. *Decreased reabsorption of fluid* occurs with abnormalities of the bowel mucosa, loss of reabsorptive surface, or the presence of unabsorbable, osmotically active materials in the bowel lumen, such as lactose in patients with lactase deficiency. Patients with diarrhea resulting from decreased reabsorption typically respond to fasting with a decrease in stool volume to less than 500 mL/24 h; stool osmolality is increased, and its sodium and potassium concentrations are low. *Increased bowel motility* decreases the contact time with the bowel mucosa, limiting fluid reabsorption; it can ensue after vagotomy or may be chemically stimulated, as in hypergastrinemia or with the use of laxatives.

Acute Diarrheas

A diarrhea is categorized as "acute" if its duration is less than 2 weeks. Infectious causes dominate and include viral, bacterial, and parasitic agents. Bacteria may cause diarrhea by producing a toxin in contaminated food or after ingestion, or by invading the bowel mucosa. Some parasites invade the bowel wall, whereas others cling to it and coat the absorptive surface.

Viruses. Viral gastroenteritis has long been the most common cause of acute diarrhea in the United States, although it was not until the late 1970s that the responsible organisms were finally isolated and identified. Epidemics of viral gastroenteritis are particularly common. More than 40% of outbreaks of nonbacterial gastroenteritis investigated by the Centers for Disease Control and Prevention (CDC) during a 5-year period were linked to the *Norwalk virus*. In children, *rotavirus* infection is a common cause. Outbreaks have been found to occur during all seasons and involve water-borne, food-borne, and person-to-person modes of transmission. They last about a week. Vomiting is the prominent symptom in children, diarrhea in adults. After an incubation period of 48 to 72 hours, symptoms usually begin abruptly with diarrhea, nausea, vomiting, headache, low-grade fever, abdominal cramps, and malaise; they resolve spontaneously within 24 to 96 hours. The diarrhea tends to be predominantly secretory in quality. Abdominal examination reveals diffuse tenderness (without guarding) and hyperactive bowel sounds. The white blood cell count is usually normal but may be elevated. Stools are usually free of leukocytes, but occasionally white cells are found, as in an invasive etiology.

Staphylococcus Aureus is a common contaminant of custard-filled pastries and processed meats. The organism produces an enterotoxin that causes nausea, vomiting, abdominal cramps, and diarrhea within 2 to 8 hours after contaminated food has been eaten. Symptoms usually last less than 12 hours. A common-source pattern and lack of fever are typical.

Clostridium Perfringens is another common food contaminant, especially of foods that have been warmed on steam tables. The organism releases an enterotoxin after sporulation in the intestine. Consequently, the incubation period of 8 to 24 hours is a bit longer than that for staphylococcal food poisoning. Symptoms include diarrhea, abdominal cramps, and occasionally some vomiting. It, too, has a common-source epidemiology, and fever is absent.

Escherichia Coli 0157:H7. This pathogen is increasingly recognized as responsible for much food-borne diarrhea. It accounts for up to 2.5% of all cases of acute diarrhea and up to a third of cases of bloody acute diarrhea. Transmission to humans is usually by ingestion of contaminated meat (typically hamburger) that is undercooked. Person-to-person transmission also occurs. Peak incidence is in the summer months. The organism does not directly invade the bowel wall, but the two Shiga-like toxins it produces cause mucosal edema, ulceration, and hemorrhage. The mean incubation period is 3 days (range, 1 to 9 days). Among those who become symptomatic, presentations range from mild, crampy, nonbloody diarrhea to life-threatening hemorrhagic colitis complicated by hemolytic–uremic syndrome or thrombotic thrombocytopenic purpura. The typical presentation starts with crampy abdominal pain followed within hours by watery diarrhea that progresses to grossly bloody stools. Children, the elderly, and compromised hosts are at greatest risk.

Salmonella species cause diarrhea by invading the bowel wall. Achlorhydric patients who lack the antibacterial action of normal gastric acidity are at increased risk. The most common form of *Salmonella* infection is a self-limited diarrheal illness resulting from ingestion of contaminated food (eggs and poultry are the major sources). Children are at greatest risk; late summer and fall are the times of peak incidence. Although most episodes of salmonellosis are mild, debilitated patients are at risk for serious bacteremia. In the typical outpatient case, symptoms begin 12 to 36 hours after ingestion and resolve within 5 days, although diarrhea may persist for up to 2 weeks. The initial presentation is rather nonspecific, although indicative of a small-bowel process: watery diarrhea, cramps, nausea, vomiting, and fever. In addition to colonization, an enterotoxin is released that stimulates the secretory diarrhea. In later stages, invasion spreads to the large bowel, and leukocytes may be noted in the stool. A distinguishing feature of salmonellosis is that the leukocytes are often mononuclear cells. In severe cases, dysentery can develop.

Typhoid fever, a rare but "must-not-miss" form of *Salmonella* disease, is caused by infection with *Salmonella typhi*. About 500 cases occur in the United States each year, mostly among young people. Infections are both water-borne and food-borne. Although diarrhea develops in only a small percentage of patients with typhoid fever, it does occur. The classic and most severe form is a "pea soup" diarrhea developing in the third week of illness. Early symptoms suggestive of the condition are progressive fever, relative bradycardia, evanescent rash on the trunk ("rose spots"), splenomegaly, cough, headache, and right lower quadrant abdominal pain.

Shigella infection produces an invasive diarrheal illness. Transmission is by the fecal–oral route, and stubborn reservoirs include day care centers, Indian reservations, urban ghettos, and rural villages in developing countries. Young children are at greatest risk and often the source of infection within a family. The illness proceeds in two stages. First, colonization takes place in the small bowel, resulting in a watery diarrhea and periumbilical pain, followed in a few days by invasion of the large bowel, associated with frequent small stools, tenesmus, and polymorphonuclear leukocytes on smear. In florid cases, the patient has fever, toxicity, bloody diarrhea, nausea, vomiting, and cramps. Most often, the disease is more subtle and may be difficult to distinguish from other diarrheal illnesses accompanied by fever.

Campylobacter Jejuni infection is responsible for more cases of diarrhea in the United States than is either *Salmonella* or *Shigella*. Infection derives most often from animal sources, such as poultry and household pets; fecal transmission between people also occurs. The incubation period is 2 to 7 days. Clinically, the illness resembles that caused by *Salmonella* or *Shigella*; however, symptoms may persist longer. The relapse rate is as high as 20%, although the illness is usually self-limited and resolves within a week. In half of all cases, a Gram's stain of the stool shows characteristic curved, gram-negative rods arranged in "sea gull wing" fashion. The organism grows best on a special medium incubated at 42°C; it will not grow on plates customarily used for isolation of *Salmonella* and *Shigella*.

Yersinia Enterocolitica also causes an illness that resembles salmonellosis. Patients become infected by eating contaminated meat or dairy products. The incubation period is 12 hours to 3 days. An intense, regional lymphoid reaction may arise in the terminal ileum (the portal of entry for the organism) and result in a clinical picture of fever, right lower quadrant abdominal pain, and diarrhea that can simulate the onset of Crohn's disease. In 10% to 40% of patients, fever, arthralgias, polyarthritis, or erythema nodosum develops. The illness is usually self-limited.

Vibrio Parahaemolyticus and non–toxin-producing *Vibrio cholerae* are pathogenic species that have caused outbreaks of diarrheal disease among people eating

raw seafood, particularly oysters and sushi-style red snapper and salmon. The incubation period is measured in hours to several days. The illness that ensues is usually mild and self-limited, although an occasional patient may present with fever, nausea, vomiting, and crampy diarrhea.

Listeria Monocytogenes is another of the food-borne pathogens found increasingly in tainted processed meats and poultry products and also in unpasteurized milk products. Person-to-person transfer does not occur. About 2,000 cases per year occur in the United States. Deaths are common, with mortality rates of 20% to 30% reported. The elderly and the immunocompromised are at greatest risk. Onset of symptoms is typically 1 to 2 days after exposure. Initial symptoms resemble those of a viral gastroenteritis (fever, cramps, myalgias, diarrhea, headache). Days to weeks later, meningitis and bacteremia may ensue, especially in the immunocompromised host.

Vibrio Cholerae causes the prototypical toxin-mediated secretory diarrheal disease that results from drinking water contaminated with the organism. Most outbreaks are pandemic in the Indian subcontinent, Southeast Asia, Africa, and the Middle East. Isolated outbreaks have been reported in Mediterranean countries. In the United States, rare outbreaks sometimes occur along the Gulf coast. The disease ranges in severity from a mild illness to fulminant, life-threatening diarrhea with copious production of gray, watery, mucoid ("rice water") stool. In severe cases, fluid losses may exceed 1 L/h and are accompanied by vomiting, muscle cramps, and severe thirst. Because it is a noninvasive diarrhea involving the small bowel, cholera does not cause tenesmus, and the stool contains no leukocytes. Dehydration, serious volume depletion, and a metabolic acidosis may ensue. In mild cases, the patient reports painless, nonbloody diarrhea of abrupt onset.

Bacillus Cereus is a toxin-producing bacterial contaminant of rice and bean sprouts. One form of toxin-induced illness leads to vomiting but no diarrhea; another is characterized by severe abdominal cramping and diarrhea. The incubation period is 8 to 16 hours after ingestion of contaminated food. The symptoms are self-limited.

Entamoeba Histolytica usually exists in a commensal relationship with its host, and most patients harboring the protozoan are asymptomatic carriers. Occasionally, this relationship breaks down and the ameba invades the colonic wall; an acute bloody diarrhea is the result. The clinical presentation ranges from mild to fulminant illness. Occasionally, the illness is mistaken for inflammatory bowel disease (see Chapter 73) and may have a protracted course with exacerbations and remissions. Asymptomatic carriers such as returning tourists and immigrants are often the source of infection in developed countries. Because the organism does not have a soil phase, amebiasis is not restricted to warmer climates. Well-documented outbreaks have occurred in the United States and Europe, in addition to those that originate in developing countries. Amebiasis can be spread by sexual contact and is prevalent among promiscuous homosexuals.

Giardia Lamblia ranks as a leading parasitic cause of diarrhea, especially overseas but also in the United States. Infection with the flagellated protozoan is particularly common where water supplies are contaminated by human sewage, but the organism is also endemic to such areas as the Rocky Mountains and St. Petersburg, Russia. The exact means by which *Giardia* causes diarrhea remains unsettled, although heavy infestations can lead to malabsorption by coating large areas of the small bowel, particularly the lower duodenum and upper jejunum. The majority of patients with giardiasis are asymptomatic, but the organism is being recognized more frequently as an important cause of acute, intermittent, and chronic diarrheas in the United States. The ensuing loose stools may be watery or greasy; mucus is often present, but blood is rare. The patient may complain of epigastric or periumbilical discomfort. Mild steatorrhea and malabsorption occur with heavy parasite burdens.

Cryptosporidium, Microsporidia, and Other Protozoans are increasingly recognized as causes of acute watery diarrhea (and sometimes of chronic disease). Point-source outbreaks occur in addition to sporadic cases. Transmission is by person-to-person contact through stool or by water or food contaminated with the spore or oocyst forms of the organism. Intestinal inflammation may develop. Children and immunocompromised adults are at greatest risk for severe and prolonged illness. A profuse, watery diarrhea can develop, with stool volumes that may exceed 3 L daily. Although the illness is usually self-limited, it may persist in immunocompromised hosts. A mild illness develops in otherwise healthy, immunocompetent patients; they may become infected during occupational contact (e.g., animal dung). For them, symptoms resolve spontaneously within 5 to 21 days.

Diarrhea in HIV-infected Patients is a major problem, with a host of possible etiologies (see Chapter 13). In HIV-infected persons who engage in receptive anal intercourse, the presentation may be one of diarrhea, tenesmus, and rectal pain. In this setting, polymicrobial etiologies are not uncommon and may include *Neisseria, Giardia, E. histolytica, Campylobacter, Chlamydia, Shigella, Salmonella*, and protozoans.

Traveler's Diarrheas

Patients traveling from industrialized to developing nations are at considerable risk for the development of diarrhea. Etiologic agents include *E. coli, Salmonella, Shigella, E. histolytica, G. lamblia, S. typhi*, and *V. cholerae*. Invasive *E. coli* strains can also cause a dysentery syndrome. Although most cases of traveler's diarrhea are associated with travel to developing nations, this is not always true. For example, there is substantial risk of giardiasis with travel to St. Petersburg, Russia, or even to the Rocky Mountains of the United States.

Toxigenic Escherichia coli is responsible for a large proportion of cases labeled as "traveler's diarrhea" or "turista." The agent is transmitted by poor food-handling practices and contaminated water. With enterotoxin production, a watery diarrhea ensues because the toxin promotes fluid secretion in the small bowel.

Drug-induced Diarrheas

Substances associated with diarrhea are listed in Table 64.1.

Table 64.1. Differential Diagnosis of Diarrhea

Acute Diarrhea. Mechanisms of acute diarrhea include excessive fluid secretion (*alcohol, phenolphthalein*, and *castor oil*), reduction of fluid absorption (*magnesium*-containing antacids), and stimulation of bowel motility (*caffeine*-containing beverages and *herbal teas*). An osmotic diarrhea with crampy pain and watery stools may follow oral or parenteral use of *broad-spectrum antibiotics*, which disrupt the salvage of unabsorbed carbohydrate by killing normal colonic flora.

Chronic Diarrhea: Pseudomembranous Colitis. Broad-spectrum antibiotics can cause chronic diarrhea by promoting overgrowth of toxin-producing species such as *Clostridium difficile*. The antibiotics most often responsible are *ampicillin* and *clindamycin*, but other broad-spectrum agents have also been implicated. Immunocompromised patients, the elderly, and those with underlying bowel disease are most susceptible. Pseudomembranous colitis is characterized by fever, abdominal pain, profuse watery stools, and fecal leukocytes. Symptoms may range from mild to severe, usually starting after the initiation of a course of antibiotics, but onset can be delayed for as much as 4 to 8 weeks after cessation of antibiotics. Symptoms may persist for months, mimicking inflammatory bowel disease. The sigmoidoscopic finding of nodular, inflammatory ulcers or yellow-white mucosal plaques is characteristic.

Chronic and Recurrent Diarrheas

Although the number of etiologies is vast, consideration of a few exemplary conditions provides a good sense of the range and types of presentations.

Irritable Bowel Syndrome is the most common of the motility disorders responsible for chronic diarrhea or hyperdefecation (see Chapter 74). It can present as diarrhea alternating with constipation, or as chronic, recurrent diarrhea. Some studies report a high frequency of associated psychiatric disease. In addition to diarrhea and constipation, patients may complain of distention, cramping, and mucus-laden stools. The condition waxes and wanes over many years. Neither fever nor fecal leukocytes are present. Any rectal bleeding that may occur is secondary to anal trauma resulting from straining and passage of hard stool.

Inflammatory Bowel Diseases are typical of the diarrheas that result from inflammatory destruction of the bowel wall (see Chapter 73). Abdominal pain, bloody stools, purulent discharge, and fever are seen in patients with active disease affecting the large bowel. Extraintestinal manifestations may involve the skin, joints, liver, and heart. Microscopic examination of the stool reveals red cells and leukocytes.

Diabetic Enteropathy results from diabetes-induced autonomic neuropathy (see Chapter 102). When the small bowel is involved, the ensuing stasis allows bacterial overgrowth. The bacteria deconjugate bile acids, which leads to fat malabsorption. With involvement of the large bowel, the patient experiences distressing nocturnal diarrhea. Postural hypotension, impotence, and other symptoms and signs of autonomic insufficiency may accompany the diarrhea and suggest the diagnosis.

Dumping Syndrome is another motility disorder, seen most commonly in patients who have undergone vagotomy and gastroenterostomy. Patients complain of sweating, postural light-headedness, tachycardia, and diarrhea following meals. Concentrated carbohydrates are most likely to trigger symptoms. Lying down minimizes symptoms, as does avoidance of concentrated sweets. Onset of the syndrome is shortly after surgery, and symptoms usually subside within 12 months,although they may persist. Besides dysmotility, osmotic factors may contribute, but their precise role remains unclear.

Villous Adenoma of the rectosigmoid causes a secretory, noninflammatory chronic diarrhea. Watery diarrhea, independent of food and fluid intake, is typical; severe potassium depletion can result. In some patients with this tumor, excessive secretion of mucus occurs, with loss of sufficient protein to produce hypoalbuminemia and a protein-losing enteropathy syndrome.

Malabsorption of Fat or Carbohydrate can lead to an osmotic diarrhea, as occurs in patients with *pancreatic inefficiency, sprue*, and *short-bowel* syndrome. Some of the osmotically active substances may also stimulate increased bowel secretion of fluids and electrolytes. Malabsorption of fat characteristically presents as *steatorrhea* (foul, bulky, greasy stools). Patients may note that the stools seem to be "sticky" and difficult to flush down the toilet. Steatorrheic stools "float," not because of their fat content but because of an increase in trapped gas. Associated symptoms are a function of the severity of the caloric and vitamin deficiencies that ensue and may include weight loss, ecchymoses, bone pain, glossitis, muscle tenderness, and peripheral neuropathy. Cramping lower abdominal pain typically precedes bowel movements. Early concerns about severe diarrhea and abdominal pain associated with the regular use of *Olestra*, a nonabsorbable sucrose ester fat substitute used in snack foods, have not been confirmed in randomized, prospective, controlled trials.

Lactase Deficiency (Milk Intolerance) leads to malabsorption of lactose and an osmotic diarrhea. It is particularly common among African-Americans, Indians, Asians, and Jews. Onset is typically in adulthood. A secondary form of the disease may develop in patients with extensive disease of the small bowel. Patients report nausea, bloating, cramps, and diarrhea after ingesting more than their customary intake of milk products. Weight loss and steatorrhea are absent or mild; appetite remains good. Avoidance of milk products (except for yogurt containing live cultures, which provide lactase) terminates symptoms. Diagnosis may be confirmed by a trial of abstinence and by abnormal results on lactose tolerance testing or hydrogen breath testing (which detects excessive hydrogen production resulting from bacterial metabolism of undigested lactose).

Laxative Abuse is an important etiology of chronic diarrhea. Patients with bulimia (see Chapter 234) tend to use laxatives constantly and surreptitiously in a relentless attempt to lose weight. Depending on the type of agent used, either a secretory or osmotic diarrhea may develop. Agents associated with secretory diarrheas include castor oil and phenolphthalein preparations. Osmotic diarrheas occur when the patient takes a preparation that contains magnesium (e.g., milk of magnesia) or another poorly absorbable substance. These substances appear in the stool and can be tested for if laxative abuse is suspected. Patients who abuse laxatives may present with unexplained dehydration, electrolyte depletion, or preoccupation with weight loss.

Lymphocytic Colitis and Collagenous Colitis. These two new conditions associated with refractory chronic diarrhea have recently been recognized. They occur predominantly in women and cause chronic watery diarrhea, often complicated by steatorrhea and malabsorption. The colonic appearance is grossly normal, but biopsy reveals collagenous or lymphocytic infiltrates. The small bowel usually is normal but may show spruelike changes in patients with lymphocytic disease, and persons with the condition may present with spruelike malabsorption unresponsive to a gluten-free diet.

Bile Acid Diarrhea is seen after cholecystectomy and ileal reaction. It is an irritant diarrhea caused by the action of excessive bile acids on the bowel and responds to bile acid sequestrants (e.g., cholestyramine).

Incontinence

A number of patients who complain of "diarrhea" actually suffer from incontinence. Typically, their stool volumes are normal (< 2.5 mL/d), although their stools may be soft poor sphincter tone and evidence of stool incontinence are found on physical examination.

DIFFERENTIAL DIAGNOSIS

Acute Diarrhea. The differential diagnosis for acute diarrhea is dominated by infectious agents (Table 64.1). Viruses are the single most important frequent cause. Staphylococcal toxin, clostridial toxin, and ingestion of *Campylobacter*, *Salmonella*, *Shigella*, and enteropathogenic *E. coli* are common bacterial etiologies. Of increasing importance are the potentially life-threatening outbreaks of food-borne disease caused by toxin-producing *E. coli* 0157:H7, *Listeria*, and protozoans such as *Cryptosporidium. Giardia* and amebae are less frequent sources of acute diarrhea in the United States. Drug-induced acute disease is associated with the use of antibiotics, laxatives, magnesium-containing antacids, and agents such as quinidine. Alcohol and caffeine-containing beverages should be considered. Most causes of chronic diarrhea are also capable of causing acute presentations.

Traveler's Diarrhea. In more than 50% of acute cases, the cause is exposure to enterotoxigenic *E. coli*. Most of the remainder are accounted for by *Salmonella, Shigella, Giardia*, or *Campylobacter*.

Chronic Diarrhea. The differential diagnosis is even more extensive (Table 64.1) and includes causes of acute disease that may become chronic (e.g., laxative abuse, pseudomembranous colitis, protozoan infections, amebic infestations) in addition to a host of intrinsic bowel diseases. A *malabsorption* picture may be the consequence of sprue, bile salt deficiency, lactase deficiency, intestinal lymphoma, Whipple's disease, pancreatic insufficiency, or the newly recognized collagenous and lymphocytic forms of colitis. *Postsurgical* diarrhea may reflect postgastrectomy dumping syndrome, fistulas, blind loops, loss of parasympathetic innervation, extensive bowel resection, or excessive bile acid. Diarrhea with *bleeding* may herald neoplasms and inflammatory bowel disease. Diarrhea *alternating with constipation* may be caused by irritable bowel syndrome, Crohn's disease, or diverticular disease of the bowel. A variety of *extraintestinal conditions* may be responsible, including cirrhosis, alcoholism, pellagra, and heavy metal intoxications from lead, mercury, or arsenic. Endocrinopathies also must be considered (e.g., diabetes mellitus, Addison's disease, hyperthyroidism).

Diarrhea of Unknown Etiology. In studies of patients referred for chronic diarrhea of unknown etiology, the vast majority turn out to be abusing laxatives or to have a subtle form of inflammatory bowel disease (including collagenous or lymphocyticvarieties) or irritable bowel syndrome. Most of the remainder have a more readily diagnosed condition that was overlooked on initial evaluation.

Diarrhea in the HIV-Infected Patient. The common infectious causes are frequently seen, but such uncommon causes as *Cryptosporidium, Mycobacterium avium–intracellulare*, herpes simplex virus, cytomegalovirus, *Neisseria gonorrhoeae, Giardia*, and *Chlamydia trachomatis* must also be considered (see Chapter 13).

WORKUP

Before embarking on a workup, one needs to confirm that the problem is indeed diarrhea and not simply an occasional loose stool or frequent defecation of formed stools. Stool volume, frequency, and water content should all be increased.

Acute and Traveler's Diarrheas

History. The *nature of the bowel movements* should be determined, including their frequency, consistency, volume, and the presence of gross blood, pus, or mucus (Table 64.2 and Table 64.3), and the presence of any *associated symptoms*, such as fever, rash, and abdominal pain, should be noted. Late onset of neurologic deficits or meningeal symptoms should suggest listeriosis.

	NATURE OF DIARRHEA			ASSOCIATED SYMPTOMS AND SIGNS	EPIDEMIOLOGIC DATA	LABORATORY RESULTS
ETIOLOGY	WS	OB	GB			

Table 64.2. Important Features of Some Acute Diarrheas

	NATURE OF DIARRHEA			ASSOCIATED SYMPTOMS AND SIGNS	EPIDEMIOLOGIC DATA	LABORATORY RESULTS
ETIOLOGY	WS	OB	GB			
Escherichia coli	+/-	-	-	Usually no fever, although occasionally toxicity	Contamination of water, food	Stool WBC -; can also be +
Entamoeba histolytica	+/- Dysentery			Can simulate inflammatory bowel disease; asymptomatic carriers	Returning tourists, immigrants	Stool + for o & p + serology
Giardia	-/+	+/-	+/-	Upper abdominal pain	Contamination of water supply	Stool + for o & p
Vibrio cholerae	+/- "Rice water"	-	-	Marked dehydration, cramps, vomiting	Contamination of water supply	Stool WBC -
Shigella	See Table 64-2					
Salmonella	See Table 64-2					

WS, watery/out; OB, occult blood; GB, gross blood; WBC, white blood cells; o & p, ova and parasites.

Table 64.3. Important Features of Traveler's Diarrheas

Epidemiologic Information is critical because the clinical presentation is often nonspecific. Reviews of travel (both international and domestic), personal contacts, and food intake are essential. Among the foods to consider are custard-filled pastries, undercooked processed meats, foods warmed on steam tables, eggs, poultry, raw seafood, unpasteurized milk and fruit juices, rice, and bean sprouts. Important contacts include children who attend day care centers because they may contract rotavirus, *Giardia, Shigella, Cryptosporidium*, or *Campylobacter*. A *sexual history* is indicated if there is concern about polymicrobial infection.

Onset and Associated Symptoms. Diarrhea occurring within hours of ingestion of a potentially contaminated food is suggestive of food poisoning, which is confirmed if others have been similarly affected. Food-borne illness with a short incubation period and no *fever* indicates ingestion of a preformed enterotoxin. Fever and a slightly longer incubation period are characteristic of an infectious etiology (Table 64.3). Some toxin-producing organisms (e.g., *E. coli* 0157:H7) require a few days of incubation.

Drug History. It is particularly important to question about the use of laxatives, magnesium-containing antacids, excess alcohol, caffeine-containing beverages, herbal teas, antibiotics, digitalis, quinidine, loop diuretics (furosemide, ethacrynic acid), antihypertensive agents, and excessive intake of sorbitol-containing "sugar-free" gums and mints.

Physical Examination. Vital signs must be checked. Postural hypotension is a sign of significant volume depletion and an indication for prompt IV repletion. Any elevation in temperatureor loss of weight also needs to be noted. The patient who appears markedly dehydrated or toxic is a candidate for hospital admission. The skin is examined for manifestations of sepsis; the macular "rose spot" rash on the trunk is an important clue for typhoid. The lymph nodes are checked for enlargement, and the abdomen for tenderness, guarding, rebound, abnormal bowel sounds, organomegaly, and masses. A rectal examination and fecal occult blood test complete the physical evaluation. When listeriosis is suspected epidemiologically, a careful neurologic examination is in order, with a search for focal deficits and meningeal signs.

Laboratory Studies: Initial Evaluation. The laboratory workup should be individualized. The patient who feels well except for frequent loose stools requires no immediate laboratory testing. On the other hand, the patient who is ill with fever, nausea, abdominal cramps, or other systemic symptoms requires more extensive evaluation, beginning with a stool test for leukocytes, which indicates a potentially serious etiology.

Stool Testing for Leukocytes. A drop of the sample is placed on a microscope slide, mixed thoroughly with two drops of *methylene blue* solution (or Wright's or Gram's stain), and topped with a cover slip for viewing under the microscope. Finding large numbers of white cells suggests an inflammatory or invasive diarrhea, such as occurs with *Shigella, Salmonella, Campylobacter*, invasive or certain toxigenic *E. coli*, and *Entamoeba*. The presence of mononuclear cells is characteristic of salmonellosis. An occasional white cell is of no pathologic significance. Leukocytes may be absent from the stool in the early phases of shigellosis and pseudomembranous colitis.

Gram's Stain of the Stool will provide etiologic information in selected instances, such as suspected *Campylobacter* infection. In about half of cases, the Gram's stain will demonstrate gram-negative rods arranged in a characteristic sea gull wing configuration.

Stool Cultures. Cultures are usually not necessary in acute diarrhea because most cases are self-limited. However, if the patient appears ill and either occult blood or leukocytes are present in the stool, then *bacterial cultures* should be obtained. Detection of *Campylobacter* or *Yersinia* requires plating on specific medium at 42°; the usual medium for *Salmonella* and *Shigella* will not suffice. The laboratory should be notified when *E. coli* 0157:H7 is a consideration because special growth media and other procedures are required to identify the pathogen.

Sigmoidoscopy. Patients with gross blood or large numbers of leukocytes in the stool and severe illness should undergo sigmoidoscopy to examine the appearance of the colonic mucosa; samples of the mucosa and cultures can also be obtained (see following section on the workup for chronic diarrhea for details). Preparatory enemas and cathartics should be avoided so as not to distort the appearance of the bowel wall (see Chapter 56).

Laboratory Studies: Subsequent Evaluation. If the diarrhea persists for 2 weeks or more, a secondary evaluation is indicated. *Stools* should once again be examined for *blood* and *leukocytes*. A second stool should be sent for bacterial *culture*, and a fresh specimen should be examined for ova and parasites.

Stool for Ova and Parasites. Ova and parasite examinations are fraught with limitations that must be kept in mind. If *giardiasis* is a consideration, at least three stool samples are necessary because excretion of the organism is intermittent. Many primary care physicians use a therapeutic trial of metronidazole when they strongly suspect giardiasis. Identifying *E. histolytica* trophozoites by stool examination can be difficult; their visualization is easily impaired by the presence of barium, bismuth, and kaolin compounds. False-negative results of stool examinations also can be caused by the use of preparatory enemas (which lyse the organism) and antibiotics

(tetracycline and sulfonamides reduce shedding of trophozoites into the stool).

Other Studies. If symptoms persist and the diagnosis remains uncertain, the patient requires further assessment for a chronic or recurrent diarrheal syndrome (see below). Persons in whom neurologic deficits or meningeal signs develop after a diarrheal illness require culturing of the *blood* and *cerebrospinal fluid* for *Listeria*.

Chronic or Recurrent Diarrhea

History. Diarrhea lasting 4 weeks or more or a pattern of recurrent diarrhea requires an etiologic assessment (Table 64.1).As in acute diarrhea, *characterization of the diarrhea* and elicitation of any *associated symptoms* are important (Table 64.4).

Table 64.4. Features of Representative Chronic Diarrheas

Suggestive Patterns. A few patterns are suggestive. Frequent passage of *small volumes* of loose stools in association with left lower quadrant crampy abdominal pain or tenesmus points to rectosigmoid pathology. *Large volumes* of loose stools in conjunction with periumbilical or right lower quadrant pain indicate disease of the small bowel, as does diarrhea occurring *shortly after a meal* or ingestion of certain foods. Diarrhea following meals should also lead to a search for malabsorption, an osmotic etiology, the dumping syndrome, or a fistula. The presence of *foul, bulky, greasy* stools further supports the diagnosis of fat malabsorption. *Bloody stools* require investigation for neoplasm, invasive infection, and inflammatory bowel disease. The presence of *fever* has similar diagnostic implications. *Frothy stools* and *excessive flatus* are signs of fermentation of unabsorbed carbohydrates, as occurs in giardiasis. *Alternating diarrhea and constipation* point to irritable bowel syndrome, as does mucus in the stool. The absence of intermittent constipation in a patient with chronic diarrhea does not rule out the diagnosis.

Travel in conjunction with diarrhea that persists for more than 2 weeks raises the possibilities of giardiasis and amebiasis; pseudomembranous colitis is a consideration if the traveler has recently taken antibiotics. The slow resolution of traveler's diarrhea suggests postdysentery lactase deficiency and postdysentery irritable bowel syndrome.

Drugs. A thorough review of drug intake is mandatory; especially important is a check for *antibiotic use*, even if it was a few months before the onset of symptoms. A history of surreptitious *laxative abuse* may be hard to elicit, but inquiring gently and nonjudgmentally about feelings of low self-esteem and a poor body image may provide suggestive information when a young, intense woman presents with chronic diarrhea and wasting.

Prior Surgery. Previous abdominal surgery should be specified, with any procedures that may have produced blind loops and allowed for bacterial overgrowth noted.

Physical Examination. Any fever, dehydration, postural hypotension, or cachexia should be noted. The skin should be inspected for jaundice, pallor, rash, and manifestations of inflammatory bowel disease. The abdomen is examined for distention, ascites, hepatomegaly, tenderness, rebound, and masses. Rectal examination may reveal fecal impaction, perirectal fistula, or a patulous anal sphincter. Stool is tested for occult blood.

Laboratory. Blood tests are helpful but rarely diagnostic. They should include a *complete blood cell count* for evidence of anemia and leukocytosis and determinations of *serum electrolytes* to detect serious losses and imbalances, *amylase* for pancreatic disease, *liver function tests* and *prothrombin time* for hepatobiliary disease, and *serum calcium* and *glucose* for metabolic conditions that can lead to diarrhea. Eosinophil counts are normal in most parasitic infections that cause diarrhea. (The only gastrointestinal parasites that stimulate peripheral eosinophilia are worms.)

Examination of Stool for White and Red Blood Cells. See above. If blood or pus is in the stool, or other evidence of rectosigmoid pathology is present, then one should proceed to sigmoidoscopy (see below).

Other Stool Tests. Additional stool testing can be helpful in selected instances. For suspected laxative abuse, one *alkalinizes the stool*; if it contains phenolphthalein (a common ingredient of many over-the-counter laxatives), it will turn pink. For suspected fat malabsorption, a stool sample is subjected to Sudan stain for *qualitative detection of fat*. Those with a positive result on qualitative study are candidates for a *72-hour quantitative stool fat determination*. Normally, stool fat should not exceed 6% of the daily fat intake. Stool fat in excess of 6 g/d while the patient is on a test diet of 100 g of fat per 24 hours indicates fat malabsorption.

Sigmoidoscopy performed without cleansing enemas is a potentially definitive procedure in persons suspected of having inflammatory bowel disease and amebiasis and helps differentiate such conditions from irritable bowel syndrome (see appendix to Chapter 56). The presence of mucosal ulceration, plaques, friability, and bleeding should be noted. The finding of mucus in the absence of evidence of inflammation helps confirm the diagnosis of irritable bowel syndrome, whereas the presence of pus directs the evaluation toward infection and inflammation. Nodular inflammatory ulcers and yellow-white mucosal plaques are characteristic of pseudomembranous colitis. Ulceration is also noted with inflammatory bowel disease and amebic colitis. If Crohn's disease or chronic neoplasia is suspected, *colonoscopy* should be substituted for sigmoidoscopy. Pseudomembranous colitis and amebic disease may produce an endoscopic appearance similar to that of inflammatory bowel disease, so that additional testing is necessary (see below).

Barium Enema and Upper Gastrointestinal Series best demonstrate anatomic abnormalities (blind loops, fistulas, and tumors). A barium enema is an alternative to colonoscopy when inflammatory bowel disease and malignancy are being considered, but the test is not as sensitive and does not allow for biopsy or mucosal sampling. Moreover, amebiasis can simulate inflammatory bowel disease. Because barium obscures the identification of ova and parasites, stool collections must be complete before a barium study is obtained.

Stool for C. difficile Toxin. Patients with recent antibiotic exposure and an inflammatory exudate on sigmoidoscopy require evaluation for pseudomembranous colitis. Up to three stool samples should be assayed for *C. difficile* toxin to maximize sensitivity, although it must be understood that some patients without disease harbor the organism and might show detectable amounts of toxin in the stool.

Mucosal Smears and Stool for Ova and Parasites. If ulceration of the rectosigmoid mucosa is present and *amebic disease* is suspected on the basis of epidemiologic data, fresh mucosal smears should be prepared. Proper technique for the identification of *trophozoites* involves sampling the periphery of the ulcers with a glass rod or metal spatula; cotton swabs are inadequate because the organisms adhere too firmly and do not readily transfer to a slide. Multiple stool examinations for ova and parasites can also be ordered. False-negative results of examinations for trophozoites are common and can be associated with the administration of preparatory enemas, recent exposure to antibiotics, and the concurrent use of barium, bismuth, or kaolin. To detect spore-forming organisms (i.e., *Cryptosporidium*, others), one needs to request that the stool be examined specifically for *spores* and *oocysts*.

Other patients who should have their stools examined for ova and parasites include those who have traveled to areas endemic for *Giardia*, homosexual men, and immunocompromised hosts, including persons with AIDS (who are at risk for harboring a host of pathogens, including *Cryptosporidium*; see below). Fresh loose stools are needed for identification of trophozoites; less fresh specimens can be used for detection of ova. Several stool examinations may be necessary.

Serologic Testing for Amebic Disease. When amebic disease is seriously suspected clinically and epidemiologically, yet results of examinations for ova and

parasites are negative, serologic testing is indicated. The standard test is an indirect hemagglutination assay. A positive titer is in excess of 1:128. It takes 2 to 4 weeks for seroconversion to occur. By the time most patients with amebic disease present with diarrhea, they are seropositive. The test is 85% sensitive in the setting of intestinal disease and 95% sensitive with extraintestinal spread. The test works best in nonendemic areas, where most people are seronegative.

Additional Testing for Giardia. Sometimes, *small-bowel aspiration* or even *biopsy* may be necessary to establish the diagnosis of giardiasis or cryptosporidiosis. *Immunologic assay of the stool* based on ELISA (enzyme-linked immunosorbent assay) technology can identify *Giardia* antigen with high sensitivity and specificity (92% and 98%, respectively); the test is rapidly obviating the need for biopsy and aspiration.

Therapeutic Trials sometimes substitute for more elaborate studies. As noted above, cessation of diarrhea in response to *restriction of milk products* strongly supports the diagnosis of lactose intolerance. Other recognized empiric trials include a course of *antibiotic therapy* in patients suspected of blind loop syndrome, and use of *pancreatic enzymes* in patients believed to have pancreatic insufficiency. The once common trial of *metronidazole* for patients with suspected giardiasis is being deferred in favor of sensitive ELISA stool testing for *Giardia* antigen. Some patients are given empiric trials of a gluten-free diet, but bowel biopsy is preferred.

Diarrhea in the AIDS Patient

Often, patients with AIDS experience acute or chronic diarrhea. They especially are susceptible not only to the common pathogens but also to such uncommon ones as *Cryptosporidium, M. avium–intracellulare*, herpes simplex virus, cytomegalovirus, *N. gonorrhoeae*, and *C. trachomatis*. Evaluation should focus on finding the pathogen and may require sigmoidoscopic biopsy to obtain tissue for viral or mycobacterial culture (see Chapter 13).

Chronic Diarrhea of Unknown Etiology

The leading possibilities are surreptitious laxative abuse, subtle forms of inflammatory bowel disease, and irritable bowel syndrome. Laxative abuse should be considered in young, professional women who are preoccupied with their weight and have low self-esteem and a poor body image (see Chapter 234). An otherwise unexplained *hypokalemia* is also suggestive. Collagenous and lymphocytic forms of colitis must be considered in women who present with chronic watery diarrhea complicated by steatorrhea and malabsorption, especially those who are thought to have sprue but fail to respond to a gluten-free diet. Irritable bowel syndrome is suggested by the presence of abdominal pain in addition to diarrhea. Although inpatient assessment is often needed, outpatient evaluation can be tried and may obviate the need for hospitalization. Stool analysis and colonoscopy with biopsy are the two most helpful studies.

Stool Analysis. One attempts to characterize the type of diarrhea further by determining *stool volume*, *osmolality*, and *electrolyte content*. A stool volume of less than 200 mL/d is strongly suggestive of irritable bowel syndrome. Osmotic diarrheas show increased stool osmolality and low sodium and potassium concentrations. The differential diagnosis of osmotic diarrhea includes ingestion of nonabsorbable solutes (magnesium, bran), maldigestion of food, and malabsorption of osmotically active substances (e.g., carbohydrates). Stool volumes in excess of 1 L/d indicate a secretory diarrhea. Occult causes include surreptitious laxative abuse, villous adenoma, carcinoid syndrome, pancreatic cholera (from secretion of vasoactive intestinal peptide), and other rare conditions.

Bowel Biopsy. Because the appearance of the bowel in *collagenous colitis* and *lymphocytic colitis* is grossly normal on endoscopic examination, biopsy is required for diagnosis. Biopsy should be considered in women with unexplained watery diarrhea, especially if complicated by steatorrhea and malabsorption. The small bowel usually is normal but may show spruelike changes in patients with lymphocytic disease.

Inpatient Study. The next step for patients whose condition remains undiagnosed is inpatient evaluation with imposition of a 24- to 72-hour fast and IV hydration. The fast helps to differentiate between osmotic and secretory causes; with the former, diarrhea ceases or is markedly reduced during fasting. Stool analysis is repeated under conditions of fasting and standardized diets.

PRINCIPLES OF MANAGEMENT

Acute Diarrheas

Hydration. The vast majority of cases of acute diarrheal illness should be managed by *maintaining hydration* and waiting for the spontaneous resolution of symptoms. Often, hydration can be maintained with oral fluids, even in cases of profuse diarrhea. Solutions rich in electrolytes and sugar facilitate absorption of water. An 8-oz glass of *fruit juice* to which are added a pinch of table salt and half a teaspoon of honey or a teaspoon of table sugar makes a well-tolerated replacement solution. Nondiet *cola drinks* that have been allowed to stand and lose their carbonation are a reasonable substitute. Either can be taken along with a similarly sized glass of water containing one fourth of a teaspoon of baking soda to replenish losses in stool electrolytes, which in acute infectious diarrhea are sodium (125 mEq/L), potassium (20 mEq/L), bicarbonate (45 mEq/L), and chlorine (90 mEq/L). If adequate hydration cannot be maintained orally, IV therapy is necessary.

Absorbent Preparations are commonly used for symptomatic therapy of simple acute diarrhea. Solutions of *kaolin* and *pectin* have no proven benefit but seem to be harmless; however, they should not be relied on for the treatment of severe diarrhea. Doses of *bismuth subsalicylate (Pepto-Bismol)* in excess of those recommended on the bottle (e.g., 2 to 3 tablespoons every 3 hours) are sometimes effective (see below).

Inhibition of Motility. *Opiates such as diphenoxylate* (dispensed as a combination with small amounts of atropine [Lomotil] to discourage abuse) and *loperamide* (Imodium) are effective in the symptomatic treatment of diarrhea by directly inhibiting the motility of the intestinal smooth muscle. Diphenoxylate and loperamide are derived from meperidine but have less effect on the central nervous system. They should be used cautiously, if at all, in conditions in which toxic megacolon is possible (e.g., inflammatory bowel disease). Their use should also be restricted in certain bacterial diarrheas, such as shigellosis, to avoid prolonging the clinical course. There is also concern for their use in outbreaks of *E. coli* 0157:H7 infection, in which an increased risk for complications has been noted.

The usual dosage of diphenoxylate is 2.5 to 5 mg every 4 hours, up to 20 mg daily. Loperamide is given as 2 or 4 mg every 4 hours, up to 16 mg daily. Lower maintenance doses are often sufficient after initial control has been achieved. Other opiates are potent antidiarrheal agents but carry a higher risk for addiction; they are useful when their coincident analgesic activity is needed. Deodorized tincture of opium (0.5 to 1 mL), paregoric (4 mL), or codeine (30 to 60 mg) can be given orally every 4 hours. *Anticholinergics* are useful only for irritable bowel syndrome (see Chapter 74).

Antibiotics. The *empiric use* of antibiotics is not recommended routinely for acute bacterial diarrheas because most infections are self-limited. Empiric antibiotics have a minimal effect on the course of illness (with the exception of shigellosis outbreaks) and may prolong the asymptomatic bacterial carrier state, especially with *Salmonella* infection. Moreover, one risks triggering an antibiotic-induced diarrhea and inducing antibiotic resistance (e.g., in *Campylobacter*). Antibiotics may also be counterproductive in *E. coli* 0157:H7 infection, in which their use has been associated in some instances with an increased risk for complications.

Antibiotics are best reserved for very ill patients who demonstrate positive stool cultures or other evidence for a specific bacterial etiology (e.g., typhoid fever, salmonellosis, shigellosis, pseudomembranous colitis, *Campylobacter* infection, and *Yersinia* infection).

Salmonella. Elderly patients and others who would be endangered by a *Salmonella* bacteremia (persons with vascular prostheses or sickle cell anemia) should receive a course of antibiotics to limit metastatic infection. *Bacteremia* and *typhoid fever* can be treated with parenteral *ampicillin* or oral *chloramphenicol*; in milder cases, oral *trimethoprim/sulfamethoxazole* (one double-strength tablet of TMS twice daily for 2 weeks) suffices.

Shigella. Patients with severe dysentery caused by shigellosis can be treated with oral *amoxicillin* (500 mg three times daily for 3 to 5 days), but antibiotic sensitivity testing is needed because amoxicillin-resistant strains are common. *TMS* (one double-strength tablet twice daily for 3 to 5 days) is an excellent alternative. Pending stool culture results, a few days of empiric therapy for shigellosis is reasonable if the epidemiologic history is suggestive and the patient is experiencing severe bloody diarrhea. Antiperistaltic drugs are contraindicated.

Campylobacter is sensitive to oral *erythromycin* (500 mg four times daily for 7 days). Most patients with *Yersinia* infection have a self-limited illness, but toxic patients are candidates for oral *chloramphenicol* (50 mg/kg daily in four divided doses for 7 days) or parenteral therapy.

Pseudomembranous Colitis usually resolves without antibiotic treatment, but oral *vancomycin* in a liquid suspension (as little as 125 mg four times daily for 7 to 10 days) and *metronidazole* (250 mg three times daily for 5 to 10 days) have proved equally capable of controlling the disease, although relapses occur in 10% to 20%,

so that retreatment is necessary. Metronidazole is preferred for initial use because it is far lessexpensive. *Cholestyramine* (one packet in water three times daily) is used in conjunction with antibiotics to help bind the enterotoxin; it has proved useful in difficult cases, as have *rifampicin* and *bacitracin*.

Parasitic Infection. Symptomatic patients with diarrhea caused by parasitic infection also benefit from definitive antimicrobial therapy. *E. histolytica* responds to *metronidazole* (750 mg three times daily for 5 to 10 days) for treatment of trophozoites and *diiodohydroxyquin* (650 mg three times daily for 21 days) for elimination of cysts. *Giardiasis* is treated with quinacrine (100 mg three times daily for 7 days) or metronidazole (250 mg three times daily for 7 to 10 days). Retreatment is often necessary.

Traveler's Diarrhea

Prevention. Although much attention has been given to pharmacologic agents for prophylaxis, care in what one eats and drinks remains the single most important means of preventing traveler's diarrhea. Use of local water supplies should be avoided when they are in question. This includes foregoing fresh vegetables, which may have been washed in such water, and even ice cubes. Drinking bottled water is preferable.

Chemoprophylaxis. Because the majority of "turista" cases are caused by enterotoxigenic *E. coli*, chemoprophylaxis has been directed at this organism. *TMS* (one double-strength tablet daily) and *ciprofloxacin* (500 mg daily) can reduce the risk for diarrhea, which ranges from 20% to 30%. For symptomatic relief of acute diarrhea, ciprofloxacin (500 mg twice daily for 3 days) is effective, as is TMS (one double-strength tablet twice daily). Some resistance to TMS is emerging, making ciprofloxacin the preferred agent. *Doxycycline*, a tetracycline derivative, taken on the day of travel (200 mg) and daily (100 mg) while away has also proved useful, although as many as 40% of the toxigenic *E. coli* strains are resistant to the drug, and the drug often causes gastrointestinal upset and photosensitivity. The prophylactic use of antibiotics had been in vogue, but the growing awareness of antibiotic-induced diarrhea, the high frequency of bacterial resistance to some agents, and the efficacy of *bismuth subsalicylate* is leading to less reliance on antimicrobials.

Treatment. Although antibiotics are sometimes used, their disadvantages (see above) suggest the use of other measures first, if possible.

Bismuth Subsalicylate (Pepto-Bismol) has proved effective as both prophylaxis and treatment for traveler's diarrhea when given in large doses (60 mL four times daily). Unlike antibiotics, it has the advantage of not altering the normal bowel flora. Its mechanism of action is believed to involve inhibiting colonization by toxigenic bacterial strains. Bismuth turns the stools black; it is useful to alert patients to this side effect so its occurrence does not cause alarm.

Diphenoxylate or Loperamide is often more convenient for symptomatic relief of traveler's diarrhea than are other measures. In most instances, these agents can be used for brief periods with safety, except when *Shigella* or *Salmonella* infection is a serious consideration (i.e., when fever or rectal bleeding is present). Loperamide has also been a useful adjunct to the antibiotic treatment of symptomatic disease.

Antibiotics are indicated in acute, severe cases. Ciprofloxacin (500 mg twice daily) and TMS (one double-strength tablet twice daily) are both effective, especially when used with loperamide (2 mg after each loose stool, up to 16 mg/d). A 3-day course of antibiotics usually suffices. Giving travelers a 3-day antibiotic supply plus loperamide to carry with them is reasonable and appreciated. Ciprofloxacin is probably preferred because of the emergence of TMS-resistant strains of *E. coli*.

Chronic Diarrhea

Unlike the treatment of acute diarrhea, in which many cases are self-limited and nonspecific measures aimed at symptomatic relief are appropriate, the effective management of chronic diarrhea requires an etiologic diagnosis and specific therapy. Simply suppressing symptoms without identifying a cause may delay identification of a serious underlying condition (e.g., colon cancer or inflammatory bowel disease). Empiric trials are limited to use in diagnosis (see above).

Many causes are treatable. For example, exacerbations of *inflammatory bowel disease* respond to steroids and sulfasalazine; collagenous and lymphocytic forms appear to benefit from a course of bismuth subsalicylate (see [Chapter 73](#)). Malabsorption associated with *pancreatic insufficiency* improves with the use of enzyme supplements (see [Chapter 72](#)). Steatorrhea caused by *sprue* responds to a gluten-free diet, but not all patients repond to the dietary change because often a concurrent contributing factor is present. *Lactase deficiency* requires limitation of milk products or the use of exogenous lactase. The *dumping syndrome* can be controlled with small feedings. Persistent pseudomembranous colitis is an indication for antibiotic therapy (see above). Cessation of surreptitious *laxative abuse* cures the diarrhea that accompanies it (see [Chapter 234](#)). In the setting of *irritable bowel syndrome*, a high-fiber diet is indicated if the clinical picture is predominantly one of constipation interspersed with brief episodes of diarrhea, but if diarrhea predominates, loperamide can be useful for symptomatic relief (see [Chapter 74](#)).

Chronic Diarrhea of Unknown Etiology. For patients whose condition remains undiagnosed after an extensive workup yet who appear otherwise well, a trial of therapy for irritable bowel syndrome is reasonable (see [Chapter 74](#)). Many such patients with unexplained diarrhea turn out to have a bowel motility disorder and associated psychosocial stresses. Clues to the diagnosis include an absence of weight loss, normal findings on laboratory studies, and a suggestive psychosocial history. Failure to respond after 4 weeks of management should lead to a gastroenterologic consultation. One should not resort to nonspecific antidiarrheal agents to treat patients who have not been given a diagnosis.

INDICATIONS FOR ADMISSION AND REFERRAL

Admission. Most patients with diarrhea can be managed on an outpatient basis. However, for those who are unable to maintain their hydration orally and become significantly volume-depleted (with postural hypotension), hospital admission and parenteral fluid replacement must be seriously considered. Sometimes, several hours of IV fluids given in the emergencydepartment will suffice and obviate an admission. Infants, elderly persons, and persons with chronic or debilitating illnesses such as diabetic renal failure are particularly vulnerable to the complications of volume depletion and warrant close monitoring. Patients with inflammatory diarrhea manifested by bloody, purulent stools and fever are also candidates for admission, as are those with neurologic deficits and meningeal signs following a diarrheal illness, who require assessment for listeriosis. Patients with undiagnosed chronic diarrhea may benefit from the observation and testing possible only during hospitalization.

Referral to a gastroenterologist is indicated for patients who have complicated acute disease (e.g., hemorrhagic diarrhea), poorly controlled inflammatory bowel disease, undiagnosed chronic diarrhea, or who require colonoscopy or intestinal biopsy.

PATIENT EDUCATION

Because most cases of acute diarrhea are self-limited, the patient with no evidence of serious underlying pathology can be reassured and advised to concentrate on maintaining hydration. The sugar and electrolyte preparations described in this Chapter are easy to take and should be encouraged. Many people think that taking fluids will seriously worsen their diarrhea, and they request opiates or antibiotics; the proper role for such agents needs to be reviewed and their unrestricted use should be limited. Many ask if kaolin and pectin preparations are helpful; there is no evidence that they alter symptoms or the course of the illness, but neither are they harmful. Although antibiotics have been in vogue for prophylaxis of traveler's diarrhea, patients should be informed of the emergence of resistant strains, the potential complications of antibiotic use, and the efficacy of bismuth preparations. A few bottles of a bismuth preparation (e.g., Pepto-Bismol), a few tablets of diphenoxylate for "emergencies," and advice to use bottled water and avoid foods likely to be contaminated (e.g., raw vegetables washed with local water) represent reasonable alternatives to antibiotic prophylaxis. Patients with chronic undiagnosed diarrhea need to be prepared for a potentially extensive evaluation. In the meantime, advice on perianal care is much appreciated and ought not to be overlooked while investigation proceeds.

Perianal Hygiene. Much can be done to relieve the perianal discomfort that accompanies severe, unrelenting diarrhea. *Sitz baths* for about 10 minutes two or three times a day can be soothing, followed by gentle drying with absorbent cotton (not toilet paper or towels). Washing with warm water on *absorbent cotton* after each bowel movement is also helpful in lieu of using toilet paper, which can be irritating. Also important is avoidance of soap. Desitin may be effective, and a short course of *hydrocortisone cream* may be useful when considerable anal inflammation is present. Some patients report that cleaning gently with cotton pads soaked in *witch hazel* (Tucks) provides considerable relief. Ointments containing topical anesthetics should be avoided; they can be irritating in themselves.

Recovery Phase. After resolution of diarrhea, it is best to avoid milk and dairy products for approximately another 7 to 10 days because mild lactose intolerance commonly accompanies many cases. The best foods to begin eating are easily digested, high-carbohydrate substances such as bananas, rice, baked potato, and

apple sauce. Continued repletion of fluid is important.

CHAPTER 65 APPROACH TO THE PATIENT WITH CONSTIPATION

JAMES M. RICHTER

Constipation is a universal affliction of Western civilization. In the United States, this malady accounts for more than 2.5 million physician visits a year. It is among the most frequent reasons for self-medication and is particularly troublesome in the elderly. More than $500 million are spent annually in the United States on laxatives; a survey of Londoners revealed 30% admitting to recent laxative use.

There is no uniform definition of constipation. To some, it means movements that are too infrequent or stools that are too hard. Others complain of incomplete or difficult evacuation. Among normal people, bowel habits vary widely, and perceptions of what constitutes normal function are diverse. Population studies show that most normal people have more than three bowel movements per week, with men likely to have at leastfive. Stools of less than 35 g daily are well below the lower limit of normal.

The primary physician must be able to uncover any underlying pathology and provide symptomatic relief to those without a structural lesion. The prevalence of excessive laxative use and inadequate dietary fiber intake make it imperative that the physician be knowledgeable about the actions and adverse effects of available laxative preparations in addition to dietary alternatives to their use.

PATHOPHYSIOLOGY AND CLINICAL PRESENTATION

Normal Physiology. The process of elimination of fecal waste requires two processes: filling of the rectum by colonic transport and reflex defecation of stool. Constipation may arise secondary to interference with either of these processes. The time it takes food to reach the anus is partially a function of the amount of fiber in the diet. Normal people placed on a diet containing 15 g of bran fiber per day have twice the number of movements per week of those on an uncontrolled diet. Patients with constipation solely on the basis of low dietary fiber usually have intermittent complaints that fully resolve with alteration of diet alone. Exercise has an important effect on the propulsion of bowel contents. Colonic transit has been observed to be significantly greater in physically active people than in those who get little exercise.

Inactivity. Previously active persons often become constipated when confined to bed on account of illness. Less dramatic, but probably no less important, is the effect of a sedentary life-style; constipation is common in inactive people.

Metabolic and Endocrine Disturbances can slow colonic transport. Hypokalemia, hypercalcemia, hypothyroidism, and diabetes are the most important of these in terms of frequency or potential reversibility. *Hypokalemia* can produce a generalized ileus and is most often seen in patients who take diuretics. *Chronic laxative abuse* may also produce hypokalemia; surreptitious use of laxatives and diuretics, self-induced vomiting, a pathologic desire to lose weight, and personality disorder are characteristic of such patients, who present with fatigue and electrolyte disturbances. When constipation is caused by *hypothyroidism*, other manifestations of the disease are usually present, although sluggish bowel movements may be the presenting complaint. Constipation is a bothersome problem in some patients with *diabetes*; 20% of those with neuropathy report severe difficulty. Significant *hypercalcemia* (serum calcium level >12 mg/100 mL) can slow bowel motility.

Mechanical Obstruction from tumor, stricture, or volvulus may be responsible for the new onset of constipation. Cramping abdominal pain and distention in conjunction with a marked change in bowel habits are characteristic. Constipation occurs in more than 50% of patients with *colorectal cancers*; it is usually a symptom of advanced disease but may be the presenting complaint. Constipation is a more common presentation of *Crohn's disease* than is diarrhea because transmural involvement predisposes to scarring and obstruction (see Chapter 73).

Motor Dysfunction. Constipation may be the predominant symptom of *irritable bowel syndrome*, a common motility disorder of unknown etiology (see Chapter 74). Patients complain of chronic abdominal discomfort related to alterations in bowel habits and relieved by defecation. They report irregular bowel movements, often diarrhea alternating with constipation (although one may predominate). Passage of mucus, a sense of incomplete evacuation, and bloating or distention add to the clinical picture.

Drug Use may precipitate constipation. *Opiates* and agents with anticholinergic activity such as *antidepressants* are frequently implicated. *Calcium-channel blockers* may slow down bowel motility, and *cholestyramine* may induce constipation by binding bile salts. *Aluminum hydroxide* and *calcium carbonate* antacids are constipating. The habitual use of *laxatives* is associated with impaired motor activity. The typical clinical picture is a long history of chronic constipation or a desire to feel "well cleaned out," followed by increasing laxative dependence, decreasing response, and ultimately a sluggish, poorly contracting bowel. The question of whether a prior underlying motor disorder or actual damage from laxative use is the cause remains unsettled.

Psychiatric Disease and Psychosocial Distress play important roles. An underlying *depression* is often contributory, and bowel complaints may be one of many somatic symptoms (see Chapter 227). Patients with *irritable bowel syndrome* have an increased prevalence of somatization, anxiety, and phobias, which have been linked to triggering disturbances of bowel function. Situational stress appears to play a similar role. The exact mechanisms by which emotional difficulties lead to constipation remain unclear, but their contribution is widely recognized. Disturbances in bowel motility and visceral perception have been documented. Constipation develops in the presence of an excessive degree of nonpropulsive contractions and segmentation of bowel contents. At other times, excessive propulsive activity is noted, typically after meals, resulting in diarrhea.

Neurologic Impairment may present as constipation. *Spinal cord injury* that leads to compression of the cauda equina can halt bowel motility and also cause urinary retention and incontinence. *Multiple sclerosis* may compromise bowel function, as can ganglionic abnormalities. In most instances, other neurologic deficits are present. Disease limited to loss of neurons in the bowel wall typically presents as chronic, refractory constipation; it may date from childhood or, as noted above, be associated with long-standing laxative use. A permanently damaged neuromotor apparatus may also occur as a consequence of *scleroderma*.

Inhibition of the Rectal Defecation Reflex has been documented in cases of painful local anal pathology, neurogenic disease (e.g., Parkinson's disease, multiple sclerosis), long-term use of laxatives, and voluntary suppression. Patients with this problem are found to have stool packed into the rectal ampulla. *Voluntary suppression* of the urge to defecate is usually a concomitant of a hectic daily pace or traveling. The resulting intermittent constipation may lead to excessive use of laxatives and enemas and damage to the reflex emptying mechanism.

Inadequate Fluid Intake may play a role, although this is not well established. Water is known to be an effective means of distending the stomach and stimulating intestinal activity. The consistency of stool is a function of how much water it contains, which is a result, in part, of how much is taken in.

Pelvic Floor Dysfunction accounts for some cases of intractable constipation of unknown etiology. It may be a consequence of inadequate relaxation or inappropriate contraction of the puborectalis and anal sphincter muscles, pelvic floordyssynergy, or both. Patients complain of the need to strain despite a strong urge to defecate. They may also report a persistent uncomfortable sense of rectal fullness and the need to remove stool digitally from the rectum to obtain relief. With pelvic floor dyssynergy, patients find that supporting the perineum helps during a bowel movement.

DIFFERENTIAL DIAGNOSIS

The causes of constipation can be grouped according to pathophysiology: impaired motility, neurologic disorders, obstruction, and local anorectal pathology (Table 65.1). Many cases remain undiagnosed after initial assessment but respond to empiric therapy. Slow colonic transit and pelvic floor dysfunction often play etiologic roles in such cases, especially in middle-aged and older women with chronic intractable constipation.

MECHANISM	ETIOLOGY
Impaired Motility	Inadequate dietary fiber
	Inactivity
	Laxative abuse
	Irritable colon syndrome
	Diverticulitis
	Hypothyroidism
	Hypokalemia
	Diabetes
	Hypercalcemia
	Pregnancy
	Scleroderma
	Drugs (opiates, anticholinergics, tricyclic antidepressants, ganglionic blockers, calcium- and aluminum-containing antacids, sucralfate, disopyramide, calcium channel blockers, antihistamines)
Neurologic Dysfunction	Multiple sclerosis
	Spinal cord injury
	Neurogangliomatosis
Psychosocial Dysfunction	Depression
	Situational stress
	Anxiety
	Somatization
	Phobias

Table 65.1. Important Causes of Constipation

WORKUP

History. Evaluation begins with a definition of the size, character, and frequency of bowel movements, followed by a determination of the chronicity of the problem. Acute constipation is more often associated with organic disease than is a long-standing problem. Chronic complaints that wax and wane for months and years point to a functional disturbance, often compounded by habitual laxative use. The patient must be asked about symptoms that suggest an underlying gastrointestinal problem, such as abdominal pain, nausea, cramping, vomiting, weight loss, melena, rectal bleeding, rectal pain, and fever. Anorexia, bloating, belching, flatus, mucus in the stool, headache, depression, and anxiety should also be recorded; these symptoms may be associated with constipation of any etiology but often accompany functional disorders.

It is helpful at the first visit to take a history of working, eating, and bowel habits. Inquiry into dietary fiber intake and physical activity is essential. Use of medications, including nonprescription agents (especially laxatives and antacids), needs to be detailed. The patient's perspective and concerns should be elicited, and a careful psychosocial history obtained, with attention to situational stresses, anxieties, and methods of coping.

Physical Examination. One begins by recording the patient's weight and noting overall nutritional status. Skin is checked for pallor and signs of hypothyroidism (see Chapter 104). The abdomen is examined for masses, distention, tenderness, and high-pitched or absent bowel sounds. Rectal examination includes careful inspection and palpation for masses, fissures, inflammation, and hard stool in the ampulla. The last finding rules out significant obstruction and poor colonic motility and suggests that the problem is inadequate rectal emptying. The stool is noted for color and consistency and tested for occult blood. Anal sensitivity and reflexes are noted. Disordered innervation of the anus is indicated if the anal canal opens wide when the puborectalis muscle is pulled posteriorly. Anoscopy is needed to identify internal hemorrhoids, fissures, tumors, and other local pathology. A neurologic examination should be performed to search for focal deficits and a delayed relaxation phase of the ankle jerks, suggestive of hypothyroidism. A mental status examination includes checking for signs of depression (see Chapter 227), anxiety (see Chapter 226), and somatization (see Chapter 230).

Laboratory Studies. Radiologic investigation is of limited use unless evidence from history and physical examination suggests obstruction or other serious pathology. The acute onset of constipation requires ruling out obstruction and ileus, especially when accompanied by abdominal discomfort. Plain *supine* and *upright films* of the abdomen, plus measurements of serum *potassium* and *calcium* levels, are indicated. More chronic or recurrent forms of constipation should be assessed with a check of the serum glucose level for diabetes (see Chapter 93) and of the serum *thyroid-stimulating hormone* (TSH) for hypothyroidism (see Chapter 104).

If colonic obstruction is suspected (especially if Crohn's disease or cancer is a possibility), *colonoscopy* or *sigmoidoscopy* plus *barium enema* is required. Barium enema is particularly useful and in conjunction with sigmoidoscopy may be preferred to colonoscopy in the assessment of constipation because it is less costly and can demonstrate potentially diagnostic features such as colonic dilation and strictures. Nonetheless, colonoscopy is the test of choice in a case with a positive result on guaiac stool testing, rectal bleeding, anemia, or weight loss in an older patient, all of which suggest the possibility of colorectal cancer (see Chapter 56 and Chapter 63). More than 25% of patients with colorectal carcinomas present with constipation.

The elderly person presenting with no evidence of obstruction, anemia, or occult blood loss can probably be followed expectantly for a few weeks, with implementation of an empiric program that includes more dietary fiber, increased exercise, and monitoring with stool guaiac tests, before a decision to subject the patient to colonoscopy or barium enema is made. If symptoms resolve and no other risk factors or findings suggestiveof colorectal cancer are present, then the patient can forego bowel visualization at least for the moment. A return visit for repeated assessment of the situation should be scheduled within 4 to 8 weeks. The finding of pigmented colonic mucosa (*melanosis coli*) on direct visualization of the bowel lumen suggests abuse of anthraquinone laxatives such as castor oil or senna.

When the cause of constipation is obscure, it is helpful to stop all nonessential medications. The codeine in a cough suppressant, the calcium in an over-the-counter antacid, or the iron in a multiple vitamin may be responsible for an otherwise puzzling diagnostic problem.

SYMPTOMATIC MANAGEMENT AND PATIENT EDUCATION

Empiric symptomatic management is appropriate for the patient with a suspected functional etiology, but only after obstruction and other forms of serious organic pathology have been ruled out.

Basic First Steps. The first intervention after a careful workup is to reassure the patient that no evidence for a serious underlying illness has been found. Cancer is a common fear, especially in elderly patients with new onset of constipation. Careful *patient education* about diet, exercise, and use of laxatives is the next priority. Explanation is needed to reassure the patient that a daily bowel movement is not essential to good health and that comfortable patterns of elimination depend on good living and eating habits. *Daily exercise* should be prescribed, based on the patient's physical capacity (see Chapter 18). Adequate fluid intake (1.5 to 2 L daily; 6 to 8 glasses of water) is also essential, especially if a high-fiber diet is prescribed.

The patient should *stop taking laxatives, enemas, and nonessential drugs* that may suppress colonic motility. Trying to establish a convenient, uninterrupted *time for defecation* each day may be useful; 15 to 20 minutes after breakfast provides a good opportunity because spontaneous colonic motility is greatest during that period. Continuing this routine each day regardless of travel or situational stress ought to be encouraged. Although no controlled studies are available to prove the efficacy of this approach, it seems to help some people, although days or weeks can pass before success is noted.

In general, these first steps can relieve constipation, but in chronic cases, it may take weeks to months for more satisfactory bowel function to return. Often, immediate results are expected; when they do not appear, the patient becomes despondent, stops the program, and returns to laxative and enema use.

Dietary Fiber and Fiber Supplements. The use of fiber and bulk laxatives can help alleviate symptoms by softening stools and reducing abdominal discomfort. Most clinicians prefer to start with fiber before resorting to bulk laxatives; data on relative efficacy and safety are limited. One begins to increase the fiber content of the diet by adding bran, fruits, green vegetables, and whole-grain cereals and breads. Most studies show that 15 g of fiber per day is needed for the best effects, but the amount can be individualized. A large breakfast including bran cereal, juice, milk or coffee, and whole-grain bread is helpful.

Some patients refuse to eat bran because it makes them feel bloated and gassy. The patient can be reassured that these side effects usually resolve within a month of continued use. If dietary and exercise efforts fail or the patient insists on medication, a *nondigestible fiber residue* such as ground *psyllium* seed (Metamucil), *methylcellulose* (Citrucel), or *polycarbophil* can be beneficial. It acts to increase bulk by means of its hydrophilic properties, but it must be taken with plenty of fluids to prevent formation of an obstructing bolus; the usual dose is one teaspoon in 8 oz of liquid three times a day. Placebo-controlled studies show significant improvement in symptoms with use, but the placebo groups also show improvement, which suggests that explanation, reassurance, and increased attention are also important to improved bowel function.

Laxatives of First Choice. The constipation of some elderly patients will remain refractory to the above measures, and they will press for prescription of a laxative. A

few classes are relatively safe and worth considering when simpler measures have failed. Efficacy in controlled trials is similar to that of fiber.

Nonabsorbable Saccharide/Bulk Laxatives (e.g. lactulose, sorbitol) have been shown to be safe and effective when used on a long-term basis in the elderly. These agents induce a potent osmotic effect, retaining fluid in the bowel lumen and softening the stool. The cost of sorbitol (30 to 60 mL daily at bedtime) is about a tenth that of lactulose, and sorbitol has been shown in double-blind crossover studies to be equal in effect and slightly better tolerated. Side effects include excessive flatulence, bloating, and cramping.

Magnesium-containing Laxatives (e.g., milk of mag-nesia, magnesium citrate) are also osmotically active, but they should be used more cautiously because they may induce magnesium and sodium overload in older persons with renal dysfunction. They are less expensive than sorbitol.

Surfactant Laxatives such as docusate soften stool by promoting the mixing of water and fat. They are worth a try in patients reporting hard stools, but evidence supporting their efficacy is limited (see below) and their cost is high.

Other Laxative Preparations. Most other laxatives are probably worth avoiding for regular use because of the potential for adverse effects (although definitive data documenting adverse effects are limited).

Stimulant/Irritant Laxatives include the derivatives of diphenylmethane (*bisacodyl*), anthraquinone (*senna*), and cascara. These irritants trigger colonic contraction acutely; long-term use is associated with an increased risk for bowel refractoriness and worsening constipation (*laxative abuse syndrome*).

Prokinetic Agents. *Cisapride* is a prokinetic agent producing dopaminergic stimulation. Experience is still limited regarding its use in chronic constipation; however, when used in esophageal reflux, it is associated with an increased risk for ventricular dysrhythmias, which limits its appropriateness in the elderly.

Enemas. When *fecal impaction* is present, a *hypertonic enema* (e.g., Fleet) will often relieve the situation. *Soapsuds enemas* should be avoided because colitis has been reported with their use. The patient with impaction who is taking an enema can be instructed to squat over the toilet by standing on a chair in front of the bowl, which provides a more favorable positionfor evacuating the rectum. Only rarely does one need to resort to disimpaction.

Prevention of constipation during an illness that requires bed rest can be achieved with a high-fiber diet, bulk agents, and use of a commode in preference to a bedpan. Correction of any coincident hypokalemia is important (see Chapter 32). There is no evidence that prophylactic use of laxatives or stool softeners is effective. A randomized, controlled study of dioctyl sodium sulfosuccinate (Colace), a popular and expensive stool softener, failed to demonstrate any effect on the quality or frequency of stools. Use of minor tranquilizers in overly anxious patients has little direct effect on constipation. When severe depression requires use of antidepressants, the least constipating agent should be selected (i.e., one with minimal anticholinergic activity). All tricyclic antidepressants have at least some anticholinergic activity, but desipramine, nortriptyline, and trazodone seem to have the least. Alternatively, a nontricyclic antidepressant such as sertraline might be a reasonable choice (see Chapter 227).

The Patient–Doctor Relationship. The importance of establishing a trusting, therapeutic patient–doctor relationship cannot be overemphasized, especially when the probability of underlying psychosocial distress is high. One facilitates the establishment of trust by eliciting concerns and perspective and taking time to explain and answer questions. A patient who has used a particular agent for decades needs to be told why it is being removed from the program; otherwise, chances of compliance are small. Long-term laxative users should be warned that it may take 4 to 6 weeks before spontaneous bowel movements return. Patience and sympathetic support can be rewarding, but expectations of quick results must not be raised (see also Chapter 74).

CHAPTER 66 APPROACH TO THE PATIENT WITH ANORECTAL COMPLAINTS

Anorectal complaints often go incompletely evaluated. Although they are usually a result of minor conditions such as hemorrhoids or fissures, causes range beyond the trivial to inflammatory bowel disease, cancer, and infection. In addition, anorectal problems generate a substantial amount of worry and discomfort. As a result, they deserve careful consideration by the primary care physician. An increasingly frequent diagnostic challenge is the evaluation of anorectal problems in male homosexuals.

PATHOPHYSIOLOGY AND CLINICAL PRESENTATION

Anorectal complaints result from traumatic, vascular, infectious, inflammatory, neurologic, and malignant causes. Symptoms include pain, discharge, itching, mass, and fecal incontinence. *Pain* is most often a manifestation of anal pathology; anal and perianal skin are richly innervated with pain-sensitive nerve fibers; rectal tissue is relatively insensitive to pain. A fissure, distention by abscess or hemorrhoid, invasion by tumor, or marked inflammation can lead to considerable discomfort. Secondary anal sphincter spasm may ensue, prolonging and intensifying the pain. *Discharge* results from inflammation of the rectal mucosa or drainage of an abscess. Cancer, abscess, and thrombosed hemorrhoids can produce an anorectal *mass*; condylomata acuminata may also cause anal skin nodularity. *Itching* represents a minor form of skin irritation that occurs with a variety of mechanical and inflammatory lesions; it is intensified by moisture in the perianal area. Chronic itching leads to excoriation, edema, thickening, fissuring, and lichenification of the perianal skin. *Bleeding* is a common and important manifestation of anorectal pathology; its causes range from hemorrhoids and fissures to carcinoma and inflammatory bowel disease (see Chapter 63).

Hemorrhoids. The most common of all anorectal problems, hemorrhoids affect about half of patients over the age of 50. They represent dilations of the anorectal vascular network. Epidemiologically, they are associated with diets high in fat and low in fiber. Theories explaining the development of hemorrhoids invoke a number of mechanisms, including increased venous pressure secondary to upright posture and straining at stool, arteriovenous communications in rectal tissue, and prolapsed cushions of tissue secondary to loss of support. Clinically, hemorrhoids are associated with pregnancy, portal hypertension, and constipation. The relative absence of hemorrhoids in African populations that have high-residue diets has led to the suggestion that an increase in dietary fiber might prevent the development of hemorrhoids.

Although the traditional view is that hemorrhoids are venous varicosities resulting from straining at stool, they do not always present in a fashion consistent with this postulate. For example, hemorrhoids appear in early pregnancy in many young women, long before the development of significant intraabdominal pressure from a large fetus. Moreover, hemorrhoidal blood is characteristically arterial in quality (bright red) rather than the dark variety that would be expected from a strictly venous source. Nonetheless, many patients with hemorrhoids have been found to have increased resting anal sphincter pressures, which supports the hypothesis that increased anal pressure causes straining at stool. The straining stresses and compromises the supporting fibrous tissue of the rectal mucosa, allowing the now poorly supported mucosa to slide down and become entrapped by the sphincter. Venous engorgement is a consequence of the entrapment.

Classification. Hemorrhoids may be classified by presentation as *first-degree* when they merely bleed, *second-degree* if they prolapse on high pressure but return spontaneously, and *third-degree* when the anal suspensory ligament is stretched to the point of permanent prolapse. Hemorrhoids are considered to be *internal* when derived from the superior hemorrhoidal plexus above the dentate line, and *external* when located below the dentate line and covered by squamous epithelium. External hemorrhoids are covered by pain-sensitive anal skin and arise from the inferior hemorrhoidal plexus. Internal hemorrhoids are covered by the much less pain-sensitive rectal mucosa and represent dilations of the superior hemorrhoidal plexus.

Clinical Presentation. Pain, incomplete defecation, constipation, excessive moisture, rectal itching, bleeding, or a prolapsed mass are the common presentations. Clinical presentation depends in part on the location of the hemorrhoid and the presence of complications. External hemorrhoids that have thrombosed present as tender, bluish swellings. Internal hemorrhoids often bleed, but only when they prolapse do they present as a mass; when irreducible, they are subject to thrombosis. Recurrent bleeding may be seen with either type; sudden rupture may cause rather dramatic, although relatively harmless, bright red bleeding. Hemorrhoids are regularly encountered as incidental findings on physical examination. Skin tags are evidence of previous hemorrhoids that have thrombosed, leaving connective tissue. The most bothersome complications of hemorrhoids include bleeding, prolapse, and thrombosis.

Fistula-in-ano is a communication between the anal canal and the perianal skin. It is usually nontender. The external opening may be single or multiple, with a granulation tissue bud and chronic seropurulent drainage. Occasionally, an indurated cord of tissue may be palpable, extending from the external fistulous opening toward the anal canal. The fistula may result from rupture or surgical drainage of a perirectal abscess; other causes include Crohn's disease, carcinoma, tuberculosis, radiation therapy, lymphogranuloma venereum, and anal fissure. Patients complain of persistent and irritating drainage of blood, pus, or mucus.

Perirectal Abscess and fistula-in-ano are two stages of the same disease process, beginning as an infection in the anal glands that empty into the anal crypts at the mucocutaneous junction, and subsequently spreading into the adjacent tissue. The abscess thus formed often drains through the perianal skin. Symptoms and signs are a function of the size and location of the abscess. The first manifestation is rectal pain, which may occur before any mass becomes palpable. Patients characteristically complain of constant, throbbing pain in the perianal region or in the rectum. A mass may be identified externally on examination of the anus or internally during palpation the rectum. The formation of perirectal abscesses is a particularly important problem in patients with Crohn's disease, immunodeficiency states, and hematologic disorders.

Infected Pilonidal Cyst or Sinus is most common in boys and young men between the ages of 16 and 30. These are midline, in the area of the natal cleft. Multiple sinuses may be present. Recurrent secondary infections are frequent.

Carcinoma of the Anus. Carcinoma involving the perianal skin or anorectal tract typically does not cause pain until relatively late in its clinical course, often in the setting of a large, ulcerated, bleeding lesion. Earlier lesions present as painless nodules or plaques. Pruritus, mucoid drainage, and changes in bowel habits are more subtle manifestations that sometimes occur.

Proctalgia Fugax, as the term implies, is fleeting but severe rectal pain believed to be related to spasm of the levator ani and coccygeal muscles. Although usually brief, symptoms can last for more than 30 minutes. Suspected precipitants include chronic trauma from poor posture; psychogenic factors may also be operative. No associated physical findings are present, except for muscle tenderness on digital examination.

Proctitis, inflammatory disease of the rectum, is associated with a wide variety of conditions, ranging from infection and trauma to radiation and inflammatory bowel disease. Regardless of the cause, the presentation is usually one of mucopurulent discharge, rectal bleeding, and, in severe cases, rectal pain and tenesmus. Patients with *ulcerative proctitis* demonstrate on sigmoidoscopy an inflamed rectal mucosa and a clearly demarcated upper border, above which the mucosa is normal. Systemic symptoms and extraintestinal manifestations are rare when the disease is limited to the rectum. The risk for carcinoma is small, and diffuse colitis develops in fewer than 10% to 15% of patients.

Infectious Proctitis occurs mostly among promiscuous *male homosexuals* who engage in frequent rectal intercourse with multiple partners. Gonorrhea, amebic disease, chlamydial infection, and herpes simplex infection are prominent in this population (see below). *Gonococcal proctitis* is especially common. The rate of asymptomatic carriage of gonorrhea among promiscuous male homosexuals is reportedly as high as 60% to 70%. Symptomatic gonococcal proctitis presents with discharge and rectal discomfort (see below). Diarrhea is the hallmark of symptomatic *amebic infection*, *shigellosis*, and *Campylobacter* infection (see Chapter 64). *Herpes simplex proctitis* can be a very painful condition, accompanied by tenesmus, constipation, rectal ulceration, and discharge. Involvement of the sacral nerve roots can lead to bladder and erectile difficulties, paresthesias, and pain in the thighs and buttocks.

Solitary Rectal Ulcer is a rare condition of unknown cause associated with rectal discharge, bleeding, and, occasionally, dull pain. The characteristic finding on sigmoidoscopy is a single shallow ulcer 7 to 10 cm from the anus; its borders may be heaped or nodular. Chronicity is the rule; complications are rare. These lesions must be distinguished from cancer and lymphogranuloma venereum by biopsy.

Pruritus Ani (chronic perianal itching) is not a diagnosis but rather a syndrome that results from a variety of mechanical and inflammatory lesions. Anatomic lesions that produce chronic discharge (such as *fistulas*, *fissures*, and *hemorrhoids* with intermittent mucosal eversion) can result in pruritus ani. Infectious causes are numerous. *Anogenital warts (condylomata acuminata)* are viral in origin and generally transmitted by sexual contact. They may be confined to the perianal region or also involve the penis, vulva, and anal canal. Multiple, soft, filiform excrescences characterize these lesions, which may enlarge, become confluent, and even bleed. *Gonococcal proctitis* can lead to anal soreness, burning, and purulent discharge. Infestations with *pinworm (Enterobius vermicularis)* typically cause nocturnal anal itchiness, especially among children, but sometimes spread to involve adult family members. Nocturnal symptoms are caused by the daily evening migration of the female pinworm downward to deposit eggs on the perianal skin. Anal involvement is characteristic of some systemic dermatologic diseases, such as *psoriasis* and scabies. *Contact dermatitis* or *eczema* resulting from use of a topical agent is common and can complicate the diagnosis of the original cause of pruritus. Applied initially as a remedy for itching, the agent may only aggravate the problem by causing skin sensitization. Itching is intensified by moisture in the perianal area and often aggravated by the use of topical agents applied in an attempt to quell symptoms. The passage of *alkaline stools* (as occurs in severe diarrhea) can have an irritant effect on the anal skin. Persistent anal itching may be a form of *neurodermatitis*; such patients characteristically present with multiple excoriations. *Candida infection* is found among diabetics, homosexuals, and those recently taking broad-spectrum antibiotics; perianal erythema and itching are presenting manifestations.

Fecal Impaction ranks as one of the major sources of anorectal discomfort among the elderly and bedridden. Chronic incomplete evacuation leads to formation of an obstructing bolus of desiccated hard stool in the rectum. Symptoms of anal discomfort and constipation are typical, but anorexia, malaise, or nonspecific lower abdominal fullness may be all that is reported. Paradoxically, diarrhea rather than constipation is sometimes the only complaint; this is caused by the collection of liquid stool that distends the proximal colon and passes around the obstructing bolus. Unless this problem is corrected by disimpaction, complications such as intestinal obstruction, rectal prolapse, and even bowel perforation may ensue.

Fecal Incontinence follows damage to the normal anal sphincter mechanism. Perianal disease, anal surgery, and neurologic disease can have devastating psychosocial consequences when the anal sphincter becomes compromised. Some patients lose the ability to sense rectal distention and to constrict the external sphincter. In others, with only a weakened sphincter, the prognosis is less grim; biofeedback methods can be employed to help them regain continence.

Anorectal Problems in Homosexuals and others engaging in receptive anal intercourse can be complex in etiology and presentation. In a major study, more than 80% of homosexual men presenting to a venereal disease clinic with anorectal or intestinal symptoms were infected with one or more sexually transmissible anorectal or enteric pathogens. Three principal syndromes were noted: a *proctitis* characterized by anorectal pain, lesions, and discharge, but no evidence of disease above the rectum; a *proctocolitis* that, in addition to manifestations of proctitis, included diarrhea, tenesmus, and inflammation extending into the sigmoid mucosa; and an *enteritis* (see Chapter 64) that consisted of diarrhea and abdominal pain, but no anorectal symptoms or signs.

As noted above, gonococcal, herpetic, chlamydial, and syphilitic forms of proctitis occur with increased frequency among these patients. *Gonorrhea* occurs in about a third of patients; *herpes simplex type 2 virus* is cultured from about one fifth, who also manifest rectal mucosal ulcerations. About 3% of symptomatic persons have anal syphilitic chancres, and another 3% show evidence of secondary anorectal syphilitic disease (erythematous nodular or indurated rectal mucosal lesions from which biopsy specimens test positive).

A clinical and sigmoidoscopic picture of *proctocolitis* occurs in about 15% of cases. Such patients complain of anorectal discomfort, tenesmus, diarrhea, constipation, and abdominal cramps. On sigmoidoscopy, inflammatory changes start at the rectum and extend beyond 15 cm into the sigmoid colon. *Campylobacter*, *Entamoeba histolytica*, *Chlamydia*, and *Clostridium difficile* are significantly correlated with the enterocolitis; often, more than one organism is recovered. Polymicrobial infection is commonplace among symptomatic male homosexuals with many sexual partners.

Although much of the proctitis in this population is infectious in origin, *culture-negative proctitis* occurs with some frequency and has been linked to exposure to the *coloring agents* and scents found in some of the lubricants used for anal intercourse. Manifestations of several causes may present simultaneously. The patient complaining of hemorrhoidal pain may actually have concurrent gonorrhea, allergic proctitis, and chlamydial infection. Traumatic complications of rectal intercourse include prolapsed hemorrhoids, anal fistulas and fissures, perirectal abscesses, rectal ulcers, and anal tears. Foreign bodies are sometimes recovered.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of anorectal problems can best be considered in anatomic terms, depending on whether symptoms and signs are predominantly anal, anorectal, or rectocolonic (Table 66.1). This is particularly true when the causes of anorectal disease in male homosexuals are considered (Table 66.2).

PROBLEM	DIFFERENTIAL DIAGNOSIS
Anal discomfort	Hemorrhoids
	Fissure-in-ano (hard bowel movement, cancer, venereal disease)
	Fistula-in-ano (perirectal abscess, Crohn's disease, carcinoma, radiation, TB, lymphogranuloma venereum)
	Perirectal abscess (Crohn's disease, immunodeficiency, hematologic disorders)
	Infected pilonidal cyst
	Carcinoma of the anal epidermis
	Infections (syphilis, candidiasis, condylomata acuminata)
Rectal discomfort	Proctitis (ulcerative, gonococcal, amebic, herpetic), often accompanied by discharge and bleeding
	Perirectal abscess
	Impaction
	Prostalgia fugax
	Solitary rectal ulcer
Pruritus ani	Excess moisture (poor hygiene), pinworms, eczema, scabies, diabetes, liver failure, irritants (topical agents, alkaline stools), fissure, early cancer, neurodermatitis, and infections (see above)
Incontinence	Rectal surgery, neurologic disease, perianal disease

Table 66.1. Differential Diagnosis of Anorectal Problems

SYNDROME	ETIOLOGY
Proctitis	*Neisseria gonorrhoeae*
	Herpes simplex
	Chlamydia (nonlymphogranuloma strains)
	Syphilis
	Condylomata acuminata
	Trauma
	Chemical irritants
Proctocolitis	*Campylobacter*
	Shigella
	Entamoeba histolytica
	Chlamydia (lymphogranuloma strains)
Enteritis	*Giardia lamblia*

Table 66.2. Differential Diagnosis of Anorectal Problems in Male Homosexuals

WORKUP

History. Although a careful physical examination is the single most important part of the evaluation, the history can provide important epidemiologic and etiologic information. Determining whether the condition is predominantly anal (local pain only), anorectal (local anal pain plus rectal discomfort, tenesmus, rectal discharge,

constipation), or rectocolonic (rectal discomfort, tenesmus, and rectal discharge plus diarrhea, abdominal pain, bloating, nausea) helps to focus the evaluation.

Patients with anal complaints ought to be questioned about masses, nodules, focal tenderness, history of hemorrhoids, psoriasis, passage of hard stool, bleeding, discharge, generalized itching, nocturnal pattern, and recent trauma. Detailed inquiry into the use of topical medications (many of which are sensitizing), involvement of other household members or sexual partners, and hygienic practices should also be made.

For patients with anorectal involvement, the physician should check into symptoms of inflammatory bowel disease (see Chapter 73), obtain a careful and detailed sexual history focusing on the number of partners and practice of receptive rectal intercourse, and note any reports of inguinal adenopathy (seen with herpes and lymphogranuloma), sacral root paresthesias, and difficulty with micturition (other telltale symptoms of herpes simplex infection). Those with rectocolonic symptoms are likely to have either inflammatory bowel disease or a polymicrobial infection from rectal intercourse; consideration of associated symptoms and risk factors is indicated.

Physical Examination. Thorough and gentle inspection of the anus and perianal region is the *sine qua non* for a successful diagnosis of anorectal problems. One examines the anal skin for erythema, eczema, psoriatic patches, ulcerations, vesicles, fistulas, fissures, condylomata, nodules, hemorrhoids, and inflammatory changes. The presence of perianal or rectal ulcers in association with proctitis in a male homosexual is indicative of syphilis or herpes simplex. If the lesions appear as scaling plaques, a look at the skin of the extensor surfaces of the extremities might provide additional evidence for a diagnosis of psoriasis. In a very anxious patient with multiple excoriations over other parts of the body, neurodermatitis should be suspected as the cause of pruritus ani. If an inflamed anorectal mucosa is encountered, gonorrhea needs to be considered and inquiry into rectal intercourse needs to be pursued.

Stretching the perianal skin will reveal fissures, which come into view at the anal verge, most often in the posterior midline but occasionally in the anterior midline. With chronic fissures, scarring and induration are seen in addition to an associated hypertrophied anal papilla at the pectinate line; a skin tag marks the external limit. Crohn's disease is likely in those with multiple fissures, recurrent fistulas, or perirectal abscesses. A painless hard nodule or plaque in the anal region may represent carcinoma. When the lesion is ulcerated, the diagnosis is more obvious and the disease is more advanced.

Digital rectal examination is almost always an essential component of the examination. However, in the presence of a painful fissure, this can be an extremely painful procedure that is likely to alienate the patient and cause such pain as to make adequate examination impossible. The same applies to the use of anoscopy in such patients. On the other hand, rectal examination should never be deferred in patients who are not acutely and severely uncomfortable.

One needs to check for masses (both fluctuant and firm), discharges, ulcerations, and other mucosal changes and also to test the stool for occult blood. Ascribing anorectal symptoms to hemorrhoids without performing as complete an examination as possible is a common reason for delay in the diagnosis of carcinoma.

Palpation for enlarged lymph nodes should not be overlooked. Prominent inguinal adenopathy is characteristic of herpetic and chlamydial infections (lymphogranuloma venereum species).

Diagnostic Studies. Unless the patient has a very painful lesion, *anoscopy* needs to be performed (see appendix, Chapter 56) to visualize the canal and mucosa adequately and obtain samples of any discharge. One inspects for mucosal inflammation, fissure, fistula, mass, plaque, ulcer, and discharge. Patients with rectal inflammation, fistula formation, nonhealing fissures, bleeding, or diarrhea are candidates for *sigmoidoscopy.* Involvement of the sigmoid mucosa suggests inflammatory bowel disease (see Chapter 73) and infectious forms of colitis (see Chapter 64). Patients with atypical fissures (especially those that fail to heal), painless hard anorectal nodules, and mucosal ulcerations are candidates for *biopsy* to rule out malignancy, inflammatory bowel disease, and chronic infection (syphilis, tuberculosis). Children with nocturnal pruritus ani can be evaluated for pinworm infestation by taking a cellophane tape impression of the anus and microscopically examining it under low power for the characteristic eggs.

Male homosexuals engaging in receptive anal intercourse with many sexual partners should undergo anoscopy to determine the nature of rectal involvement and to obtain samples of mucus for *Gram's stain* and culture on *Thayer-Martin plates.* A positive smear with Gram's stain is excellent presumptive evidence of gonorrhea, although a negative smear does not rule out the diagnosis. Any chancrelike lesions should be subjected to *dark-field* examination for spirochetes. *A serologic test for syphilis* is also obtained.

Homosexual patients with evidence of rectal pathology on anoscopy require *sigmoidoscopy;* establishing the extent of mucosal involvement helps narrow the list of possible causes. Those with a *proctocolitis* picture of mucosal involvement extending above 15 cm or symptoms of colitis (diarrhea, nausea, abdominal cramping) should have specimens *cultured for Campylobacter, Chlamydia* (lymphogranuloma strains), and *Shigella* and have their stools examined for the *ova* and *trophozoites* of *Entamoeba histolytica.* Those with *proctitis* only (no mucosal disease above 15 cm) are more likely to have gonorrhea, herpes simplex, or chlamydial infection (nonlymphogranuloma strains), and specimens can be cultured accordingly. Viral cultures are not necessary because the diagnosis of herpes simplex proctitis can usually be made on the basis of its characteristic clinical presentation (severe anorectal pain, multiple perianal ulcers, rectal ulceration, inguinal adenopathy, difficult micturition, impotence, and paresthesias in the S-4 and S-5 distributions).

SYMPTOMATIC MANAGEMENT AND INDICATIONS FOR REFERRAL

Acute Anal Fissure. Patients with anal pain caused by fissure should initially be treated symptomatically. Lubricants, such as mineral oil, and agents providing a soft, bulky stool, such as methylcellulose, will decrease trauma and counteract the attendant sphincter spasm. Frequent warm sitz baths provide intermittent relief of pain and spasm. Topical analgesics are of limited use and may result in skin sensitization. Systemic analgesics are sometimes necessary, but if narcotics are used, constipation may be aggravated.

Chronic Anal Fissure. If the pain has not improved with conservative measures in several days to weeks, the patient should be referred for consideration of surgical treatment, which has a high success rate. In general, chronic or recurrent fissures will require surgery more often than acute or superficial fissures. In patients in whom the pain of fissure precludes digital or instrumental examination at the first visit, these may be performed at the time of surgical treatment under adequate anesthesia. *Sphincterotomy* is used to counter the internalsphincter spasm that maintains the tear, but because the procedure permanently weakens the sphincter, it may be followed by incontinence. Up to 30% of patients undergoing sphincterotomy may be so affected. Less invasive alternatives include one to two injections of *botulinum toxin* into the internal anal sphincter (95% healing rate) and daily application of *topical nitroglycerine* ointment for 2 to 6 weeks (60% healing rate). Botulinum toxin injection appears to heal fissures with a frequency equal to that of surgery without inducing long-term incontinence.

Perirectal Abscess will not resolve on antibiotics alone; the proper treatment is surgical drainage. Antibiotic therapy should be reserved for patients with extensive cellulitis, signs of systemic infection, immunosuppression, valvular heart disease, or intravascular prostheses. Incision and drainage of a perirectal abscess usually requires anesthesia and is not often an office procedure. Similarly, the treatment for an infected pilonidal sinus is surgical drainage, which is accomplished satisfactorily under local anesthesia.

Fistula-in-ano. The only successful treatment is surgical. However, patients with inflammatory bowel disease should not undergo surgery for fistula because this will usually fail as long as any active proximal disease is present. Surgery is reserved for palliation of the complications of fistula (i.e., drainage of recurrent perirectal abscess).

Suspected Carcinoma and the need for biopsy require surgical consultation, as does the patient with severe recurrent discomfort from *hemorrhoids* (see appendix).

Pruritus Ani. Specific therapy is related to identification of a specific cause (e.g., diabetes in the patient with candidiasis). Identification of the cause may be a challenging exercise to the primary physician. Pruritus resulting from anatomic lesions generally remits after correction of the underlying problem. *Anogenital warts* are effectively treated with topical application of 25% podophyllin in tincture of benzoin repeated every 1 to 2 weeks. The patient is instructed to bathe between 6 and 12 hours after the application. Care should be taken to avoid applying the compound to intact skin. If anoscopy reveals intraanal warts at the initial examination, curettage and electrocoagulation under anesthesia will be necessary.

Pinworms. All family members should be treated simultaneously. Pyrantel pamoate (Antiminth) is the drug of choice; a one-time oral dose of 11 mg/kg of body weight usually suffices. Preventive measures are difficult to enforce, except for hand washing before meals and after bowel movements. The best prevention is simultaneous treatment of all members of the household.

Idiopathic. No specific cause is found. Pruritus appears to be a form of neurodermatitis affecting the perianal skin. However, the symptoms are often relieved by careful attention to *perianal hygiene* after bowel movements; the perianal skin is kept dry with the application of witch hazel, and topical steroid ointments (0.25% hydrocortisone ointment) are used for several weeks to break the cycle of itching and skin changes caused by scratching. When contact dermatitis is thought to be caused by topical agents, the offending medication should be discontinued.

Gonorrheal Proctitis. See Chapter 137.

Proctitis in Homosexuals. Pending the results of cultures, those with a nonspecific *proctitis* (inflammation limited to the lower 15 cm of the bowel and no ulcers) should be treated empirically by covering for gonorrhea and *Chlamydia* (see Chapter 136 and Chapter 137). Both infections may be present simultaneously. The presence of ulceration suggests syphilis and herpes simplex but does not rule out concurrent gonorrhea and chlamydial infection; polymicrobial infection is found in about 25% of patients.

Fecal Incontinence. Patients have achieved some benefit from *biofeedback* technique. However, only those who retain some degree of rectal sensation are candidates for biofeedback. The technique requires responding to the feeling of rectal fullness. Manometry is sometimes helpful to retrain the anal sphincter response to rectal distention.

PATIENT EDUCATION

When poor or excessive personal hygiene, application of irritating agents, or neurotic behavior is responsible for symptoms, the relationship between rectal discomfort and precipitants should be explained so that the patient can take appropriate corrective action. Patients who obtain temporary relief of symptoms by applying a topical sensitizing agent may be reluctant to halt their medication if no other therapy is advised. Daily sitz baths can be prescribed in its place. Prevention through counseling is an important component of therapy in male homosexuals. Patients need to know that receptive anal sex with multiple partners carries a very high risk for intestinal infection and that they should certainly refrain from sexual activity if they become symptomatic.

CHAPTER 67 APPROACH TO THE PATIENT WITH AN EXTERNAL HERNIA

Abdominal hernias are exceedingly common, often causing occupational disabilities and posing the risk for incarceration and strangulation of bowel. Fortunately, adequate evaluation can usually be performed in the office by means of history and physical examination. The primary physician must distinguish between patients who require surgical referral and those who may be managed expectantly.

PATHOPHYSIOLOGY AND CLINICAL PRESENTATION

Pathophysiology. A hernia is a defect in the normal musculofascial continuity of the abdominal wall that permits the egress of structures not normally passing through the parietes. In general, the significant feature of hernia is not the size of the protrusion or the sac, but the size and rigidity of the defect in the abdominal wall. Fixation and rigidity of the hernial ring are the features that lead to incarceration and strangulation. The distinction between congenital and acquired hernia is not often clear because many hernias that appear after trauma or straining represent a congenital predisposition, such as indirect inguinal hernia in the adult. This distinction has little bearing on management, although it can make a considerable difference to the patient, who may be compensated if the hernia can be attributed to trauma at work. Some of these hernias are incidental to, and antedate, the perceived injury.

Disorders resulting in increased intraabdominal pressure may contribute to the appearance of a hernia and affect the postoperative management also. For example, chronic cough resulting from cigarette smoking or bronchitis can precipitate or worsen herniation; the same is true of symptomatic prostatism.

Clinical Presentations

Reducible Hernia. The symptoms of an uncomplicated or reducible external hernia are related not to its size but to the degree of pressure on its contents. Patients with large scrotal hernias containing much intestine may have few symptoms other than a dragging sensation. A mass appears on standing, which reduces when the patient is supine. Pain may be intermittent,disappearing when the hernia is reduced. Patients with small hernias containing an entrapped knuckle of bowel may have rather severe pain and nausea. Many patients with femoral, umbilical, or epigastric hernias may be entirely unaware of their existence.

Irreducible or Incarcerated Hernia is one in which the contents cannot be replaced into the abdomen. Here, the mass remains palpable with the patient relaxed and in the supine position. A *strangulated hernia* is an irreducible hernia in which the blood supply to the entrapped bowel loop has been compromised, resulting in small-bowel obstruction and infarction. These patients complain of colicky abdominal pain, nausea, and vomiting and show signs of small-bowel obstruction with distention, tympany, and hyperperistalsis. In addition, careful examination demonstrates a tender, irreducible groin or ventral hernia.

Inguinal Hernias. Indirect inguinal hernias, which account for one half of all hernias in adults, pass through the internal abdominal inguinal ring along the spermatic cord through the inguinal canal and exit through the external inguinal ring. In male patients, these can descend into the scrotum. *Direct inguinal hernias* pass through the posterior inguinal wall medial to the inferior epigastric vessels, through Hesselbach's triangle. *Femoral hernias* pass through the femoral canal inferior to the inguinal ligament and become subcutaneous in the fossa ovalis. It is often difficult to distinguish between these three forms, especially when incarceration is present and the sac is large.

Indirect inguinal hernias are eight to ten times more common in men than in women, whereas femoral hernias are three to five times more common in women than in men. Nevertheless, the most common hernia in women is the indirect inguinal type. The diagnosis is less often made in women because physical examination of the external inguinal ring is more difficult. Direct hernias increase in incidence with advancing age and are the least likely of the external hernias to become incarcerated or strangulated.

Strangulation is common in femoral hernias. The majority of patients with strangulated inguinal hernias are aware of the hernia before strangulation. In contrast, nearly half of those with strangulated femoral hernias are unaware of the hernia before strangulation. In addition, groin pain and tenderness are absent in a significant percentage of cases of strangulated femoral hernia.

Ventral Hernias. The commonly encountered ventral hernias include umbilical, epigastric, and incisional varieties. Ventral hernias are often more obvious when the patient is standing. *Umbilical hernias* pass through the umbilical ring and represent failure of the ring to be obliterated after birth. In the infant, these often close spontaneously within the first 2 years of life. In the adult, they are more common in women and are associated with obesity, multiparity, and cirrhosis with ascites. Umbilical hernias are often missed because they are obscured by subcutaneous fat. They are associated with a high risk for incarceration and strangulation, and mortality rates are higher than with inguinal hernias because large bowel is frequently entrapped.

Incisional Hernias are those that develop in the scar of a previous laparotomy or in a drain site. They are associated with a previous postoperative wound infection, dehiscence, malnutrition, obesity, and smoking. They are more common in vertical than in transverse scars. Incisional hernias often have multiple defects and several rings. They are frequently irreducible or only partially reducible because of adhesions within the sac. Patients with very large incisional hernias may be remarkably free of symptoms of intestinal obstruction, although incarceration is common; strangulation is relatively uncommon because of the usually large size of the defects.

Epigastric Hernias occur through the linea alba between the xiphoid process and the umbilicus. They may be difficult to detect in the obese patient and must be looked for in patients with epigastric pain. Incarcerated epigastric hernia may produce symptoms that mimic those of peptic ulcer disease or biliary colic.

DIFFERENTIAL DIAGNOSIS

Recognizing a hernia usually presents little difficulty, although distinguishing one type of inguinal hernia from another can sometimes be complicated. The differential diagnosis of an entrapped femoral hernia includes not only inguinal hernia but femoral lymphadenopathy, saphenous varix, psoas abscess, and hydrocele. On occasion, it is impossible to differentiate an incarcerated femoral hernia from a single enlarged femoral lymph node (the lymph node of Cloquet). Other causes of groin pain or swelling include muscle strain, hip arthritis, inguinal adenopathy, and undescended testicle.

WORKUP

The diagnosis and evaluation of external hernias require no more than a brief history and careful physical examination; laboratory and radiologic studies are unnecessary unless major complications have resulted.

History. The patient is questioned about groin pain, swelling, ability to reduce the hernia, circumstances of onset, and aggravating and alleviating factors, such as exacerbation on standing, straining, or coughing. Acute onset of colicky abdominal pain, nausea, and vomiting suggest entrapment and strangulation in a patient with a known hernia.

Physical Examination is directed toward differentiating herniation from other causes of inguinal swelling or pain and distinguishing among (a) hernias that are uncomplicated and require no therapy, (b) those that can be repaired electively, and (c) those in which emergency surgery is the safest course. The physical examination is also important in distinguishing the anatomic type of hernia; the prognosis and likelihood of incarceration and strangulation differ among the various types.

Inspection. Patient should be examined in both the supine and standing positions. Inspection is often as important as palpation for detection. Examination should include Valsalva's maneuver to increase intraabdominal pressure. In male patients, small inguinal hernias are looked for by invaginating the scrotal skin while the

patient is standing. To detect ventral hernias, patients should be supine and then asked to lift their head from the examining table and bear down to tense the abdominal wall.

Palpation. Palpation follows and is best performed with the patient standing. In male patients, one inserts the index finger into the *inguinal canal* by following the spermatic cord. Distinguishing a direct from an indirect hernia can be difficult. An indirect hernia projects more inferiorly, and protrusion into the scrotum is almost always a sign. To detect a femoral hernia, one palpates the *fossa ovalis*, inferior to the inguinal canal. If a groin hernia is detected, one should gently attempt reduction of the hernia while the patient relaxes the abdominal muscles.

Examination of the Irreducible Hernia. If a hernia is irreducible, the physician should look for local tenderness, discoloration, edema, fever, and signs of small-bowel obstruction. It is often difficult to distinguish a simple incarceration from early strangulation; for this reason, these two lesions are managed identically by immediate referral to a surgeon. Surgical exploration is the only way to be certain that no compromised bowel is trapped in the hernia sac. Conversely, when signs of small-bowel obstruction are present, it is essential to examine thoroughly for a strangulated femoral hernia because groin pain and tenderness may be absent.

Additional Groin Examination. The groin area also is checked for *lymphadenopathy* and other masses that do not change with position or Valsalva's maneuver. If groin pain is present but no mass, then a musculoskeletal cause is suggested and a careful examination of *hip* movement is indicated.

Checking for Associated Conditions. A few conditions are believed to have more than a chance association with hernias, and some argue that they should be screened for. Whether the adult patient with a recent hernia is more likely to have an occult *carcinoma of the colon* remains a source of controversy. It has been suggested that patients undergo screening for colorectal cancer (see Chapter 56). However, if the patient reports no change in bowel habits and the stools are repeatedly negative for blood on guaiac testing, it is unnecessary to submit the patient to more extensive investigation for occult malignancy. Symptoms and signs of prostatism are frequently present in elderly men with hernia and may require relief before herniorrhaphy. The entire abdomen ought to be examined for masses, hepatomegaly, and ascites, which are sometimes associated with hernia formation.

PRINCIPLES OF MANAGEMENT AND INDICATIONS FOR REFERRAL

Conservative Therapy versus Surgery. The key determination is the need for surgery, which can be based on the findings at physical examination.

Reducible Inguinal Hernia. Patients with an *asymptomatic*, easily reducible inguinal hernia can be managed expectantly without resorting to surgery. Surgery is elective but should probably be carried out if the patient is young. Should pain ensue or signs of incarceration develop, then surgery may be indicated. Patients with a *symptomatic* reducible inguinal hernia should undergo elective repair for relief of symptoms and prevention of strangulation. Reduction by means of a *truss* may be unsatisfactory, even in patients with relative medical contraindications to surgery. Moreover, surgical repair can be performed under local anesthesia in the high-risk patient, and newer laparoscopic techniques (see below) make for less perioperative morbidity.

Nontender Incarcerated Inguinal Hernia. If the hernia is of recent onset and signs of inflammation or bowel obstruction are absent, it may be safe to attempt *gentle reduction* ("*taxis*"). This is best accomplished with the patient supine and the hips and knees flexed. If gentle pressure over the hernial sac fails to reduce the mass further, efforts should be abandoned and the patient should be referred for surgery forthwith. Often, patients have more experience in reducing their own hernia than does the physician. Patients with evidence of strangulated groin hernias should be subjected to immediate operation regardless of medical contraindications; if they are not treated, death will result from bowel necrosis.

Reducible Femoral Hernias should undergo prompt elective repair because of the high incidence of strangulation. Whenever there is a question of an incarcerated femoral hernia, it is safest to proceed immediately with surgical exploration.

Umbilical Hernias. Surgery is unnecessary if physical examination reveals a small, asymptomatic fascial defect without protrusion. When herniation is detected, however, umbilical defects should be repaired because the risk for incarceration and strangulation is high. The danger of strangulation is compounded by the greater likelihood of colonic entrapment, which is associated with a higher mortality rate than is strangulation of small intestine. Therefore, all incarcerated umbilical hernias should be managed as if they were strangulated. Elective umbilical herniorrhaphy should be avoided in patients with ascites; instead, efforts should be directed toward reducing the ascites (see Chapter 71). The problem in patients with cirrhosis and ascites is made more difficult when the skin overlying the sac thins out and poses the risk of rupture.

Small-neck Incisional Hernias or Tender Incarceration should undergo repair on an urgent basis. Patients who have trophic changes or ulceration in the skin overlying incisional hernias are also candidates for urgent surgery. In some instances, cellulitis of the skin overlying the hernia sac develops and is difficult to distinguish from strangulation of the contents of the sac. Management of large incarcerated incisional hernias that occur in the abdomen in very obese patients is a particular problem. Major efforts should be directed toward weight reduction before repair if it is possible to procrastinate. If, however, the presence of intestinal obstruction is a possibility or the viability of the contents of the sac is doubtful, the advice of a surgeon should be sought promptly.

Treatment of Contributing Factors. Factors contributing to hernia formation should be corrected if possible. *Prostatism* that leads to straining at urination needs attention, be it medical or surgical (see Chapter 138). Patients with *chronic cough* secondary to chronic obstructive pulmonary disease, cigarette smoking, asthma, or esophageal reflux should have the underlying condition addressed promptly (see Chapter 41) to diminish symptoms caused by the hernia and to decrease the possibility of postoperative complications.

Conventional versus Laparoscopic Hernia Repair. The effective application of laparoscopic techniques to the repair of inguinal hernias provides an alternative surgical approach for patients. In the largest multicenter, randomized prospective study to date, laparoscopic repair proved superior to open repair in terms of time required for recovery from surgery (1 week vs. 2 weeks), return to work (2 weeks vs. 3 weeks), and resumption of athletic activities (3 weeks vs. 5 weeks). In addition, the risk for recurrence was reduced by 50%, and fewer wound infections were noted. Most recurrences that did follow laparoscopic surgery were traceable to errors in surgical technique. The duration of surgery was similar for both procedures. The time to discharge was less, as was the degree of postoperative pain, with laparoscopic surgery. Disadvantages include the higher cost of surgery, need for general anesthesia, and additional surgical skill required. (A clear and prolonged learning curve is associated with laparoscopic surgery, with the potential for inexperienced operators causing serious complications, such as viscus perforation, when unsupervised.) If the requisite surgical skill is available, then patients capable of undergoing general anesthesia and desiring a more rapid return to activity can be offered laparoscopic repair.

PATIENT EDUCATION

Patients who are to be managed conservatively must be taught to watch for signs of complications. It is the responsibility of the physician to instruct the patient in the symptoms of incarceration and strangulation and in the urgency of seeking help should they occur. If the patient is deemed incompetent to make such observations and to obtain help promptly, a strong case can be made for proceeding with surgery. Patients scheduled for elective surgery also require instruction because incarceration occasionally occurs before the planned operation.

Many patients with asymptomatic or mildly symptomatic reducible hernias will be reluctant to undergo surgery because their symptoms are minimal. If they fall into the high-risk group (e.g., femoral or small-neck incisional hernias), they should be informed of the strong likelihood of strangulation and the minuscule morbidity and mortality associated with surgery.

Patients who are advised to have surgery appreciate estimates of time to walking (same day for local anesthesia and general anesthesia in the morning), time to return to physically undemanding work (2 to 3 weeks), time to resumption of unlimited activity (3 to 6 weeks), risk for recurrence (10%), and effect on sexual function (none). A discussion of the advantages and disadvantages of open versus laparoscopic repair is also worthwhile in the context of a review of the patient's surgical candidacy.

CHAPTER 68 MANAGEMENT OF PEPTIC ULCER DISEASE

Peptic ulcer disease continues to be a major source of morbidity, affecting up to 2.0% of the U.S. population at any one time. Men outnumber women by two to one. The peak prevalence for duodenal ulcer (which accounts for 80% of cases) is between ages 45 and 54; gastric ulcer peaks between the ages of 55 and 64.

Advances in understanding peptic ulcer pathogenesis have revolutionized treatment and markedly improved outcomes. The primary care physician must be capable of designing and implementing a cost-effective program that alleviates pain, promotes healing, limits complications, and prevents recurrences. Other tasks include the timely identification of patients who require endoscopy or consideration of surgery. The management of non-ulcer dyspepsia, which may mimic peptic ulcer disease, shares aspects of peptic ulcer treatment (see Chapter 74).

PATHOPHYSIOLOGY AND CLINICAL PRESENTATION

Peptic ulcers arise principally in the stomach and duodenum, areas exposed to gastric acid and pepsin. Although the precise mechanisms of ulcer formation remain incompletely understood, the process appears to involve the interplay of acid production, pepsin secretion, *Helicobacter pylori* infection, and mucosal defense mechanisms.

Gastric Acid Production, Pepsin Secretion, and Mucosal Defenses

Acid Production and Pepsin Secretion. Excess acid production is the hallmark of duodenal ulcer disease, with significant increases noted in basal and peak acid outputs, parietal and chief cell masses, and responses to food and hormonal stimulation. Zollinger-Ellison syndrome (with its associated hypergastrinemia and parietal cell overproduction) is the prototypical acid hypersecretory condition resulting in ulcer formation. Some patients with duodenal ulcer demonstrate *rapid gastric emptying*, which raises the acid exposure of the proximal duodenum. Pepsin secretion is also elevated in duodenal ulcer disease. Gastric acid production is relatively normal in patients with gastric ulcers.

Mucosal Defense. An appreciation for the importance of mucosal defense mechanisms is emerging. Major determinants of mucosal integrity include secretion of mucus, production of bicarbonate, mucosal blood flow, and cellular repair mechanisms. *The mucous barrier may become compromised* by an increased degradation of mucus, decreased secretion, or production of defective mucus. Bile acids, pepsin, pancreatic enzymes, and mechanical forces contribute to the degradation of mucus. *Gastric prostaglandin production* appears important to sustainingproduction of mucus, secretion of bicarbonate, and mucosal repair. By helping to maintain a neutral pH and aqueous environment at the surface of the gastric epithelium, mucus and bicarbonate protect the mucosa from acid, pepsin, and other potentially injurious agents (see below).

Role of Aspirin and Other Nonsteroidal Antiinflammatory Drugs

Mechanisms. The relation of aspirin and nonaspirin NSAIDs to ulcer disease largely involves their potent *inhibition of gastric mucosal prostaglandin synthesis*. With long-term use, all NSAIDs (including enteric-coated and non-aspirin salicylates and NSAID prodrugs) are capable of producing solitary deep *gastric ulcers*. The risk for clinically important ulceration is estimated by the U.S. Food and Drug Administration to be 2% per patient-year of NSAID use. No major differences are found among NSAID preparations in regard to ulcer risk (despite highly advertised claims to the contrary). About 15% of long-term NSAID users demonstrate gastric ulceration at endoscopy. Risk generally increases with dose and duration of therapy, but up to one fourth of complications have been observed within the first month of therapy. The elderly are at greatest risk (reported relative risk of about 4.0).

In addition to inhibiting prostaglandin synthesis, many NSAID preparations produce acute diffuse mucosal injury by means of a *direct erosive effect*. Endoscopic study has shown significant mucosal injury to result from both plain and tablet forms of buffered aspirin, although not with enteric-coated aspirin preparations, unless gastric emptying is delayed. Similar acute erosions occur with uncoated NSAIDs, but not with enteric-coated preparations or prodrug formulations. Such diffuse acute injury is rarely associated with symptoms or clinically significant ulceration, although minor occult bleeding may ensue. Smoking, alcohol use, alcohol-related disease, and preexisting peptic ulcer disease greatly increase the risk for ulcer and ulcer complications in NSAID-treated patients. Concurrent *H. pylori* infection also may predispose the patient to NSAID-related injury.

Gastric versus Duodenal Disease. NSAID use is associated primarily with gastric ulceration, not with new *duodenal ulceration*, but preexisting duodenal ulceration may be exacerbated and complicated by NSAID use. It is estimated that more than half of ulcer complications associated with NSAID use occur in patients with preexisting duodenal ulcers. Much of the ulcer morbidity associated with NSAID use may be related to preexisting, subclinical disease.

Role of *Helicobacter pylori* Infection

Infection with *H. pylori* has emerged as a major, if not the major, precipitant of peptic ulcer disease; it is associated with 95% to 99% of cases of *duodenal ulcer* and ulcer recurrence and with more than 90% of *gastric ulcers* unrelated to NSAID use. *Helicobacter* infection also is strongly associated with antral *gastritis* and is a risk factor for *gastric carcinoma* and *MALT lymphoma* (mucosa-associated lymphoid tissue) of the stomach; its eradication results in remission of the latter. Cancer risk appears to increase when *H. pylori* is present in the setting of atrophic gastritis.

Cure of *Helicobacter* infection can speed ulcer healing and greatly reduce rates of recurrence. The organism does not appear to cause ulcers *per se*, but rather seems to enhance mucosal susceptibility to the injurious actions of acid and pepsin. Acid hypersecretors may be particularly vulnerable to ulcer formation in the context of *Helicobacter* infection and subject to slow healing and a high rate of recurrence. The prevalence of *H. pylori* infection increases with age, approaching 90% in ulcer patients over age 65. The mode of transmission is unclear, although person-to-person fecal-oral spread is suspected because clusters occur in families.

Other Precipitants

A host of psychological, dietary, pharmacologic, and hereditary factors have been implicated in the cause or aggravation of ulcer disease.

Stress has long been considered a key precipitant, a view supported by a higher incidence of chronic stress in ulcer patients than in controls, increased acid production in response to stress, and a more prolonged course and poorer prognosis in those with chronic severe anxiety. Patients in whom ulcers develop view life stresses more negatively than do controls. Acid hypersecretion and ulcer formation have been observed in small-scale studies of patients undergoing severe emotional stress; with subsidence of stress, acid secretion falls and ulcers heal. Confirmation of these small-scale observations will strengthen the association between stress and ulcer disease.

Smoking is an important risk factor, identified by epidemiologic studies. For example, ulcers are twice as likely to develop in cigarette smokers as in nonsmokers. The risk for gastric ulcer correlates with the number of cigarettes smoked, and those with ulcers have increased rates of smoking. The rates of recurrence are dramatically increased in those who smoke, and healing is markedly slowed. Impaired prosta-glandin production has been demonstrated in the gastric mucosa of smokers.

Alcohol and Coffee have also been implicated. Coffee, including decaffeinated forms, stimulates acid secretion, as do other caffeine-containing beverages, but evidence proving ulcer causation is lacking. *Ethanol* can compromise the mucosal barrier and cause gastritis, and beer is almost as potent a stimulant of acid secretion as is gastrin. Nonetheless, data on the link between alcohol use and ulcer disease are conflicting. However, patients with alcohol-related cirrhosis are at increased risk for ulcer formation and complications.

Glucocorticosteroids. Their contribution has been debated ever since these agents first became available, with randomized controlled trials and metaanalyses producing conflicting results. Discrepancies are related in part to failure to control for concurrent NSAID use. The risk appears to be nil if the patient is not taking NSAIDs concurrently and the dose is less than 30 mg daily. However, high-dose steroid therapy (>30 mg/d) may confer an increment of risk, as might the underlying disease for which the prednisone is being taken. In the absence of concurrent NSAID use, overall risk appears to be very modest.

Heredity plays some role. The incidence of ulcer in the parents, siblings, and children of ulcer patients is increased, and studies of twins show greater concordance (e.g., both twins affected) among identical than among fraternal twins. Increased meal-stimulated gastrin release and pepsin secretion have been found to be hereditary traits among ulcer patients and their families.

Clinical Presentation

Peptic ulcers usually occur at or near mucosal transition zones, areas thought to be particularly vulnerable to the effects of acid, pepsin, bile, and pancreatic enzymes. Gastric ulcers are found in the *antrum* at the *lesser curvature*, near the junction of the acid-secreting parietal cells and the antral mucosa. Duodenal ulcers arise mostly at the *junction* of the *antrum* and *duodenum*.

The clinical presentations of gastric and duodenal peptic ulcers often overlap and may be nonspecific. Patients can present with pain, bleeding, or obstruction, or they may be symptom-free. Epigastric pain, relieved by antacids and occurring as clusters of daily symptoms for a few weeks separated by pain-free periods of months, is characteristic of peptic disease. Duodenal ulcer pain is classically relieved by food, absent before breakfast, and responsible for awakening the patient at night; it starts 2 to 3 hours after a meal. However, careful studies of patients with documented duodenal ulcers have shown that in some of them pain is often worsened by meals, present before breakfast, and continuous rather than periodic. Gastric ulcer pain is more likely to be precipitated by food and often radiates from the epigastrium to the back or substernal region. It too can awaken the patient and be relieved by food. In both conditions, the pain may be dull, aching, gnawing, or burning in quality, consistent with its visceral quality.

Symptoms may be absent and dissociated from mucosal changes. Silent disease is particularly common among the elderly and those using NSAIDs. A complication is the first clinical manifestation of ulcer disease in about 25% of persons with ulcer disease unrelated to NSAID use; the figure is considerably higher in the setting of NSAID use.

Natural History and Clinical Course

Natural History and Clinical Course without *Helicobacter* Eradication. Because most patients receive some form of treatment, available data reflect the clinical course more than the true natural history. Studies performed before the advent of aggressive use of antacids or histamine $_2$ (H$_2$)-receptor antagonists showed that a large majority of ulcers heal completely by 4 weeks, although large ones in the stomach can take up to 12 weeks. The majority of patients in such studies became pain-free within the first 4 weeks; however, little correlation was noted between the cessation of pain and healing of the ulcer. Recurrences were frequent. The 5-year recurrence rates ranged from 30% to 90%. Although it was rare for a patient to have more than two or three recurrent gastric ulcers, multiple recurrences were not unusual for those with duodenal ulcers. No correlation was found between recurrence rate and ulcer size, duration of symptoms, or location. Recurrent ulcers healed just as rapidly and completely as original lesions. The rate of development of a major complication, such as hemorrhage, perforation, or obstruction, was less than 1% annually. Bleeding was slightly more common from duodenal than from gastric ulcers and two to three times more common than perforation.

Clinical Course with *Helicobacter* Eradication. With eradication of *H. pylori* infection and the use of potent agents to suppress acid production, the clinical course of peptic ulcer disease has improved markedly. Complete *healing* is now achieved in up to 95% of cases within 4 to 6 weeks of initiation of treatment with antibiotics to eradicate *H. pylori* and proton pump inhibitors (PPIs) to suppress acid production maximally (see below). The 1-year risk for relapse is about 5% with eradication of *Helicobacter*, but more than 50% when acid suppression is the only form of initial therapy.

Surgical therapy has also affected the clinical course. Antrectomy lowers the recurrence rates for duodenal ulcer to 5% annually; selective proximal gastric vagotomy also substantially lowers recurrences, although to a lesser extent (see below).

WORKUP

A presumptive diagnosis of acid-peptic disease can often be made on clinical grounds alone (see Chapter 58). Aside from the testing of all patients for *H. pylori* infection (see below), the initial workup of uncomplicated peptic ulcer disease need not include confirmation by barium study or endoscopy. Cost-effectiveness studies demonstrate that commencement of empiric therapy is superior to prior confirmation of the diagnosis by endoscopy or upper gastrointestinal series. The only time confirmatory studies are needed initially is when clinical findings suggest a complication of peptic ulcer disease or gastric cancer (e.g., weight loss, dysphagia, recurrent nausea and vomiting, iron-deficiency anemia, and stool test positive for occult blood, especially in a person over 40 years of age).

Testing for Helicobacter infection. There is no "gold standard," but the reference method remains endoscopic antral mucosal *biopsy* with *special staining* [Warthin-Starry (silver) stain, with a sensitivity of 90% and a specificity of 100%]. The CLO test provides a more rapid means of endoscopic diagnosis (sensitivity 90%, specificity 96%). Noninvasive testing is possible with the ^{13}C-urea breath test (sensitivity 91%, specificity 91%) and by *serologic testing*, which measures immunoglobulin G and immunoglobulin A antibodies to *Helicobacter* (sensitivity 71%, specificity 85%). Because no statistically significant difference between these test performances has been found in head-to-head study, noninvasive testing is preferred in persons who do not need to undergo initial endoscopy.

Role of Serologic Testing. Serologic testing is used by many primary care physicians in lieu of endoscopic examination or breath testing because it is readily available, convenient, reasonably sensitive and specific, and inexpensive. This approach has proved cost-effective for the detection of infection in persons who have never been treated, but it cannot be used to determine cure or recurrence of infection because the test result often remains positive for years after eradication of the organism. Positivity means only prior exposure to the organism.

Role of Breath Testing. Breath testing takes advantage of the urease production of the organism and, unlike serology, provides direct evidence of active infection. Consequently, breath testing is considered the preferred noninvasive method for *determining the eradication of infection*, which becomes important in the settings of relapse, recurrence, and disease complicated by bleeding. Utilizing carbon dioxide labeled with ^{13}C or ^{14}C, this technology provides diagnostic sensitivity and specificity approaching that of endoscopic measures. The test is still not widely available, and its cost is currently greater than that for serology, so that it is relegated to a secondary role for initial testing.

Role of Endoscopy and Upper Gastrointestinal Series. At the time of *initial presentation*, patients over 40 years of age who have any clinical findings that raise concern about gastric cancer or complicated ulcer disease (see above) should promptly undergo visualization of the stomach and duodenum. The most cost-effective approach to initial testing remains a subject of debate. Endoscopists correctly argue that gastroscopy is superior to barium study for the detection of gastric ulcer, malignancy, and *H. pylori* because brushings, biopsy, CLO test, and cultures can be performed at the same time. However, radiologists aver that with the use of air-contrast techniques, the sensitivity of endoscopy to detect malignancy can be approached with a procedure that entails one-third the cost and is safer and more comfortable for the patient. The debate continues; test selection should be individualized.

Later in the course of illness, the patient with refractory or recurrent disease in the absence of evidence for persistent *H. pylori* infection should undergo endoscopy to check for gastric malignancy, as should the person with an ulcer that appears suspect on barium study.

Evaluation of the Benign-appearing Ulcer on Barium Study. About 4% of all gastric ulcers prove to be malignant. The sensitivity of barium study for the detection of gastric malignancy is in the range of 80% to 85%, compared with 95% for endoscopy with biopsy and brushing. Most malignant ulcers manifest radiologic signs of cancer, including irregular shape, nodular base, absence of radiating gastric folds, folds that are blunted or stop before the ulcer, and rigidity of adjacent stomach. Ulcers in the fundus are more likely to be malignant; those within 1 cm of the pylorus are almost always benign. Ulcers that appear malignant by any of these criteria require biopsy.

Subjecting all patients with benign-appearing ulcers on barium study to endoscopy is likely to be of low yield and add little to survival. For persons presenting with an ulcerated gastric carcinoma, the 5-year survival is only 25% to 35%. A more productive alternative might be to refer for endoscopy and biopsy only those patients with

a radiologically suspect gastric ulcer and those with an ulcer that fails to heal fully despite documented eradication of *Helicobacter* infection (see below). The literature should be followed for further cost–benefit studies.

PRINCIPLES OF THERAPY

Treatment Objectives and Therapeutic Options: Overview

The major objectives of therapy are to speed healing, reduce pain, and prevent complications and recurrences while minimizing the costs and side effects of therapy. Although peptic ulcer disease represents a heterogeneous set of disorders, the overall approach to medical therapy is similar and centers on eradicating any *Helicobacter* infection, reducing gastric acidity, and protecting the mucosal barrier.

Antibiotics that eradicate *Helicobacter* infection are critical to effective treatment of peptic ulcer disease (except in cases related to NSAID use). Their use promotes effective ulcer healing and prevents relapse. Combination programs are required because of the high frequency of antibiotic resistance to single agents.

Antacids, Histamine$_2$ Blockers, and Proton Pump Inhibitors all speed ulcer healing by reducing gastric acidity, but unless they are used on a long-term basis, they do not prevent recurrence. *Antacids* provide a low-cost, safe means of neutralizing gastric acid but require frequent dosing. *H_2-receptor antagonists* and *PPIs* block acid secretion; they are well tolerated and convenient to use but very expensive when taken for prolonged periods.

Sucralfate acts locally, forming a cytoprotective coating over the injured mucosa, perhaps also absorbing pepsin and inactivating bile acids. Its principal use is to facilitate ulcer healing. It must be taken frequently, is costly, and can cause gastrointestinal upset.

Misoprostol, a prostaglandin analogue, counters the prostaglandin inhibition associated with NSAID use. The drug reduces the risk for ulcer formation associated with NSAID therapy and prevents the recurrence of NSAID-induced gastric ulceration and bleeding. Its cost is high and gastrointestinal side effects are common.

Avoidance of substances and activities potentially injurious to the gastric mucosa (aspirin, NSAIDs, smoking, stress) complement the therapeutic effort.

Surgery remains an option for the treatment of refractory disease and its complications.

Combination Programs are often utilized, particularly in instances of *Helicobacter*-induced disease. Antibiotics are prescribed to treat the underlying infection, and acid suppression is given to speed ulcer healing and promote relief of symptoms. Misoprostol plus acid suppression with a PPI is an effective combination in ulcers related to NSAID use.

Nonpharmacologic Therapies

Avoidance of Agents Injurious to the Mucosal Barrier. Any program to speed healing, limit recurrences, and prevent complications must address both short-term and prolonged use of agents injurious to the mucosal barrier. *Aspirin* and most *NSAIDs* should be avoided, if possible, because they greatly increase risk and refractoriness to therapy. Using *enteric-coated* and *prodrug* NSAID formulations and taking them with meals might mitigate superficial erosive injury but do little to prevent the deep ulcers that ensue with long-term use of these potent prostaglandin inhibitors. Consequently, if NSAID therapy must be continued, other means must be found to ensure their safe use (see below).

Although not an independent risk factor, *alcohol* should probably be restricted because it may impair healing and cause complications. Although *glucocorticosteroids* may exacerbate the chance of an ulcer developing in the context of NSAID therapy, they pose little direct risk, and a concurrent prophylactic regimen is not required unless other risk factors are present or large doses (e.g., >30 mg of prednisone daily) are going to be used for prolonged periods.

Alleviating Emotional Stress. Persons with difficult home or work situations may benefit from counseling. Treatment begins with a careful history eliciting pertinent psychosocial information. The very act of discussing these issues and the opportunity to ventilate one's feelings to a supportive listener may lessen tension and help point the way to solutions. A brief course of minor tranquilizer therapy is sometimes helpful to augment supportive psychotherapy and enable the patient to cope with the combination of stress and illness (see Chapter 226). Before the days of cost containment, very stressed patients were hospitalized to facilitate ulcer healing; however, only stays in excess of 4 weeks were shown to be effective.

Smoking Cessation. Smoking impedes the healing of peptic ulcers and may interfere with the action of H_2-receptor antagonists (gastric ulcer patients who continue to smoke have blunted responses to cimetidine therapy). Cessation should be urged during recovery from an ulcer. Although the role of smoking as a causative factor in ulcer disease is less well established, there is ample medical justification to advise its discontinuation (see Chapter 54).

Diet. Contrary to common belief, evidence is lacking that any particular dietary manipulation promotes healing or reduces acidity. The one exception is that not eating before bedtime probably reduces nocturnal gastric acid levels because the postprandial stimulus to acid secretion is avoided. Otherwise, bland diets, frequent feedings, small feedings, and avoidance of spices, fruit juices, and acidic foods have never been shown to affect the course of ulcer disease. Milk is also without specific benefit; in fact, its high content of protein and calcium stimulates gastric acid secretion. Some patients claim that certain foods "disagree" with them; these can be avoided, but not for the sake of altering acid production. Intake of *coffee* (including decaffeinated forms) and other caffeinated beverages ought to be limited but need not be eliminated entirely; their link with ulcer disease is not especially strong.

Pharmacologic Therapies

Antibiotics. The eradication of *H. pylori* infection is emerging as the principal treatment objective for peptic ulcer disease (except in cases related to NSAID use). The efficacy of such treatment in preventing relapses, resolving refractory disease, and eliminating the need for expensive, long-term acid suppression/inhibition therapy is becoming increasingly evident. One to two weeks of antibiotic therapy reduces the relapse rate at 1 year from 50% to as little as 5% to 10%. As effective as antibiotic therapy is, empiric use is not recommended because of the emerging risk for *Helicobacter* drug resistance in the community. However, selective empiric use may be reasonable when the clinical probability of infection is very high (e.g., objectively documented duodenal ulcer in a person not taking NSAIDs).

Cost-effectiveness. The efficacy, safety, and low cost of antibiotic therapy have made eradication of *Helicobacter* infection the mainstay of cost-effective management for peptic ulcer disease; antibiotic therapy usually obviates the need for long-term or recurrent use of expensive acid suppression therapy. Even with the cost of endoscopy figured in, antibiotic treatment for *Helicobacter* is a far more cost-effective approach to peptic ulcer disease than is maintenance acid suppression. Cost-effectiveness data strongly favor the treatment of *Helicobacter* over traditional acid suppression therapy. Once infection is eradicated, the rate of recurrence falls not only dramatically but often permanently.

Available Agents. Multidrug regimens are required because of the high frequency of resistance to single agents. Agents with anti-*Helicobacter* activity include *tetracycline*, *amoxicillin*, *bismuth subsalicylate*, *metronidazole*, and *clarithromycin*, in addition to the *PPIs*. Antibiotic resistance has been reported, particularly for metronidazole (in 10% to 50%) and more recently for clarithromycin. Persons with prior exposure to these antibiotics should be treated with other agents. Acid suppression therapy (with H_2-blockers or PPIs) is often added to speed ulcer healing and provide more rapid symptomatic relief, but prevention of relapse depends primarily on the eradication of *Helicobacter*.

Standard Triple Therapy. The standard regimen is so-called *triple therapy* with *metronidazole*, *tetracycline* (or *amoxicillin* for those patients allergic to tetracycline), and *bismuth subsalicylate* given four times daily for 2 *weeks*. Rates of eradication are in excess of 90% under study conditions but are probably lower in everyday practice. A lack of compliance and antibiotic-induced diarrhea are common problems with triple therapy, especially when 2 weeks of therapy are prescribed. A *1-week program* that adds a *PPI* (omeprazole or lansoprazole) to the regimen achieves similar eradication results while shortening the length of treatment.

Dual Regimens. Because triple antibiotic therapy poses problems related to compliance and side effects, simpler, better-tolerated programs have been explored. *Clarithromycin*-based regimens, which combine the antibiotic (taken three times daily for 2 weeks) with either *omeprazole* or *ranitidine/bismuth citrate* (taken twice daily for a month), improve compliance and are better tolerated; however, eradication rates are not quite as good as with triple therapy (70% to 85%), and cost increases substantially (an order of magnitude more expensive than triple therapy)! Substituting amoxicillin for clarithromycin in a dual regimen markedly reduces

eradication rates and is not recommended.

Two Antibiotics Plus Proton Pump Inhibitor. Treatment programs that enhance compliance and minimize side effects without compromising efficacy or affordability continue to be tested. A particularly promising program involves two antibiotics (*clarithromycin* plus *metronidazole* or *amoxicillir*) in combination with a *PPI* (omeprazole or lansoprazole). The principal advantages include twice-daily dosing and few side effects. The cost is considerably greater than with standard triple therapy, but eradication rates are in excess of 90%. Comparative cost-effectiveness data are not yet available.

Antacids. Because they are effective, inexpensive, and safe, antacids remain a mainstay of therapy. The preferred preparations are those containing magnesium hydroxide, aluminum hydroxide, or a combination of the two. Those containing calcium carbonate (e.g., Tums, Rolaids) have considerable acid-neutralizingcapacity and are inexpensive, convenient, and well tolerated, but laboratory studies have demonstrated rebound acid hypersecretion with the use of calcium-containing antacids. Nonetheless, no clinical evidence suggests that acid rebound is clinically important, but more study of the issue is needed. In persons with renal disease, antacid use can cause hypercalcemia and systemic alkalosis.

Effectiveness. When taken in four-times-daily regimens, antacids have been shown endoscopically to be more effective than placebo, and comparable with H_2-blockers and sucralfate in promoting the healing of duodenal ulcers. Their effectiveness in gastric ulcer disease and in preventing recurrences of gastric and duodenal ulcers is less well established. These agents are no more effective than placebo for the relief of pain from duodenal ulcer, although they are better than placebo for symptoms attributable to gastric ulcer. This effect on gastric ulcer pain and the recently demonstrated efficacy of frequent but nonneutralizing antacid doses has stimulated speculation, especially in regard to aluminum-containing antacids, about mechanisms of action beyond simple acid neutralization (e.g., protective coating, inactivation of irritant bile acids, stimulation of prostaglandin synthesis).

Buffering Capacities of liquid antacid preparations vary considerably, ranging from 6 to 128 mEq/15 mL. Liquids are superior to tablets in buffering capacity. Calcium carbonate preparations are among the most potent in neutralizing capacity but can cause acid rebound of unclear significance. The most effective liquid antacids contain magnesium and aluminum hydroxides. When the aluminum hydroxide mixes with acid, nonabsorbable aluminum salts are formed, which are constipating. The magnesium salts formed are also poorly absorbed but frequently cause diarrhea, an effect that may not be completely canceled by the constipating action of the aluminum. If diarrhea becomes a problem, one can alternately use an antacid containing only aluminum hydroxide. Many of the liquid antacids contain considerable amounts of sodium. A low-sodium preparation is sometimes needed to avoid sodium excess in patients who must restrict salt intake.

Dosage. Substantial doses of antacids are needed in the treatment of duodenal ulcer; however, as little as 120 mEq daily has proved effective in healing gastric ulcers. Previous failures to demonstrate the effectiveness of antacids may have been a consequence of inadequate doses. About 140 mEq at a time is necessary to bring the gastric pH into the range of 3.5 to 5.0. Typical 30-mL doses of many popular antacids provide only 60 mEq. Although the contents listed on labels of weak and strong antacid preparations are similar, the relative amounts and solubilities of ingredients do vary, which accounts for differences in potency.

Timing of the antacid dose affects the degree of acid neutralization. If given with a meal, the antacid is wasted because food is a perfectly adequate buffer. When an antacid is given 1 hour after eating, gastric acidity is minimized for another 1 to 2 hours, countering the food-induced stimulation of acid secretion. A second dose 3 hours after a meal provides another hour of acid neutralization and tides the patient over to the next meal.

Side Effects are relatively few but important to recognize. Diarrhea is common as a result of the cathartic effect of insoluble magnesium salts. Alternating with an antacid containing only aluminum hydroxide can help. Antacids enhance the absorption of dicumarol and L-dopa and decrease the absorption of H_2-blockers, phenothiazines, sulfonamides, isoniazid, and penicillin. Potent antacids can cause the premature release of aspirin from enteric-coated tablets when both are taken simultaneously. *Phosphate depletion* is possible in patients using an aluminum-containing antacid; insoluble aluminum phosphate forms. In renal failure, excess aluminum may accumulate and cause central nervous system toxicity. There is also concern, although no proof, about the relation of dementia to serum aluminum excess in the elderly (see Chapter 169). Excess sodium absorption has already been mentioned. Magnesium-containing antacids should be avoided in renal failure because of the risk for *hypermagnesemia*; the small amounts of magnesium absorbed cannot be eliminated. Calcium can be absorbed and precipitate *hypercalcemia* if renal function is depressed. As noted, calcium also triggers *rebound acid secretion*, raising at least a theoretical concern about overall efficacy.

Cost-effective Prescribing for duodenal ulceration employs an agent with a high degree of neutralizing capacity and a low cost per therapeutic dose. Several liquid preparations have such qualities and stand out as the best buys; moreover, they have low sodium levels (Table 68.1 and Table 68.2). Compared with tablets, they are less expensive but not as convenient; tablets are particularly well suited for patients who must take medication while at work. Although antacids are safe and effective, their cost and inconvenience can mount when they must be taken seven times a day. Trying to achieve adequate acid neutralization with antacid tablets alone can become difficult; at least eight tablets must be taken just to obtain 140 mEq of acid-neutralizing capacity. For the treatment of gastric ulcer,acid neutralization is less of an issue, and much smaller doses may suffice (e.g., two to three extra-strength tablets of an aluminum-containing antacid, such as Mylanta Double Strength or Extra Strength Maalox Antacid Plus taken four times daily). The cost of antacid regimens is about one-fourth that of H $_2$-blocker therapy or sucralfate.

Table 68.1. Characteristics of Major Liquid Antacids

Table 68.2. Characteristics of Major Antacid Tablets

Histamine$_2$-Receptor Antagonists. These drugs block the H_2-receptors of parietal cells, which results in a 50% to 80% reduction in basal, postprandial, and vagally stimulated acid production. The available preparations include cimetidine, ranitidine, famotidine, and nizatidine. Despite advertising claims of major differences among these agents, they are remarkably similar in efficacy. No clinically significant differences have been found in rates of ulcer healing or prevention of relapse. About 75% of duodenal ulcers are healed by 4 weeks, and 84% to 97% by 8 weeks; 55% to 65% of gastric ulcers are healed by 4 weeks, and 80% to 90% by 8 weeks. Recurrence rates after completion of therapy range from 45% to 70% at 3 months to 75% to 90% at 1 year and are no different from those noted with other treatments.

Rarely is maintenance therapy necessary if *Helicobacter* infection has been eradicated.

Cimetidine was the first H$_2$-blocker and is available in generic formulation, so that it is the least expensive of the drugs in its class. It is also available without prescription in half-strength doses.

Pharmacokinetics. Absorption is rapid and complete after oral administration. Peak blood levels occur 45 to 90 minutes after a 300-mg dose. Originally thrice-daily or four-times-daily dosing was recommended, but equivalent results have been achieved with a single 800-mg dose at bedtime or 400 mg twice daily. A low-dose maintenance program (400 mg daily at bedtime) has been shown to reduce the recurrence rate substantially to 15% to 25% yearly. Absorption is reduced 10% to 20% by concurrent intake of magnesium- or aluminum-containing antacids; a 2-hour staggering of doses helps maximize benefit, although it is not essential. Absorption is not affected by meals. Most of the drug is excreted unchanged in the urine; 15% is metabolized by the liver. Patients in renal failure require less frequent administration (e.g., every 12 hours when the serum creatinine rises above 3.0 mg/dL). The drug crosses the placental barrier.

Side Effects and Adverse Reactions are relatively minor and occur infrequently (<5% of patients). In controlled studies, the frequency of side effects was indistinguishable from that for placebo; however, in long-term studies, the frequency of adverse reactions exceeds that for placebo. The most commonly experienced adverse reactions include *diarrhea, nausea, vomiting, rash, dizziness, and headache.* The incidence of each is less than 1%. The drug crosses the blood-brain barrier in humans and can cause *lethargy, confusion, slurred speech, agitation*, and *visual hallucinations*, particularly in the elderly, the very young, patients with renal or liver disease, and those receiving high doses. *Gynecomastia* and *sexual dysfunction* rank among the most troubling of side effects and are especially prevalent among patients taking the drug at high doses (2,400 mg daily) for the treatment of Zollinger-Ellison syndrome. The mechanism is believed to involve the ability of the drug to impair estradiol metabolism and bind to androgenic receptors, which also results in a slightly reduced sperm count.

Isolated cases of *bone arrow suppression* have been reported in the setting of severe underlying illness and use of multiple drugs. Small, clinically insignificant decreases in *creatinine clearance* are sometimes noted. The effect is dose-related and more common when daily doses exceed 2,000 mg. On occasion, the creatine clearance might fall by as much as 25%, but no permanent renal injury results. Frank *hep-atotoxicity* is rare, but transient twofold to threefold increases in aminotransferase (transaminase) levels sometimes ensue; however, these usually disappear, even with continuation of therapy.

Drug–Drug Interactions. Cimetidine slows hepatic drug metabolism by *inhibiting microsomal enzymes.* These effects are dose-related but occur with as little as 800 mg daily. Clearance is reduced by 20% to 30%, so that serum half-lives are increased. Although such impairment is usually not clinically significant, it can be important when hepatically metabolized drugs with a narrow therapeutic range are taken concurrently (e.g., *warfarin, benzodiazepines, phenytoin, procainamide, and theophylline compounds*). Cimetidine also reduces the hepatic metabolism of *propranolol* and *carbamazepine* by about 20%. The net effect is a potentiation of drug effect. Dose reductions are essential, as is monitoring of serum levels. The effect of cimetidine on hepatic microsomal enzymes lasts for about 2 weeks after the drug is stopped. *Ketoconazole* absorption is reduced by up to 65% when the drug is taken within 2 hours after a cimetidine dose, so that it must be administered at least 2 hours before intake of an H$_2$-blocker.

Ranitidine, Famotidine, and Nizatidine were developed after cimetidine and are more potent on a weight basis. Their single-dose ability to inhibit acid secretion is equal or superior to that of cimetidine, and the effect of a single dose lasts 12 to 24hours. They can promote healing in a proportion of patients with refractory gastric ulcer, duodenal ulcer, or Zollinger-Ellison syndrome who have not responded to cimetidine. A single dose at night has been found to be as effective as cimetidine in preventing recurrence of duodenal ulcer; recurrence rates are reduced to less than 25%.

Pharmacokinetics. Absorption after oral administration ranges from 45% for famotidine to 100% for nizatidine, a difference that is not clinically important. Concurrent intake of food does not reduce absorption, but the use of aluminum or magnesium antacids does, by 10% to 20%. About 30% of each of these agents is metabolized by the liver. Metabolites plus unmetabolized drug are excreted by the kidneys. Drug half-life is prolonged in renal failure. Like cimetidine, ranitidine is excreted in breast milk.

Side Effects are similar and only slightly different from those of cimetidine (which can be attributed at least in part to less clinical experience with the newer agents). *Headache* occurs in about 5% of patients taking famotidine and in 3% of those taking ranitidine; migraine may be exacerbated. *Confusion* is slightly less common with these agents than with cimetidine but still may occur, especially in elderly patients taking large doses. Gynecomastia has not been reported, but *impotence* has been encountered among a few patients taking extremely high doses. The only reported cases of bone marrow suppression are a few isolated instances of thrombocytopenia in patients taking famotidine. Renal function is unimpaired, but hepatoxicity has been noted in a few instances. These drugs interfere less with *microsomal enzyme* function than does cimetidine, but interference may occur with ranitidine, although usually only at high doses. The clearance rates of warfarin, theophylline, benzodiazepines, phenytoin, and procainamide appear normal, but the metabolism of propranolol may be slowed, as may absorption of ketoconazole.

Choice of Histamine$_2$ Blocker. When prescribed in therapeutic doses, these agents are similar in efficacy and side effects. Drug–drug interactions are slightly more common with cimetidine because inhibition of hepatic microsomal enzymes occurs at lower doses. Most other adverse effects are typically minor and usually of concern only when these drugs are used in the elderly or when very large doses are prescribed (as in treatment of hypersecretory states). The predominant difference among H$_2$-blockers is cost, with generic cimetidine being the least expensive (at about half the daily cost of the other agents). In the past, when it was recommended that cimetidine be taken three or four times daily, the once- or twice-daily dosing of the newer H$_2$-blockers offered a considerable compliance advantage. However, now that twice-daily dosing of cimetidine has been shown to be effective, this advantage is less important, although the newer H$_2$-blockers may have a slight advantage in efficacy. With ranitidine becoming available generically, it too may offer a reduced-cost option. Billions of dollars per year are spent on H$_2$-blocker therapy, so that a cost-conscious approach to their use is necessary.

Proton Pump Inhibitors. The gastric H$^+$/K$^+$-ATPase ("proton pump") inhibitors are the most potent of the acid-inhibiting drugs, reducing 24-hour acid production by more than 90% with a single daily dose of 20 to 30 mg. In comparison, acid production is reduced 50% to 80% with standard doses of H$_2$-blockers. With higher PPI doses, acid production is almost completely stopped.

Effectiveness. The speed of ulcer healing and pain reduction (40% to 80% at 2 weeks and 80% to 95% at 4 weeks) are greater with these agents than with standard doses of H$_2$-blockers. Ulcers refractory to high doses of H$_2$-blockers can be healed by 20 to 40 mg of a PPI daily, a principal indication for their use. However, rates of relapse are similar to those with other forms of acid suppression therapy, so that treatment directed against *H. pylori* infection must be considered (see below). Interestingly, these agents appear to have some antibacterial effect on *Helicobacter* and are useful in regimens to eradicate *Helicbacter* infection (see above). The PPIs are the drugs of choice for *Zollinger-Ellison syndrome.*

Adverse Effects. These agents are well tolerated. Some patients experience mild gastrointestinal upset. Important adverse effects include drug–drug interactions and an increase in serum gastrin levels. *Drug–drug interactions* are a consequence of the metabolism of PPIs by *hepatic microsomal enzymes.* Omeprazole displaces such microsomally metabolized drugs as benzodiazepines, phenytoin, and warfarin (but not theophylline and propranolol), so that serum levels of these agents are increased. It also increases absorption of digoxin and decreases prednisone efficacy. Lansoprazole increases clearance of theophylline.

Risk for Gastric Carcinoid. One consequence of potent inhibition of gastric acid production is hypergastrinemia. Most patients experience a twofold to fourfold increase above baseline (still within normal limits). About 10% exhibit a 10-fold increase (>500 ng/L), which is associated with an increased rate of argyrophil cell hyperplasia and atrophic gastritis (but not of dysplasia or cancer). Prolonged hypergastrinemia has been associated with hyperplasia of enterochromaffin cells and development of *carcinoid tumors* in rats given high doses of omeprazole—presumably a consequence of the trophic effects of *hypergastrinemia* on enterochromaffin cells. No such tumors have been reported with prolonged omeprazole use in humans (see Chapter 61).

Atrophic Gastritis. Although PPI therapy by itself might not increase cancer risk, there is concern about its contribution in the setting of *Helicobacter* infection. *Atrophic gastritis* (a precancerous change) seen in the context of high-dose, long-term PPI therapy may exacerbate the gastric cancer risk associated with *H. pylori* infection (see above). Lack of gastric acid may contribute to bacterial overgrowth and the elaboration of bacterial carcinogens. Any person requiring long-term, high-dose PPI therapy ought to be tested and treated for *H. pylori* infection.

Vitamin B$_{12}$ Deficiency. Patients with Zollinger-Ellison syndrome requiring long-term PPI therapy to suppress gastric acid overproduction demonstrate significant (30%) reductions in vitamin B$_{12}$ levels, especially when achlorhydria is achieved. Whether this effect pertains to other persons taking long-term, high-dose PPI

therapy remains to be established, but periodic monitoring of serum B$_{12}$ levels might be reasonable, especially in the elderly.

Prostaglandin Analogues (Misoprostol). NSAID-induced cases of peptic ulcer disease are related to prostaglandin inhibition. Misoprostol is a prostaglandin analogue used for the treatment and prophylaxis of NSAID-induced peptic ulcer disease.

Efficacy and Cost-effectiveness in NSAID-induced Ulcer Disease. Although more effective than placebo, misoprostol is less effective than H$_2$-blockers or PPIs for the treatment of non–NSAID-induced peptic ulcers. However, the prostaglandin analogue is very effective in the treatment of *NSAID-induced* peptic ulcers, with resolution achieved in more than 70% of cases at 8 weeks, about the same rate achieved with H$_2$-blockers but somewhat less than that achieved with PPI therapy. Misoprostol is the only drug approved by the Food and Drug Administration for the *primary prevention of NSAID-induced* peptic ulcers; it is effective when taken in full doses at least two to three times per day concurrently with NSAID therapy. (No prospective comparisons with PPI therapy for primary prevention have been undertaken.)

For treatment and prophylaxis in persons with a history of NSAID-induced ulceration who require continued NSAID use (*secondary prevention*), misoprostol is less effective than PPI therapy for sustaining a remission, although both agents are effective for healing the initial ulcer and superior to H$_2$-blockers.

Misoprostol has also been examined for ability to prevent the complications of NSAID-induced ulcer disease, such as gastrointestinal bleeding. Because of its high cost, misoprostol has not proved cost-effective in the *primary prevention* of NSAID-induced *upper gastrointestinal bleeding*, but its use for *secondary prevention* does appear more reasonable from a cost-effectiveness perspective. NSAID-induced primary duodenal ulceration is infrequent, but complications are common, and misoprostol is thought to help reduce their frequency (as might PPI therapy).

Side Effects. Dose-related *diarrhea* is common (20% with 100-μg doses four times daily, 40% with 200-μg doses four times daily) and an important form of intolerance to the drug that results in its discontinuation by patients. A reduced dose is often tried, but efficacy is reduced. Maintaining full doses but reducing dosing frequency to twice or three times daily appears to be a more productive strategy for sustaining a prophylactic program; much of the benefit is preserved while gastrointestinal side effects are substantially reduced. Taking the drug with meals also helps to reduce the severity of diarrhea. The drug is an *abortifacient*; it is contraindicated in women who are pregnant or who may be pregnant and should be prescribed for sexually active women of childbearing age only with proper warning and detailed patient education. Those considering taking misoprostol should be capable of reliable use of birth control. Consideration of an alternative to misoprostol is probably a safer approach in such women.

Sucralfate is a complex of aluminum hydroxide and sulfated sucrose; it is believed to act by forming a barrier on the ulcer base, inhibiting pepsin activity, and binding bile salts. It has no acid-neutralizing activity and little is absorbed, although aluminum salts are released and some aluminum is absorbed. Its principal role in outpatient management of peptic ulcer disease is as an alternative to acid suppression therapy in persons who cannot tolerate antacids, H$_2$-blockers, or PPI therapy.

Efficacy. The drug is comparable to cimetidine and ranitidine for healing of *duodenal ulcers*. Maintenance therapy (1 g twice daily) to prevent recurrences appears slightly less effective than that with H$_2$-blockers. Available data suggest some benefit for treatment of *gastric ulcer*; however, more data are needed, and the Food and Drug Administration has not yet approved sucralfate treatment for this condition. Although some clinicians add sucralfate to H$_2$-receptor antagonist therapy to promote healing of gastric ulcers, evidence to support this approach is lacking. The claim that sucralfate preferentially heals ulcers in smokers has not been substantiated. Sucralfate is most effective when taken 1 hour before meals and at bedtime, although twice-daily administration of double-strength doses has proved adequate for treatment of duodenal ulcer.

Side Effects. The main side effect is constipation. The drug binds phosphate and has been reported to cause *hypophosphatemia* and *aluminum toxicity* in patients with chronic renal failure. Sucralfate may interfere with the *gastrointestinal absorption* of tetracycline, fluoroquinolone antibiotics (e.g., ciprofloxacin, norfloxacin), digoxin, phenytoin, and, to a clinically insignificant degree, H$_2$-blockers. No data are available regarding safety in patients who are pregnant, nursing, or of advanced age. The cost of daily sucralfate therapy is intermediate between that of cimetidine and other H$_2$-blockers.

Anticholinergic Agents can suppress the parasympathetic muscarinic activity that triggers gastric acid secretion, especially the nocturnal surge. These agents are not nearly as potent as H$_2$-receptor antagonists in suppressing acid production. The frequency and severity of anticholinergic side effects make therapy intolerable for many patients. Because agents that are more effective and better tolerated are available, anticholinergics are rarely prescribed anymore.

Follow-up

Monitoring Response: Gastric Ulcer. If a *gastric* lesion has been detected initially by radiography and has all the hallmarks of a benign lesion (see above), if symptoms resolve fully, and if no clinical findings suggestive of cancer or complicated disease are present (see above), then follow-up barium study or endoscopy can probably be foregone. Although some authorities advocate routine endoscopic or radiologic *documentation of healing*, no studies show this to be cost-effective in uncomplicated cases in which symptoms resolve within 4 to 6 weeks and do not recur. However, if a refractory gastric ulcer is suspected (e.g., persistent pain after 8 weeks despite a full medical regimen), then *endoscopic examination* and *biopsy* are needed, especially in patients over age 40, who are at increased risk for gastric cancer. Barium study is not sufficient because even malignant ulcers may shrink in size in response to therapy. Earlier endoscopic evaluation is indicated if evidence of bleeding or obstruction or another reason for concerned about gastric carcinoma is present (see above).

Monitoring Response: Duodenal Ulcer. In the case of a *duodenal* ulcer (where cancer risk is nil), follow-up radiologic or endoscopic evaluation should be restricted to patients with persistence or recurrence of pain, symptoms of gastric outlet obstruction, or evidence of bleeding. Periodic repetition of studies is unnecessary and expensive, even when typical symptoms recur, unless a different course of therapy, such as surgery, is contemplated. Following results of stool guaiac tests and blood cell counts can help detect bleeding, as can careful questioning of the patient.

Duration of Therapy. The standard duration for an initial acid suppression regimen is 4 weeks to achieve full healing in 90% of patients. Up to 12 weeks of such treatment may be necessary for very large benign ulcers. However, without eradication of *Helicobacter* infection, the risk for ulcer recurrence within 1 year is greater than 50%, so that long-term acid suppression therapy is often implemented. As noted earlier, 1 to 2 weeks of combination antibiotic therapy eradicates more than 90% of *Helicobacter* infections, reduces 1-year recurrence rates by 90%, and eliminates the need for most courses of long-term acid suppression therapy. Resolution of pain cannot be used as a therapeutic end point because cessation of pain correlates poorly with completion of healing or eradication of infection. Unfortunately, patients commonly terminate treatment when their symptoms resolve, which increases their risk for relapse.

Maintenance Therapy for Secondary Prevention. The need for maintenance acid suppression to prevent *recurrence* has declined markedly with the eradication of *Helicobacter* infection. One-year recurrence rates for non–NSAID-related ulcers are about 5% when initial therapy is aimed at elimination of *Helicobacter* and in excess of 50% without use of antibiotics. Before the advent of treatment for *Helicobacter* infection, maintenance acid suppression was commonly prescribed to prevent recurrences. Although prevention of ulcer recurrence has been demonstrated with the long-term use of H$_2$-receptor antagonists and PPIs, the risk returns to its previous level once such acid suppression therapy has been discontinued. Even with continuation of adequate maintenance therapy, silent breakthrough ulceration can be demonstrated by repeated endoscopy in up to 50% of patients, although most is usually of little clinical consequence. Just a single course of antibiotic therapy that eradicates *H. pylori* infection reduces the risk for recurrence to less than 5%. Medical therapy that cures *H. pylori* infection also markedly reduces the risks for *hemorrhage*, *perforation*, *and obstruction* but shows little advantage over placebo for pain relief, in part because of a very strong placebo effect.

Indications. Maintenance suppression of gastric acid production is currently recommended only for those with a history of *upper gastrointestinal bleeding*, concurrent *oral anticoagulation* and recent peptic ulcer (see Chapter 83), an *ulcer recurrence* within 1 year that fails to respond to *Helicobacter* therapy, or a history of *NSAID-induced peptic ulcer* that requires continued NSAID therapy.

Efficacy. Effective long-term suppression of gastric acid production is provided by a maintenance program of PPI therapy (e.g., 20 mg of omeprazole daily), which reduces 24-hour acid production by more than 90% with a single daily dose. This compares with a 50% to 80% reduction in acid production with standard doses of H$_2$-blockers. Almost complete cessation of acid production is achieved with higher PPI doses. As noted earlier, PPI therapy can markedly reduce the risk for ulcer recurrence and complications in the settings for which maintenance therapy is recommended. H$_2$-blocker maintenance is signficantly less effective.

Dosing. Daily dosing is required to achieve the best outcomes. Concern about the effects of long-term suppression of acid production (see below) have prompted

some to suggest an every-other-day or every-3-days PPI maintenance program; the impact on efficacy is not known, nor is the benefit. The rationale for less frequent dosing is to allow some acid production to occur, which reduces hypergastrinemia and its possible adverse consequences (see below). Another alternative to daily maintenance therapy is empiric treatment of pain recurrences, a common self-treatment approach. Its safety and efficacy are unknown but likely to be problematic, given the poor correlation between symptoms and risk for complications of ulcer disease.

Cost. Long-term PPI therapy is very expensive, but the cost is likely to decrease markedly as these drugs come off patent and become available generically. The least expensive preparation should be sought. H_2-blockers are less effective and not much less expensive. *Misoprostol* (200 µg twice daily) is a reasonable alternative for prophylaxis in persons who need long-term NSAID therapy, but expense is high and gastrointestinal side effects can be troublesome. Antacids are much less costly, but their efficacy as maintenance therapy is unknown.

Duration. Although most authorities recommend continuing maintenance treatment for 1 year or for the duration of the indication (e.g., NSAID or anticoagulation use), the optimal duration of such therapy remains unknown; the consequences of prolonged suppression of gastric acid production are also unknown (see below). The relapse rate for medical maintenance therapy is 10 times that for surgical therapy, but most patients can be spared an operation, particularly if attention is paid to *Helicobacter* infection as a major cause of relapsing disease.

Concerns Regarding Long-term Acid Suppression. Debate continues about the safety of shutting down gastric acid production on a long-term basis, as is possible with prolonged PPI therapy. Concerns include a risk for carcinoid tumors, gastric cancer, and vitamin B_{12} deficiency (see above). The best means of avoiding these potential adverse consequences is to minimize the need for prolonged PPI therapy, which is best achieved by eradicating *Helicobacter* infection and minimizing the use of NSAIDs. The literature should be followed closely for more data on the consequences of prolonged suppression of gastric acid production.

Refractory or Recurrent Disease

Persistence of pain 4 weeks after the initiation of proper therapy suggests an unhealed ulcer. If endoscopic evaluation was carried out initially to rule out a malignant lesion and a large ulcer was found, then acid suppression therapy can be continued, with high-dose PPI therapy utilized to speed healing. Eight to 12 weeks of treatment may be necessary. If *H. pylori* infection was not tested for and treated initially, then it should be at this time. If compliance with the anti- *Helicobacter* treatment regimen has been complete, then testing for the eradication of infection can help guide further action. If, despite eradication of *Helicobacter* infection, symptoms persist beyond 4 to 8 weeks, then endoscopic evaluation is needed (if not performed initially) to rule out malignancy or complicated disease. Recurrent disease raises the question of persistent *Helicobacter* infection, repeated NSAID exposure, Zollinger-Ellison syndrome, and malignancy.

Testing for Active *Helicobacter* Infection. The potential contribution of *Helicobacter* infection to persistent or recurrent disease necessitates testing for active infection. *Serologic testing* is appropriate for the initial identification of *H. pylori* infection; eradication may be documented by repeated serologic testing, but test sensitivity for detecting cure of infection is wanting. Much more sensitive is ^{14}C or ^{13}C *breath testing* (see above). If this is unavailable, repeated quantitative serologic testing may suggest eradication if antibody has cleared from the serum or titers are significantly reduced from initial levels. If persistent infection is found, it should be fully treated with a different multidrug antibiotic regimen to counter any possible antibiotic resistance (see above).

Checking for Noncompliance and Aggravating Factors. In addition to checking for *Helicobacter*, it is crucial to check for noncompliance and aggravating factors such as *smoking* and *stress.* Many instances of refractory disease and recurrence are closely linked to continued smoking, severe stress, and failure to follow a prescribed medical regimen. Concurrent *NSAID* use may also contribute to refractoriness.

Switching to Another Agent is worth consideration when an ulcer is slow to heal. Patients genuinely failing H_2-blocker treatment may achieve a more rapid and complete response with *PPI* therapy, but more important is eradicating *Helicobacter* infection (see above) and checking for malignancy and Zollinger-Ellison syndrome (see below).

Assessing for Malignancy and Zollinger-Ellison Syndrome. Truly refractory cases (i.e., those in which *Helicobacter* infection, aggravating factors, and noncompliance have been addressed) ought to be evaluated endoscopically for malignancy and studied biochemically for *Zollinger-Ellison syndrome,* especially if multiple ulcers, occurrences in unusual places, marked abdominal pain, or a secretory diarrhea (resulting from hypergastrinemia) is present. Patients with Zollinger-Ellison syndrome often manifest evidence of multiple endocrine adenomatosis (e.g., concurrent hyperparathyroidism and pituitary adenomas). A fasting serum gastrin level in excess of 500 pg/mL in the presence of acid hypersecretion is diagnostic.

Consideration of Prophylactic Therapy. If an NSAID must be continued (e.g., because of disabling rheumatoid disease), then prophylactic treatment with *misoprostol* or a *PPI* may be required (see above). Sometimes, *increasing the dosage* of a prophylactic agent may help. If the patient has been on low-dose maintenance therapy when a recurrence develops, full-dose therapy should be initiated. Those taking an H_2-blocker may benefit from doubling the dose or *switching* to a PPI, which provides better prophylaxis. Convincing evidence is lacking that the addition of a second agent (e.g., H_2-blocker plus sucralfate) achieves better results in the treatment of refractory disease than does the administration of full doses of a single agent.

Surgery. Surgery for peptic ulcer disease is becoming increasingly uncommon with the advent of effective medical therapy. The most compelling *indications for surgery* include brisk bleeding of 6 to 8 U of blood in 24 hours (see Chapter 63), recurrent episodes of bleeding, perforation, gastric outlet obstruction refractory to medical therapy, and failure of a benign gastric ulcer to heal after 15 weeks. Operations are most often performed on patients who fail to respond to medical therapy and have disabling symptoms.

The *proximal gastric vagotomy* effectively limits recurrences without producing the disabling side effects associated with earlier forms of surgery for duodenal ulcer disease. The operation involves selective severing of the nerve supply to the acid-secreting fundus; the nerves to the antrum are left intact, so that control of gastric emptying is preserved. The incidence of ulcer recurrences is slightly higher (10%) than with vagotomy and antrectomy (5%) but similar to that with vagotomy and pyloroplasty (12%). Surgical mortality is lower, and such potentially disabling postsurgical side effects as the dumping syndrome and diarrhea are much less common. The operation is technically demanding and should be considered only by surgeons specifically trained to perform it. The procedure should not be carried out in patients with delayed gastric emptying. Distal gastrectomy with excision of the ulcer remains the procedure of choice for gastric ulcer.

PATIENT EDUCATION

Enlisting the patient's active involvement and overcoming much of the mythology surrounding ulcer disease are prime objectives of the patient education effort.

Advice. Patients appreciate dietary instruction, such as knowing what foods they can eat and what substances to avoid. Many ulcer patients unnecessarily put themselves on a "bland diet" and increase their intake of milk products, hoping these actions will help their ulcers to heal. Others take aspirin or over-the-counter NSAIDs for relief of ulcer pain. Use of coffee, alcohol, and tobacco also needs to be reviewed. Many physicians insist that coffee drinking be stopped, although this may cause more difficulty than is warranted by its role in pathogenesis. Switching to decaffeinated coffee offers little advantage. On the other hand, cessation of smoking is essential and detailed cessation counseling is critical (see Chapter 54) because continuation of the habit greatly impedes healing. Alcohol intake should also be discouraged

Maximizing Compliance. Even when an effective medical program has been designed, inadequate compliance can be a problem. Full compliance with the multidrug antibiotic regimens used to treat *Helicobacter* infection can be especially problematic, particularly when a 2-week thrice-daily or four-times-daily dosing regimen is required. The more expensive twice-daily regimens may be worth the extra initial expense for patients whose ability to comply fully is questionable. Alternatively, a 1-week thrice-daily program can be considered, which is almost as effective.

Other common compliance errors that need to be addressed include stopping medication as soon as symptoms disappear, taking antacids with meals (which wastes the antacid), and taking cimetidine at the same time as antacids (which partially impairs cimetidine absorption).

Counseling the patient with situational stress is often beneficial, but any suggestion to change jobs or family situations because an ulcer has developed is probably unwarranted and potentially counterproductive. There is no evidence that such extreme solutions contribute to healing, and they may actually heighten stress. One useful supplement to counseling is teaching simple *relaxation techniques*; these are especially useful for patients bothered by multiple somatic manifestations of

stress (see Chapter 226).

Self-Monitoring. The patient needs to be taught to watch for complications of ulcer disease. In particular, the manifestations of gastrointestinal bleeding (see Chapter 63) should be well understood so that the patient does not delay in seeking help.

Shared Decision Making. If the question of elective surgery arises, the patient should be made a full partner in the decision because few definite guidelines for operation are available. A value judgment is necessary, and the costs and benefits of surgery versus continued medical therapy need to be discussed.

INDICATIONS FOR REFERRAL AND ADMISSION

Refractoriness to therapy is an indication for referral to a gastroenterologist for review of the program and consideration of endoscopy. Admission is mandatory when symptoms of *hemorrhage, peritoneal irritation, or gastric outlet obstruction* are present; both surgeon and gastroenterologist need to be consulted.

A most difficult issue is when and whom to select for *elective surgery*. Much has to do with the patient's preferences; gross generalizations are meaningless. Clearly, those with recurrent major bleeds, gastric outlet obstruction, or evidence of malignancy need to be seen by the surgeon. Seventy-five percent of patients with intractable pain obtain relief when treated surgically, but subgroups with alcohol abuse, character disorders, or severe neuroses do poorly after surgery. The decision to resort to elective surgery for recurrent disease should be made in conjunction with the patient, and the small risk for operative mortality and the morbidity of postgastrectomy syndrome should be weighed against the morbidity and cost of recurrent pain, time lost from work, and the need for long-term drug therapy.

THERAPEUTIC RECOMMENDATIONS

Nonpharmacologic Interventions and Initial Testing

- Avoid, or at least limit to the extent medically possible, the use of agents potentially injurious to the mucosa, including aspirin, excess alcohol, NSAIDs, and perhaps long-term, high-dose glucocorticosteroids.
- Insist on total *cessation of smoking* (see Chapter 54).
- Suggest a decreased intake of coffee (including decaffeinated forms) and other caffeine-containing beverages; however, complete cessation of intake is unnecessary.
- Do not restrict any foods or insist on a bland or milk-laden diet. Frequent small feedings are unnecessary, and a bedtime snack may stimulate nocturnal acid secretion. The patient should avoid only foods that cause discomfort.
- Attend to stress-related issues, but avoid recommending a major job or geographic change.
- Test for *Helicobacter* infection. For initial noninvasive testing, obtain quantitative serology and use a reference laboratory. Alternatively, perform a ^{14}C or ^{13}C breath test for noninvasive detection. If endoscopy is required (see below), have a rapid urease test (e.g., CLO test) performed at the same time.
- Order upper gastrointestinal endoscopy or barium study before initiating therapy if clinical findings suggest malignancy or complicated disease (e.g., patient manifests weight loss, gastrointestinal bleeding, or persistent nausea and vomiting).

Initial Pharmacologic Therapy

- For ulcer patients who test positive for *Helicobacter*, begin a multidrug antibiotic program.
  1. When cost is a major consideration but compliance is not, prescribe 250 mg of *metronidazole* four times daily, 500 mg of *tetracycline* four times daily (or 500 mg of *amoxicillin* four times daily if the patient is unable to tolerate tetracycline), and two tablets (525 mg) of *bismuth subsalicylate* (e.g., Pepto-Bismol) four times daily; continue for 2 weeks or limit to 1 week by adding a concurrent course of *PPI* therapy (e.g., 20 mg of omeprazole daily or 30 mg of lansoprazole daily).
  2. When side effects and compliance with a four-times-daily regimen are major concerns but cost is not, consider a 2-week program consisting of 500 mg of *clarithromycin* and 20 mg of *omeprazole* twice daily plus 500 mg of *metronidazole* or 500 mg of *amoxicillin* twice daily.
  3. Acid suppression therapy is *not required* in patients with *Helicobacter* infection, but it speeds healing and attainment of symptomatic relief.
- For all patients, begin an *acid suppression* program consisting of either antacids [e.g., 30 mL of a high-potency magnesium hydroxide–aluminum hydroxide liquid antacid after meals and at bedtime (Table 68.1)], an H$_2$-receptor antagonist (e.g., 400 mg of cimetidine twice daily), or a PPI (e.g., 20 mg of omeprazole twice daily or 30 mg of lansoprazole daily). Base selection on affordability, severity of disease, capacity for compliance, and potential for interaction with other medications.
- For patients with an active NSAID-induced ulcer, begin treatment with either a *PPI* (e.g., 20 mg of omeprazole twice daily) or *misoprostol* (200 mg with each meal and before bed); continue for 4 to 8 weeks depending on severity at time of presentation. There is no need to test for or treat *Helicobacter* infection because its eradication does not improve outcome in NSAID-induced disease.
- For patients with a prior history of NSAID-induced peptic ulceration or of upper gastrointestinal bleeding who absolutely require continuous NSAID therapy for maintenance of function, initiate prophylaxis with a PPI (e.g., 20 mg of omeprazole daily); consider *misoprostol* (200 mg with breakfast and supper) as a slightly less effective alternative for secondary prevention of NSAID-induced disease, but as a reasonable (although not very cost-effective) first choice for primary prevention.
- Thoroughly instruct the patient on how to carry out the therapeutic program and review common misconceptions to maximize compliance.

Refractory or Recurrent Disease

- Check for failure to eradicate *H. pylori* infection, preferably by *breath test* (if available); alternatively, repeat quantitative serology and compare pretreatment titers with current titers (seroconversion from positive to negative is highly specific but not sensitive).
- Reemphasize the importance of compliance, smoking cessation, and avoidance of NSAIDs.
- Institute PPI therapy, but limit its duration if possible; if not, be sure to eradicate any concurrent *H. pylori* infection so as to avoid development of atrophic gastritis. Institute long-term PPI therapy for treatment of Zollinger-Ellison syndrome.
- If *Helicobacter* infection persists, retreat with a new antibiotic regimen rather than repeating the original program.
- For persistent or recurrent disease unresponsive to treatment, refer for endoscopic examination and biopsy to rule out malignancy and complicated disease, especially if endoscopy was not performed initially.
- Refer the patient with refractory multiple ulcers, frequent recurrences, or associated secretory diarrhea for consideration of Zollinger-Ellison syndrome when symptoms are accompanied by marked hypergastrinemia in the context of acid hypersecretion.
- Admit patients with evidence of bleeding, gastric outlet obstruction, or perforation and obtain surgical consultation.

CHAPTER 69 MANAGEMENT OF ASYMPTOMATIC AND SYMPTOMATIC GALLSTONES

Gallbladder disease afflicts over 20 million Americans, with more than 500,000 undergoing cholecystectomy each year. Prevalence is particularly high among middle-aged obese women. Most patients with gallstones are asymptomatic, whereas a few suffer from recurrent bouts of abdominal discomfort. Occasionally, a complication such as acute cholecystitis, pancreatitis, or choledocholithiasis may ensue. The primary physician needs to know when treatment is necessary and how to help the patient choose between elective surgery, medical therapy, and expectant management.

PATHOPHYSIOLOGY, CLINICAL PRESENTATION, AND COURSE

Pathophysiology and Risk Factors. Most gallstones are cholesterol laden, developing as a consequence of bile becoming supersaturated with cholesterol. Hereditary factors play a strong role, as do female gender and obesity, due to the lithogenic effects of estrogen and the increased risk associated with even moderate degrees of weight gain and caloric excess (relative risk, 2 to 3). Rapid weight loss is also an important risk factor. In men, regular exercise protects against developing symptomatic disease (the effect is unknown in women).

Presentation. Gallbladder disease may be asymptomatic or manifested by recurrent pain. Characteristically, *biliary colic* is rather sudden in onset, builds to a maximum within 1 hour, is steady, localized to the right upper quadrant or epigastrium, lasts 2 to 4 hours, and occasionally radiates to the left or right scapula. There is often nausea and vomiting. *Dyspeptic symptoms*, fatty food intolerance, belching, and bloating have also been attributed to chronic gallbladder disease, but the association has never been proven. Prospective studies have shown that such symptoms are just as common in middle-aged women without gallstones as in those with them. When patients with these symptoms are operated on, the dyspepsia often persists after cholecystectomy. Reflux of bile into the stomach has been noted in such individuals.

The clinical presentation of choledocholithiasis may be highly variable, ranging from acute nausea, vomiting, fever, upper abdominal pain, and jaundice to mild recurrent episodes of biliary colic. In many instances the patient may be asymptomatic for years before an attack develops, occurring when a stone blocks the distal end of the common duct.

The rare patient with true biliary colic but a normal gallbladder study on ultrasound may have *acalculous gallbladder disease* (an uncommon condition) or multiple small stones undetectable by conventional methods. These subtle forms of gallbladder disease may be discovered by observing delayed gallbladder emptying in response to a fatty meal or cholecystokinin.

Clinical Course. The clinical course of untreated gallbladder disease depends whether the patient has been asymptomatic or not. Two prospective studies, totaling 1,300 symptomatic patients who had at least one bout of pain, showed that over a follow-up period of 5 to 20 years, 30% had *recurrent pain* and 20% experienced *complications* such as jaundice, cholangitis, or pancreatitis; half remained *asymptomatic*. Because all patients in these studies had pain requiring a hospital admission, this patient population probably represents a group with a greater likelihood of complications than one with a predominance of *asymptomatic* stones. In a more representative retrospective cohort study of 123 people with silent gallstones, there was no mortality from the condition and a 15-year accumulative probability of biliary pain of only 18%.

Although there is no certainty that the onset of complications will be preceded by episodes of biliary pain, a study of 600 patients found that more than 90% of patients who suffered a complication of gallbladder disease had prior warning symptoms of biliary colic, although these were often mild and ignored. Most patients with pain on presentation had similar patterns of pain on follow-up. When 112 patients with asymptomatic stones were followed without surgery for 10 to 20 years, 27% eventually complained of dyspepsia, 19% had biliary colic, and 4.5% experienced transient jaundice. No deaths resulted from delay of surgery. In a separate study of symptomatic patients, those with small stones (diameter less than 5 mm) demonstrated a fourfold increase in risk of pancreatitis. In men, increased physical activity correlates inversely with risk of symptomatic disease.

Overall, asymptomatic patients appear to have a relatively favorable prognosis, but symptomatic individuals with episodes of true biliary colic have twice the rate of complications. Increased risk in asymptomatic patients is associated with very large stones (greater than 2.5 cm), age over 60, and diabetes. In symptomatic patients, small stones (less than 0.5 cm) may increase the risk of gallstone pancreatitis.

Some authorities believe there is a cause-and-effect relationship between gallstones and *carcinoma of the gallbladder*. The cancer occurs mostly in older women. The initial association with stone formation was based on circumstantial autopsy data. Community-based study has shown a much weaker association, pertaining only to men.

DIAGNOSIS

Asymptomatic Gallstones. Asymptomatic disease is usually detected as an incidental finding during radiologic or ultrasound investigation that encompasses the upper abdomen for a reason other than suspected gallbladder disease. With the advent and widespread application of ultrasound and computed tomography (CT) techniques, the frequency of detection of asymptomatic disease has been on the increase.

Acute Cholecystitis. The occurrence of classic biliary colic provides strong presumptive evidence for the diagnosis of cholecystitis; dyspepsia and fatty food intolerance do not. Real-time *ultrasouna* of the gallbladder and biliary tree is the test of choice for evaluation of symptomatic patients with suspected acute cholecystitis. The only preparation necessary is 6 hours or more of fasting. The test takes about 15 minutes. Adequate images are obtained in about 98% of instances, although obesity can reduce visualization. Ultrasound can be performed rapidly, provides anatomic information, is low in cost, and allows examination of other potentially causative abdominal structures. Major criteria for a positive study are presence of stones or nonvisualization of the gallbladder (no fluid-filled lumen). Minor criteria include tenderness of the gallbladder during ultrasound examination, thickening of the gallbladder wall, and a rounded shape. Sensitivity and specificity are in excess of 95%.

Patients with a nondiagnostic ultrasound, but still strongly suspected of having acute cholecystitis (e.g., presence of biliary colic, mild elevations in liver function tests), should have the test repeated. The stone may have passed from the gallbladder into the common bile duct (see below). Besides presence of stone, other findings correlate with presence of cholecystitis, including localized tenderness over the gallbladder ("*sonographic Murphy's* sign") and gallbladder wall thickening.

An alternative to ultrasound for detection of acute cholecystitis is *scintigraphy* with the radionuclide *HIDA*. The isotope is taken up by the liver and excreted into the bile. Images are obtainedafter 1 hour. The patient needs to be fasting (but no longer than 2 to 4 hours) and free of underlying hepatocellular disease and alcoholism (which cause false-positive tests). The gallbladder, cystic duct, common bile duct, and duodenum are visualized by 60 minutes in the normal person. Nonvisualization of the gallbladder after 1 hour is characteristic of acute cholecystitis (the common bile duct and duodenum remain visualized). Sensitivity and specificity approach that of ultrasound, but cost is greater and the test takes more time. Scintigraphy can help determine patency of the cystic duct.

Ultrasound has largely replaced the *oral cholecystogram* for the diagnosis of acute cholecystitis, because it is more sensitive, equally specific, and provides results much faster and with none of the gastrointestinal upset and allergic reactions associated with oral cholecystography. *CT* of the gallbladder is not sufficiently sensitive to warrant its use for detection of stones; gallstones and bile can have the same density.

Choledocholithiasis. Symptomatic patients with recurrent pain plus persistent mild elevations in liver function tests, a dilated common bile duct, jaundice, or signs of acute pancreatitis require further evaluation for a stone in the common bile duct. As noted, ultrasound may be nondiagnostic because the sensitivity of a single study for detecting stones in the duct is only 50% when there is no ductal dilatation and 75% when ductal dilatation is present. Overlying bowel gas can obscure

visualization of a common duct stone. If clinical suspicion remains high, a repeat ultrasound study is indicated. *CT* has about the same sensitivity (75%) as ultrasound for detection of a common duct stone. If noninvasive testing is nondiagnostic in the setting of suspected common duct stone, then *endoscopic retrograde cholangiopancreatography* (ERCP) deserves consideration. Sensitivity exceeds 90%, and therapeutic sphincterotomy can be performed at the same time. *Magnetic resonance imaging* of the biliary tree appears promising; initial reports of test sensitivity are in excess of 90% and no contrast or invasive procedure is required. Magnetic resonance imaging cholangiography has the potential to obviate the need for diagnostic ERCP and improve selection of candidates for a therapeutic ERCP.

Chronic Cholecystitis. *Ultrasound* is the diagnostic test of choice in patients with recurrent episodes of biliary colic. The *oral cholecystogram* has come back into use in patients who are being considered for lithotripsy or gallstone dissolution, because the test can provide information on gallbladder function and stone composition (see below).

PRINCIPLES OF MANAGEMENT

Given the rather benign natural history of asymptomatic stone disease, watchful waiting usually suffices in most patients, but one still needs to identify high-risk patients who require closer follow-up and possible consideration of elective cholecystectomy. Symptomatic patients want advice on treatment options, which include open cholecystectomy, laparoscopic cholecystectomy, and gallstone dissolution, both chemical and physical. There have yet to be randomized controlled clinical trials comparing treatment options, necessitating extrapolation from available data on natural history of disease and on the risks and outcomes of interventions.

Asymptomatic Gallstones

There is no evidence that the vast numbers of patients with asymptomatic gallstones would benefit from surgery or stone dissolution. Although surgical mortality is only 0.5%, only 20% of asymptomatic patients will ever develop biliary colic and acute cholecystitis, and only a small fraction of these people will experience a complication such as pancreatitis. In most patients, the risks of conservative management are not much different from those of surgery and involve far less expense, morbidity, and time lost from work. A substantial fraction of the 500,000 cholecystectomies done each year for asymptomatic gallstones and stones accompanied by dyspeptic symptoms (but not true biliary colic) could probably be avoided. Many such patients continue to have symptoms after surgery. Similarly, there is no evidence that stone dissolution therapy improves outcomes in patients with asymptomatic stones, although data on this issue are sparse. Patients at high risk for gallbladder cancer might be reasonable candidates for prophylactic cholecystectomy, but few risk factors have been identified (other than calcified gallbladder and stones more than 3 cm in diameter).

Acute Cholecystitis

Patients presenting with symptoms of acute cholecystitis require hospitalization for prompt diagnosis, intravenous fluids, and surgical consultation. The elderly, diabetics, and other debilitated persons are at particularly high risk of a complication from cholecystitis. Although *immediate surgery* may not be necessary, inpatient care for assessment and initial supportive care is warranted. There is considerable debate among surgeons as to whether urgent surgery is indicated. Available analyses suggest little risk to delaying surgery until the acute inflammatory phase of the illness has receded, provided there are no acute complications such as choledocholithiasis or pancreatitis. Performing nonelective open cholecystectomy raises the mortality risk fourfold (i.e., up to 10% in the elderly). Long-term outcomes are similar for *open* and *laparoscopic cholecystectomy* (see below). In general, laparoscopic surgery shortens length of hospital stay and time required for return to work but also increases risks of injury to the common bile duct and retained stones.

Symptomatic Gallstones

Symptomatic patients with recurrent attacks of biliary colic and confirmed gallstones should be advised to undergo *elective cholecystectomy*, provided they are reasonable surgical candidates. Before the advent of laparoscopic surgery, it was unclear which form of therapy was best for such patients, and several analytic studies found little difference between medical versus traditional surgical approaches. However, with development of minimally invasive laparoscopic surgical techniques, the decision has shifted in favor of gallbladder removal by laparoscopic cholecystectomy (see below). Here, the risk of complications from gallbladder disease (although relatively low) exceeds the risk of surgery.

Patients unwilling or too frail to undergo general anesthesia and surgery are candidates for medical therapy, which aims at stone dissolution by use of bile acids, lithotripsy, ether instillation, or a combination of modalities. Some patients will refuse all forms of treatment, preferring to "see how it goes." Suchpatients subject themselves to a small increase in mortality risk, but recent studies suggest the risk is actually modest and that the real issue is the patient's willingness to risk future attacks of pain and possible morbid complications (e.g., pancreatitis). Patients with only a single episode of biliary colic and no risk factors for complications of gallstone disease (i.e., diabetes, age more than 60, stones more than 2.5 cm or less than 0.5 cm) are probably the best symptomatic candidates for an expectant approach to treatment, having a reasonable chance of remaining symptom free into the future.

Surgery is the most definitive means of effecting a long-term cure. *Conventional open cholecystectomy* remains one of the most commonly performed of all surgical procedures, although laparoscopic cholecystectomy has become very popular and has replaced the traditional cholecystectomy in many settings (see below). Mortality rates for conventional open cholecystectomy range from 0.3% to 0.5% in patients under the age of 50 and rise to 1.4% to 2.7% in those over age 70. The complication rate from traditional elective surgery is 5% and doubles for nonelective surgery. Conventional surgery is successful; only about 4% experience chronic postoperative pain, with a retained stone often the cause. Surgery is sometimes undertaken to relieve dyspeptic symptoms, although results are inconsistent and usually disappointing. This is not surprising given the poor correlation between stones and dyspepsia.

Laparoscopic cholecystectomy provides the opportunity for a much less invasive procedure, with length of hospital stay reduced from an average of 6 days to 1.2 days. Over three fourths of patients return to work within 10 days, compared with a month for conventional gallbladder surgery. The procedure takes about 30 minutes longer to perform than an open cholecystectomy. The reported complication rate among surgeons experienced in the technique is 5%, similar to that for open surgery in such patients, but the proportion of serious complications is reduced. The overall rate of bile duct injury is slightly higher (0.5% versus 0.2%) but in a major study fell to 0.1% after a 2.2% rate for the initial 13 cases. Only one case of trocar-induced bowel perforation occurred in over 1,500 procedures, and no deaths were attributable to surgery or a postoperative complication. The most common problem was superficial infection at the site of the insertion of the umbilical trocar. About 5% of cases had to be converted to open procedures, mostly due to poor visualization of the gallbladder.

The laparoscopic approach represents an excellent option in patients with uncomplicated symptomatic gallstone disease. Suspicion of common duct stone necessitates consideration of an open procedure; however, common duct exploration is possible with laparoscopic surgery. If a common duct stone is found, the procedure needs to be converted to an open cholecystectomy or followed postoperatively by ERCP to achieve stone removal. With increasing availability and surgical skill, this procedure is likely to become the treatment of choice for uncomplicated symptomatic gallbladder disease. Although cost per patient has declined markedly with the advent of laparoscopic surgery, total costs have not fallen because more patients are undergoing surgery.

Medical Therapy is an option for patients who are poor surgical candidates or reluctant to undergo elective cholecystectomy. The objective is stone dissolution by biochemical or physical means.

Bile Acids. Up to 80% of gallstones have cholesterol as the major constituent, making them potentially dissolvable in the presence of increased bile acid. Only the naturally occurring bile acid *ursodeoxycholic acid (ursodiol)* has proven both effective in dissolving stones and free of the serious gastrointestinal side effects that accompanied trials of other bile acids (e.g., *chenodiol*, which causes liver injury, diarrhea, and low-density-lipoprotein cholesterol elevations). Ursodiol is safe for long-term use. The agent not only dissolves stones directly but also desaturates the cholesterol content of the bile by suppressing hepatic cholesterol synthesis and biliary cholesterol secretion. It is the only bile acid approved by the U.S. Food and Drug Administration for stone dissolution, replacing chenodiol.

Gallstone dissolution is achievable in patients with small (2 cm) *cholesterol stones*, especially if there is a *functioning gallbladder* (as determined by oral cholecystogram). The overall stone dissolution rate is just under 50% and higher for those with pure cholesterol stones (as determined by the oral cholecystogram findings of floating radiolucent stones in a functioning gallbladder). Results are best in those with a few small stones. Many patients become pain free even before full stone dissolution is achieved, and 40% become stone free after 2 years of continuous bile acid therapy. Patients with larger (more than 10 mm) or calcified stones fail to achieve complete stone dissolution.

The effects of therapy can be well documented by periodic oral cholecystogram or gallbladder ultrasound. Therapy is contraindicated in patients with inflammatory bowel disease or peptic ulcer, because the drug increases bile acids, which may be harmful to colonic and gastric mucosa. Stones recur at the rate of 15% per year.

This high recurrence rate suggests a role for chronic suppressive therapy. Continued symptoms despite dissolution occur in about 4%.

Ursodiol is expensive, costing upward of $2 to $3 per day. However, a major cost-to-benefit analysis showed that ursodiol treatment is a reasonable alternative to surgery in patients deemed poor surgical risks (although comparisons with laparoscopic surgery have not been performed). Some authorities have even advocated using ursodiol initially in all symptomatic patients and operating only on those who fail medical therapy. However, the excellent results reported with laparoscopic surgery, particularly the marked reductions in recovery time and perioperative morbidity, have probably tilted the equation back in favor of surgery for most patients who can tolerate general anesthesia.

Bile salt treatment has an adjuvant role in patients treated with lithotripsy or methyl- *tert*-butyl ether (see below). Stone fragments that remain after initial therapy are subjected to a course of ursodiol in an attempt to dissolve them. Bile salt treatment is also prescribed to prevent new stone formation in high-risk persons such as morbidly obese persons attempting rapid weight reduction.

Extracorporeal Shock-Wave Lithotripsy is worth considering in the 10% of symptomatic gallstone patients who have a small number of *calcium-containing stones* (with the calcium deposited in the core or along the rim) and a *functioning gallbladder*. Lithotripsy will effectively shatter such stones in over 95% of instances. Results are not as good with more than three stones or if greater than 3 cm in diameter. After the stone is shattered, follow-up therapy with ursodiol is required toachieve full dissolution or at least painless stone passage. The procedure is contraindicated in patients with acute cholecystitis or a coagulation deficit and can cause such adverse effects as cardiac arrhythmias, pain, bacteremia, hematuria, cutaneous abdominal wall petechiae, and transient liver injury. About 10% suffer stone-related symptoms after the procedure due to passage of stone fragments. Although transiently popular as a nonsurgical means of gallstone removal, lithotripsy has been supplanted by laparoscopic surgery . However, for patients with calcium-containing stones who are not surgical candidates, it remains a treatment option available at a few centers. The availability of lithotripsy has been limited by very high equipment costs and concerns about cost effectiveness.

Methyl-Tert-Butyl Ether dissolves cholesterol stones and has been used in a few centers to treat highly selected populations of patients with multiple or large cholesterol stones. Instilled directly into the gallbladder by way of a percutaneous catheter, the ether can dissolve stones in less than 3 days of continuous application. However, catheter placement and ether installation are difficult and potentially dangerous, necessitating an experienced team to perform the procedure. Stones reform in about 15%, and another 20% report biliary colic after treatment, probably due to a retained small insoluble nidus. Ursodiol is often used as an adjunct.

In summary, medical therapy represents an alternative for symptomatic patients with cholesterol gallstones who are too sick or unwilling to undergo elective cholecystectomy. Definition of stone composition, size, and number is required, as is willingness to take bile acid medication for a prolonged period of time.

Choledocholithiasis

Stones in the common duct are associated with increased risks of complications and death. Consequently, they need to be removed. Endoscopic sphincterotomy and retrieval of stones by balloon catheter or basket can performed during ERCP. Stones too large to be extracted can be performed broken up by lithotripsy or dissolved by use of ursodiol.

Prevention

Diet and Exercise. Although obesity and caloric excess are major risk factors for gallstone formation in women, there is no evidence that a low-fat low-cholesterol diet per se alters the course of gallbladder disease. Some gallstone patients with dyspeptic symptoms feel better if they avoid fatty foods; however, the relationship between stones and fatty food intolerance is tenuous at best (see Chapter 74). Multivariate analysis shows that it is the number of calories consumed rather than the proportion of calories coming from saturated fat or cholesterol intake that seems to correlate best with risk. One case-control epidemiologic study did find a reduction in risk associated with increased consumption of vegetable protein and vegetable fat, but this finding needs to be confirmed. Although obesity and caloric excess can lead to stone formation, rapid weight loss through fasting and starvation diets are contraindicated because they cause bile to become very lithogenic. Perhaps modest weight reduction achieved in gradual fashion might be of some prophylactic value in high-risk patients such as obese women. Prospective study of dietary factors is sorely needed. Exercise appears to be protective of symptomatic disease in men; it has not been studied in women.

Alcohol and Tobacco. Daily consumption of small amounts of alcohol (about 1 oz per day) has been found in retrospective studies of women to correlate with a 20% reduction in risk of symptomatic gallstone disease. This closely parallels the 20% lower bile cholesterol saturation found among modest drinkers compared with control subjects. Smoking also appears to reduce risk in women, probably by its adverse effects on estrogen production and degradation.

Avoidance of Lithogenic Medications. Risk of gallstone formation rises markedly with use of *estrogen* and *clofibrate*. Patients with known gallstones should not take them, and those taking such drugs should be monitored for gallstone formation, particularly if there is a strongly positive family history of stone disease. *Thiazide* use is associated with a modest increase in relative risk of gallstones (relative risk, 2.0 to 2.9).

PATIENT EDUCATION

The truly asymptomatic gallstone patient can be reassured of the low probability of becoming symptomatic or suffering a complication. Such patients can be followed expectantly and should not be pushed into surgery, medical therapy, or unnecessary dietary restriction. Previously, asymptomatic patients with large stones, diabetes, or advanced age were considered candidates for prophylactic stone removal because they had an increased mortality risk from a complication. However, improvements in medical and surgical therapy of symptomatic patients have greatly reduced risk for such patients, making prophylactic surgical or stone-dissolution therapy unnecessary.

Because symptomatic patients have a slightly increased mortality risk and a modest chance of a complication, they need to be informed of the available therapeutic options so that patient preferences and treatment modality can be matched. The principal therapeutic benefit is a reduction in frequency of symptoms and in risk of complications; mortality benefit is small and almost clinically insignificant. The wish to refuse therapy can be respected, so long as the patient understands the risks of choosing expectant therapy. However, the short hospital stay, low morbidity, and speedy recovery afforded by laparoscopic cholecystectomy may be particularly appealing to previously reluctant symptomatic patients. Ursodiol is also well tolerated and may be an attractive option for qualifying patients fearful of any surgery.

Any dyspepsia should be clearly differentiated from biliary colic. Patients need to know that the link between dyspepsia and gallstones is not well founded and that the presence of dyspeptic symptoms is not an indication for surgery, lithotripsy, or medical therapy, although other measures might help (see Chapter 74).

INDICATIONS FOR REFERRAL AND ADMISSION

Patients with evidence of acute cholecystitis should be admitted to the hospital for evaluation, surgical consultation, and supportive measures. Consultation with a surgeon regardingelective cholecystectomy is also indicated for patients with recurrent biliary colic. Referral for consideration of laparoscopic cholecystectomy should be made exclusively to a surgeon skilled and experienced in performing the procedure. High levels of morbidity (e.g., bile duct injury, perforation) and mortality have resulted from inadequately trained personnel performing the procedure. A gastroenterologic referral may be useful for symptomatic patients who are deemed too frail to undergo elective surgery as well those with a suspected common duct stone who may require ERCP.

THERAPEUTIC RECOMMENDATIONS

- Patients with asymptomatic cholelithiasis can be managed expectantly, because the risk of developing symptomatic disease or a complication is only 1% per year.
- Patients with a single episode of biliary colic are also reasonable candidates for expectant management, as long as they continue free of recurrent pain.
- Patients with documented gallstones and recurrent biliary colic or a history of a complication of gallstone disease (cholecystitis, pancreatitis) should be advised to undergo elective cholecystectomy, provided they can tolerate general anesthesia and surgery. *Laparoscopic cholecystectomy* has become the surgical procedure of choice, reducing perioperative morbidity and shortening the recovery period when performed by a surgeon skilled in the procedure.
- Symptomatic nonsurgical patients with a functioning gallbladder and radiolucent (i.e., cholesterol) gallstones can be given a trial of bile acid therapy with *ursodiol* (10 to 15 mg/kg/d). Therapy is continued for at least 12 months and often for 24. Results are best in those with stones that are less than 2 cm in

diameter and three in number. Presence of calcification rules out bile acid therapy. The effects of therapy should be monitored with a gallbladder ultrasound every 6 months. Risk of recurrence is high after bile acid therapy is stopped.

- *Lithotripsy* is worth consideration in symptomatic nonsurgical patients with calcium-containing stones. Results are best in those whose stones are less than 3 cm in diameter and less than four in number. Patients require referral to a center with expertise in the procedure.
- Estrogen preparations, clofibrate, and other drugs that may trigger stone formation should be stopped or dosages should be decreased in persons with gallstones or high risk of developing them.
- Restricting *fat* and *cholesterol* is of little or no benefit in altering the clinical course of gallstone disease. However, obesity and caloric excess are major risk factors, and gradual weight reduction through modest caloric restriction might be helpful. Fasting and starvation diets are to be avoided because they make the bile even more lithogenic. Modest *alcohol* consumption (less than 1 oz per day) is not harmful. *Exercise* can be recommended as a preventive measure.
- Dyspeptic symptoms should not be considered grounds for medical or surgical treatment because their relation to gallstone disease is tenuous at best. Dyspeptic symptoms are likely to respond better to other measures (see Chapter 74).

CHAPTER 70 MANAGEMENT OF HEPATITIS

JULES L. DIENSTAG

Viral and nonviral forms of hepatitis are more common than generally thought. More than 50,000 cases of viral hepatitis in the United States are reported to the Centers for Disease Control and Prevention each year, although the actual number is estimated to be 10 times as high. Hepatitis B accounts for 30% to 35% of cases of acute viral hepatitis, hepatitis A for 45% to 50%, and hepatitis C for 15% to 20%; a few percent cannot be attributed to any known hepatitis virus. In addition, a proportion of patients with acute types B, C, and D progress to chronic infection. Some become asymptomatic carriers; others have chronic hepatitis, which is associated with an increased risk of cirrhosis and death. Approximately 25% to 40% of chronic liver disease in the United States and Europe derives from chronic hepatitis C infection and 10% to 15% from hepatitis B. Other important causes include chronic alcohol abuse, hemochromatosis, and autoimmune hepatitis. In about 15% to 20% of cases, the cause is unknown ("cryptogenic").

The primary physician needs to be skilled in the management of both viral and nonviral forms of hepatitis, because these are illnesses usually encountered in the outpatient setting. Effective outpatient management requires knowledge of diagnosis (see Chapter 57 and Chapter 62), natural history, and treatment options. Immunosuppressive therapy for nonviral disease, interferon and nucleoside analogues for viral disease, and transplantation for end-stage forms have widened the therapeutic options greatly. Although many treatment decisions require subspecialty consultation, the primary physician retains responsibility for long-term management and follow-up. This requires knowing the indications and contraindications for the various treatment options and the best means of monitoring clinical course and therapeutic interventions.

CLINICAL PRESENTATION AND NATURAL HISTORY

Acute Viral Hepatitis

In most instances, acute viral hepatitis is a self-limited illness; on the order of 85% of hospitalized patients and over 95% of outpatients recover completely and uneventfully within 3 months(except in hepatitis C; see below). Most persons with acute viral hepatitis never become jaundiced; their illness is mistakenly labeled as a nonspecific viral syndrome unless liver biochemical tests, such as aminotransferase levels, are ordered. A large proportion of patients remain asymptomatic, especially children. In elderly or immunologically compromised patients, the prognosis is more guarded, with an increased risk of severe and protracted disease.

Prodromal symptoms occur after an *incubation period* of 2 to 4 (rarely 6) weeks for hepatitis A, 4 to 24 weeks for hepatitis B (with or without simultaneous acute delta hepatitis infection), and 3 to 15 weeks (80% within 5 to 10 weeks) for hepatitis C. Characteristically, *prodromal symptoms* consist of 1 to 2 weeks of malaise, anorexia, nausea, vomiting, change in senses of taste and smell, low-grade fever, right upper quadrant or midepigastric abdominal discomfort, and fatigue. Aminotransferase elevations may precede or coincide with the onset of prodromal symptoms.

If jaundice develops, it usually does so as prodromal complaints begin to subside, although persistence of prodromal symptoms is observed in more severe cases. By the time 6 to 8 weeks have elapsed, most patients are well on their way to full recovery. Occasionally, an isolated mild aminotransferase elevation persists after clinical recovery. If it resolves within 3 to 6 months, the mild elevation has no prognostic significance.

Fulminant Acute Disease. This is the most ominous form of acute disease, characterized by overwhelming liver cell necrosis and signs of liver failure—encephalopathy, ascites, and coagulopathy. This complication is seen more often in cases of hepatitis B (especially with simultaneous delta hepatitis infection) than in those of hepatitis A or C, although, as noted earlier, the frequency is particularly high among pregnant women with hepatitis E. Before the availability of liver transplantation, the mortality of fulminant hepatitis approached 80%, despite the best intensive medical care.

Other Variants of Acute Hepatitis. In 5% to 10% of cases of acute type B hepatitis, the prodromal phase of illness may be characterized as a *serum sickness–like syndrome*, with urticaria, arthralgias, fever, and polyarticular arthritis. Some patients with acute viral hepatitis, especially those with hepatitis A or E, have a *cholestatic* illness, with marked jaundice, elevation of serum alkaline phosphatase activity, and pruritus lasting 1 month to several months.

Approximately 5% to 10% of patients with viral hepatitis appear to suffer mild *relapses* during convalescence. Such clinical and biochemical relapses are now well recognized in patients with acute hepatitis; in patients with acute hepatitis B, what appears clinically as a relapse may represent the clinical expression of simultaneous delta hepatitis infection. Episodic swings in aminotransferase levels are common during acute and chronic hepatitis C. In some instances, these recurrent elevations are accompanied by clinical "relapses."

Progression to Chronic Hepatitis. The risk of progression varies among the several types of viral hepatitis. Although an occasional case of hepatitis A may be slow to resolve and last more than 6 months, no cases of chronic hepatitis have been linked to hepatitis A infection. Similarly, hepatitis E does not progress to chronic infection. There are no reliable early predictors of chronicity. In patients with hepatitis B, persistence of *hepatitis B surface antigen (HBsAg) and hepatitis Be antigen (HBeAg)* increases the risk of chronic hepatitis, although early presence of either has no predictive value. Similarly, no reliable predictors of chronicity have been identified in patients with acute hepatitis C. Clinical manifestations of progression to chronic viral hepatitis may be subtle, with little more than persistence of mild symptoms and biochemical abnormalities for 6 or more months. Many patients remain asymptomatic and almost all remain anicteric.

Hepatitis B can progress to chronic hepatitis, but usually at a very low rate (1% to 2%) among immunocompetent adults. When accompanied by high levels of hepatitis B virus (HBV) replication, patients with chronic hepatitis B tend to have chronic liver injury categorized as mild, moderate, or severe chronic hepatitis. Those with negligible virus replication become asymptomatic carriers of HBsAg.

The likelihood of chronic HBV infection is higher, approaching 90%, when acute infection occurs at birth or in *early childhood* or when acute infection occurs in an *immunocompromised host*. Most patients who present with chronic hepatitis B have no history of having experienced an acute hepatitis-like clinical illness, acquiring their infection subclinically. In patients with simultaneous acute *hepatitis B and D* (delta hep-atitis), the likelihood of *chronicity* is not increased, but *severity* of acute and chronic hepatitis is increased.

Although most HBsAg carriers are asymptomatic and have a nonprogressive course, a small proportion may actually have subtle and insidious progression to chronic liver disease. Rarely, acute hepatitis-like exacerbations can occur. Such events may represent superimposed infection with another hepatitis virus (A, C, D) or reactivation of hepatitis B. Occasionally, an acute hepatitis-like elevation of aminotransferase activity represents a successful spontaneous seroconversion from highly replicative, HBeAg-positive, high-level HBV DNA infection to relatively nonreplicative, anti-HBe–positive, low-level HBV DNA infection; when such seroconversions occur, chronic liver injury gives way to an asymptomatic carrier state. With early-generation clinical assays for HBV DNA, the level of HBV DNA in "nonreplicative" carriers fell below the detection threshold, but with exquisitely sensitive amplification techniques, HBV DNA can be detected in carriers, albeit at a threshold below 10^5 to 10^6 virions per milliliter.

More recently, another category of chronic hepatitis B has been recognized, "*pre-core*" *mutant hepatitis B.* The C gene, which codes for the nucleocapsid core protein (HBcAg), also codes for HBeAg protein; HBeAg production requires an intact pre-core gene sequence. When one of several mutations in the pre-core region prevents elaboration of HBeAg, HBcAg and intact virus particles can still be synthesized, leading to highly replicative hepatitis B, despite the absence of HbeAg. Patients with such pre-core mutations can have high levels of HBV DNA and substantial liver injury despite the absence of HBeAg, the conventional marker for high-level HBV replication and infectivity. Often, these variants emerge after many years of HBeAg-reactive chronic hepatitis B. Pre-core–mutant chronic hepatitis B appears to be relatively refractory to anti-viral therapy.

Patients with chronic hepatitis B, especially those with infection acquired early in life, are at markedly increased risk of progression to *cirrhosis* and *hepatocellular*

carcinoma.

Hepatitis C. In hepatitis C, 50% to 60% of patients experience elevations in aminotransferase that persist for more than a year after acute infection, and almost all of these go on to have long-standing chronic hepatitis. Moreover, even among patients in whom aminotransferase elevations resolve within the first 6 months, chronic viremia persists in almost all. Between the 50% and 60% with chronic hepatitis after acute hepatitis C virus (HCV) infection and the remainder with *chronic viremia*, chronicity of HCV infection occurs in more than 85% of acutely infected persons. What is more, patients with chronic viremia remain at risk for the development of chronic hepatitis.

Among patients with chronic hepatitis C, *cirrhosis* develops in 20% of cases within 10 years after onset of acute infection. Most have little impact of their disease for many decades, but in patients with moderate to severe chronic hepatitis on liver biopsy, the risk of progression to cirrhosis over 10 to 20 years remains high. Among those with cirrhosis, 10-year survival is very good, approximately 80%; in compensated cirrhotics with chronic hepatitis C, hepatic *decompensation* occurs in approximately 4% to 5% per year; the risk of *hepatocellular carcinoma* (rare during the first three decades of infection) increases at a rate of 1% to 3% per year.

Toxic and Drug-induced Hepatitis

Drugs can trigger hepatocellular injury through a direct toxic effect or by means of an idiosyncratic reaction. Some agents are associated with a cholestatic reaction, either as part of an idiosyncratic process or independent of it.

Direct Toxins. Directly toxic reactions are dose-related and predictable. The latency period is short, and there are no manifestations suggestive of a hypersensitivity reaction. *Acetaminophen* is the most commonly used drug that is directly hepatotoxic, though only when taken in massive doses.

Idiosyncratic Reactions. These were once thought to be immunologically mediated but actually result from the hepatotoxic effects of drug metabolites. They are less predictable than direct toxins. Latency is variable, and there is little relationship to dose. In about 25% of patients, extrahepatic manifestations suggestive of a hypersensitivity reaction (e.g., fever, rash, arthralgias, eosinophilia) occur. Hepatitis resulting from *halothane, isoniazide, methyl dopa, valproic acid,* and *trimethoprim-sulfamethoxazole* has a strong idiosyncratic component.

Cholestatic Reactions. There are two types of cholestatic reactions, *bland cholestasis*, with little evidence of hepatitis and *inflammatory cholestasis*. As is the case for other types of drug hepatotoxicity, some categories of cholestatic drug injury appear to represent predictable, dose-dependent, direct toxicity and others unpredictable, non–dose-dependent, idiosyncratic reactions. Oral contraceptives cause bland cholestasis, and the reaction is dose dependent and variable in onset. *Erythromycin* (especially the estolate preparation but also other forms) and *chlorpromazine* are capable of causing idiosyncratic cholestasis with hepatitis, as are other phenothiazines, amoxicillin-clavulanic acid, and oxacillin. *Anabolic steroids* (17 a-substituted androgens) also can cause cholestasis, often accompanied by a mild degree of hepatocellular injury. Other drugs cause a clinical picture reminiscent of sclerosing cholangitis, with inflammatory destruction of intrahepatic bile ducts (e.g., the chemotherapeutic agent FUDR), whereas others (e.g., carbamazepine, chlorpromazine, tricyclic antidepressant agents) can result in disappearance of bile ducts, "ductopenic" cholestasis, reminiscent of chronic rejection after liver transplantation.

Drug-induced Steatosis. Macrovesicular or microvesicular steatosis or fatty infiltration with accompanying hepatitis (steatohepatitis) complicates therapy with several drugs. Among patients treated with antiretroviral infection for HIV infection, severe steatohepatitis, a reflection of mitochondrial toxicity, has been observed in association with reverse transcriptase inhibitors such as *zidovudine* and *didanosine* and with *protease inhibitors* such as indinavir and ritonavir.

Clinical Course. Severity of drug-induced hepatitis can range from an asymptomatic increase in liver enzymes to life-threatening illness. Prompt cessation of the drug is essential to limiting further hepatic injury; rechallenge may lead to an exaggerated reaction. Most cases are self-limited, provided that severe injury has not already occurred.

Chronic Hepatitis

Classification by Grade and Stage. The distinctions between what used to be labeled "chronic persistent" and "chronic active" hepatitis are no longer recognized as valid and are being phased out of clinical use. Chronic persistent hepatitis, which now is called *minimal* or *mild chronic hepatitis*, referred to more indolent disease, whereas chronic active hepatitis was the designation for more progressive disease that is now labeled as *moderate to severe chronic hepatitis*. The obsolete distinctions have been replaced by assessments of relative inflammatory activity (grade) and fibrosis (stage). In clinical trials of chronic hepatitis, especially of chronic viral hepatitis, a numerical histologic index is used to assess severity (grade) and progression (stage). The *histologic activity index* includes numeric scores for periportal necrosis (including piecemeal and bridging necrosis; range, 0 to 10), intralobular necrosis (range, 0 to 4), portal inflammation (range, 0 to 4), and fibrosis (range, 0 to 4).

Mild Chronic Hepatitis has mononuclear-cell inflammation confined to the portal tract, the limiting plate of periportal hepatocytes is not eroded, hepatocellular necrosis and inflammation do not extend into the lobule, and fibrosis is absent or very limited. This mild category of chronic hepatitis was believed in the past to be predictive of a good prognosis and limited progression; however, although the benignity of mild chronic hepatitis tends to persist, the prognostic value of this designation is now recognized to be more limited and does not preclude progression to more severe chronic hepatitis or even cirrhosis.

Moderate to Severe Chronic Hepatitis is characterized histologically by a mononuclear-cell portal infiltrate that not only expands portal zones but also extends beyond the portal tract into the adjacent periportal lobular area with erosion of the limiting plate of periportal hepatocytes (" *piecemeal necrosis*" or "*interface hepatitis*"). Fibrous septae extending into the lobule are also characteristic, fibrosis can range from mild to severe, and a proportion of such patients may have cirrhosis on their initial liver biopsies. A more severe form of this lesion includes " *bridging necrosis*," in which confluent necrosis and cell dropout span lobules (portal–portal and portal–central bridges).

Chronic Viral Hepatitis. In the chronic forms of viral hepatitis, the *level of virus replication* appears to be the most important determinant of progression, even more so than histologic pattern. Nonetheless, *histologic appearance*, especially as a reflection of the degree of virus replication, may also serve as a determinant of prognosis. In patients with chronic hepatitis B, one fourth of patients with mild chronic hepatitis B can still become cirrhotic. Similarly, in patients with histologically mild chronic hepatitis C, 20% can progress to cirrhosis over one to two decades. Superinfection with *hepatitis D* can cause progression to more severe liver disease among persons with chronic mild hepatitis B.

Hepatitis B. The 15-year survival of histologically mild chronic hepatitis B is in excess of 95%, that of more severe chronic hepatitis B about 85%, and of the more histologically severe forms of chronic hepatitis B *with* cirrhosis about 40%. Progression to cirrhosis has been noted in 13% of those with mild chronic hepatitis B, in 16% of patients with moderate chronic hepatitis B (without bridging necrosis), and in 88% of those with severe chronic hepatitis B (with bridging necrosis).

The determinant of prognosis that underlies histology in chronic hepatitis B is virus replication. *Level of virus replication* (as measured by serum concentration of HBV DNA and presence of HBeAg) is probably the most important determinant of progression to cirrhosis in patients with chronic hepatitis B. For example, in one study, cirrhosis developed in 53% of those with persistent HBV DNA but in none of those able to clear HBV DNA. In patients with chronic hepatitis B, *conversion from HBeAg to anti-HBe* may signal an improvement in liver histology, whereas superinfection with the *delta agent* is usually associated with a deterioration in histology in up to one third of patients and an acceleration of the disease process.

In sum, although histologic appearance is important, liver biopsy provides only a measure of disease at one point in time. Degree of virus replication activity may be the best predictor of prognosis. *Life-long infection* with HBV, such as occurs primarily among those infected at or shortly after birth, is associated with an increased risk of *hepatocellular carcinoma*, whether cirrhosis is present or not.

Hepatitis C. Episodic bursts of inflammatory activity often punctuate the clinical course of patients whose liver biopsies show mild chronic hepatitis C. Like hepatitis B, histologic features of chronic hepatitis C can change, and even patients with clinically and histologically mild chronic hepatitis C can progress insidiously and slowly to cirrhosis. Chronic hepatitis C is commonly associated with erosion of the limiting plate of periportal hepatocytes (piecemeal necrosis) but rarely with clinical or histologic criteria for severe chronic hepatitis (10-fold elevation of aminotransferase activity, disabling symptoms, multilobular collapse). Still, despite this apparent relative benignity, chronic hepatitis C may progress insidiously, even in the absence of symptoms or marked elevations in aminotransferase activity, and may lead to cirrhosis in 20% within 10 years. Although a wide range of frequencies of progression to cirrhosis have been reported and although most patients with chronic hepatitis C do very well with limited clinical consequences over several decades, patients with long-standing chronic infection often demonstrate histologic

progression. Although a correlation exists between HBV replication and disease progression, a similar correlation between HCV replication and disease progression cannot be demonstrated invariably. Among the several variables associated with progression in chronic hepatitis C, duration of infection is probably the most important. The best clinical predictor of progression may be histologic stage and grade. Mild inflammation and necrosis and mild fibrosis characterize a cohort of patients with an excellent prognosis and limited progression to cirrhosis over time, whereas moderate to severe necrosis/inflammation and/or fibrosis portend progression to cirrhosis almost invariably over one to two decades.

Nonviral (Autoimmune, Idiopathic) Chronic Hepatitis. An autoimmune mechanism is believed to account for many cases of nonviral chronic hepatitis. The sensitivity of histologic change may have a degree of prognastic value. Although in autoimmune hepatitis histologic severity may have a degree of prognostic value. Like other autoimmune diseases, the condition predominates in women between ages 20 and 40. An acute form with severe fatigue, jaundice, fever, amenorrhea, and anorexia sometimes occurs, but some present asymptomatically. There is a high incidence of extrahepatic manifestations, including arthritis, rash, thyroiditis, glomerulonephritis, and pleuropericarditis. Asymptomatic patients are typically discovered when an incidental modest elevation in aminotransferase is noted on routine testing. Marked elevation in *gamma globulin* (more than two times normal) is characteristic, as are high titers of *antinuclear antibody* and *antibody to smooth muscle*. Enzyme immunoassays for antibody to hepatitis C may yield false-positive readings in such patients; therefore, in patients with what appears to be autoimmune hepatitis, if screening tests for anti-HCV are reactive, a confirmatory test, such as a test for HCV RNA, should be done. The bilirubin may be higher than in viral hepatitis. Histology and disease activity are more important determinants of prognosis for nonviral disease.

Untreated severe autoimmune hepatitis (defined by disabling symptoms, sustained aminotransferase elevations more than 10 times normal, gamma globulin levels twice normal, bridging or multilobular collapse on biopsy) may progress to cirrhosis and eventual death. The 6-month fatality rate is 40% in patients with these findings. Bridging or multilobular necrosis on biopsy specimen is associated with cirrhosis in 40% and death in 20% after 5 years. In contrast, patients with less severe disease (piecemeal necrosis alone, minimal symptoms) are usually not at risk for death, and progression to cirrhosis is rare (3% to 10%).

Mild autoimmune chronic hepatitis has a good prognosis in most cases but is not uniformly benign. This lesion has been documented to deteriorate to more severe chronic hepatitis and to progress to cirrhosis in certain patients, such as those with an initial histologic diagnosis of severe hepatitis whose liver biopsies improve with therapy and in immunosuppressed patients with a histologic diagnosis of mild chronic hepatitis.

PRINCIPLES OF MANAGEMENT

Acute Viral Hepatitis

Being a generally benign and self-limited illness, acute viral hepatitis can be managed in most cases on an outpatient basis.Hospitalization should be reserved for high-risk patients (e.g., elderly, immunocompromised, difficult-to-manage underlying chronic diseases) and those with signs of severe hepatocellular injury (e.g., marked prothrombin time prolongation, encephalopathy, ascites and edema, inability to maintain oral intake, hypoglycemia, or hypoalbuminemia). Other than specific antiviral therapy (see below), there is no specific therapy for acute viral hepatitis that will accelerate convalescence or prevent sequelae. The usual goals of care are to maintain *adequate nutrition* and *patient comfort*, to *avoid* additional *hepatocellular insults* from hepatotoxic medications and alcohol, and to *prevent the spread* of infection to others.

Neither *specific dietary manipulations, corticosteroids, nor bedrest* has any beneficial effect on the course or prognosis of acute uncomplicated or acute severe viral hepatitis. *Oral contraceptives* do not necessarily need to be stopped, but *alcohol* intake should be omitted, and use of other drugs known to cause liver injury should be discontinued or monitored carefully. *Exercise* does not interfere with recovery; patients should be encouraged to engage in as much physical activity as they can tolerate without discomfort or undue fatigue.

Symptoms may be incapacitating. Nausea and vomiting can be controlled by cautious use of antiemetics; however, because phenothiazines cause cholestatic hepatitis in approximately 1% of patients, *nonphenothiazine antiemetics*, such as *trimethobenzamine*, should be used. Small *frequent feedings*, especially in the morning when nausea is at a low ebb, can ensure adequate calorie intake. No specific foods need be restricted. In patients with cholestasis and pruritus, *cholestyramine* usually provides relief. Certainly, the identification of a patient with acute viral hepatitis should prompt consideration of prophylactic measures to limit the spread of infection to contacts (see Chapter 57).

Hepatitis B. Because patients with clinically apparent acute hepatitis B almost always recover, specific antiviral therapy is not indicated. For the unfortunate 1% to 2% who remain chronically infected, antiviral therapy can be instituted once chronicity is documented.

Hepatitis C. For patients encountered with acute hepatitis C, antiviral therapy during early acute hepatitis has been shown to reduce the frequency of chronicity and is recommended (see below). In clinical practice, such acute cases are being recognized in growing frequency among health workers who sustain accidental needle sticks or other percutaneous exposures.

Monitoring and Follow-up. The patient is monitored clinically by observing symptoms and checking hepatocellular function. An *aminotransferase* level obtained weekly at the outset and then monthly is useful to judge the presence of ongoing disease, although the absolute level is not a particularly sensitive determinant of disease severity in the acute phase of illness. *Prothrombin time* is a good measure of hepatocellular synthetic function and should be checked when the patient first presents and when there is suspicion of worsening. *Serum bilirubin*, a marker of hepatic excretory function, also correlates with severity. A fall in *serum albumin* indicates reduced hepatocellular synthetic function, but because its half-life is 28 days, this change does not become apparent until late in the acute illness. In patients with acute hepatitis C, early antiviral therapy with a standard course (see above) of interferon and ribavirin should be initiated.

An office visit 1 to 2 weeks after the first presentation is often helpful to be sure there is no worsening and that the patient is managing satisfactorily. Thereafter, follow-up depends on how well the patient feels. At 3 months, a repeat aminotransferase, bilirubin, albumin, prothrombin time, and, in cases of hepatitis B, an *HBsAg* determination should be performed to ascertain disease activity, severity, and antigen status.

If symptoms and laboratory evidence of activity persist after 3 months, repeat evaluations at monthly intervals are indicated. *Liver biopsy* is not indicated in patients with acute viral hepatitis unless clinical suspicion of chronic hepatitis is present.

Fulminant Acute Hepatitis. Neither corticosteroids nor any other specific medical therapy has proven effective. The best approach involves meticulous attention to details of the multisystem dysfunction that accompanies acute liver failure. Such patients should be admitted to an intensive care unit and considered for early referral to a transplantation center. *Liver transplantation* is the only intervention that has truly life-saving potential. With timely transplantation, survival rates of 50% to 60% are possible. Recurrent viral hepatitis may occur in the new liver, but not invariably, and antiviral therapy for hepatitis B and C can be used after transplantation to reduce the impact of reinfection. Experimental trials are underway to assess a variety of hepatic assist devices, but none have yet been proven effective. Reversal of acute fulminant hepatitis B has been observed anecdotally with early administration of the nucleoside analogue lamivudine (see below).

Drug-induced Hepatitis

Treatment is largely supportive. All possible offending agents should be stopped. Immunosuppressive and anti-inflammatory drugs are of no benefit.

Chronic Viral Hepatitis

Treatment of viral chronic hepatitis depends on the etiology and severity of disease. Therapy focuses on termination of viral replication, the principal determinant of prognosis. Immunosuppression, which is useful in nonviral hepatitis (see below), has no place and may even be detrimental, resulting as it does in an increase in viral replication. Therapeutic decisions may be made independently of histologic severity, but *liver biopsy* is indicated to establish the presence of necroinflammatory liver disease, to assess the stage and grade of the disease, and to exclude other causes for abnormal liver chemistry tests (e.g., infiltration with fat or iron). In patients considered for antiviral therapy, a brief period of observation before instituting treatment is helpful to ensure that the patient is not in the process of spontaneous improvement.

Hepatitis B. Antiviral therapy is the cornerstone of treatment, using the interferon alfa or the inhibitor of viral replication, lamivudine.

Interferon alfa was the first antiviral drug to be approved for treatment of chronic hepatitis B. When given to patients with *compensated replicative chronic hepatitis* B (i.e., with circulating HBV DNA and HBeAg), approximately 30% experience seroconversion to nonreplicative infection (loss of HBeAg and HBV DNA detectable by conventional hybridization assays). Treatment consists of a 16-week course of either daily subcutaneous injections of 5 million units or thrice weekly injectionsof 10 million units. About one fourth of responders in early trials also lost detectable HBsAg. Improvements in serum aminotransferase activity and liver histology occur as well in those with sustained reductions in viral replication.

Interferon is effective in patients with modest levels of HBV replication and with elevated aminotransferase activity but ineffective in those with very high levels of HBV replication and in those with normal or near-normal aminotransferase activity. Among patients who respond (as manifested by disappearance of circulating HBV DNA and HBeAg), there is improvement in the natural history of the disease (80% clearing of HBsAg over the decade after therapy), improved survival without decompensation, and reduced risk of hepatocellular carcinoma. Those not responding well to interferon include immunosuppressed patients, those infected in early childhood, and patients with pre-core hepatitis B mutations (see above). In *decompensated patients*, the acute hepatitis-like exacerbation that accompanies successful interferon therapy may precipitate liver failure, making them poor candidates for routine interferon treatment.

Adverse Effects. Major adverse effects of interferon include *flulike symptoms, marrow suppression, irritability* (sometimes depression), and autoimmune *thyroiditis* (rarely, other autoimmune disorders). Successful interferon therapy is often accompanied by a transient, acute, hepatitis-like elevation in aminotransferase activity, believed to represent an enhancement of cell-mediated immune cytolysis of HBV-infected hepatocytes.

Lamivudine, a potent inhibitor of HBV and HIV reverse transcriptase, has been approved for routine use in patients with chronic "replicative" hepatitis B. For hepatitis B, lamivudine therapy is rapidly supplanting interferon as first-line therapy, because lamivudine does not require injections, has no appreciable side effects, and is at least if not more effective than interferon. Patients with decompensated chronic hepatitis B are not good candidates for interferon therapy but may respond to lamivudine, sometimes with reversal of clinical signs of decompensation.

Efficacy. Daily doses of 100 mg/d (a third of the dose for HIV infection) suppress HBV DNA by four orders of magnitude. A 12-month course of therapy results in HBeAg loss in approximately 30%, seroconversion from HBeAg to anti-HBe in approximately 16% to 20%, normalization of alanine aminotransferase in more than 40%, and histologic improvement in more than 50%. Among the histologic changes are a reduction in necroinflammatory activity in 60% and a halting of progression to fibrosis in 20%. Among those with HBeAg responses (loss or seroconversion), the antiviral response is durable in approximately 80%; an HBeAg response can be used as a landmark for discontinuing therapy. In the absence of an HBeAg response, however, continued therapy may be required.

Although lamivudine suppresses HBV replication substantially in almost all patients, a sustained response is less likely in patients with normal aminotransferase activity and in patients with pre-core HBV variants who nevertheless do benefit histologically and biochemically. Side effects are negligible, and transient elevations in aminotransferase activity occur in about one fourth of patients but no more frequently than in placebo recipients. After discontinuation of therapy, however, in the absence of an HBeAg response, aminotransferase elevations (acute hepatitis-like flares) occur in 20% to 30% of patients, but these flares are transient and clinically mild in most cases. Close posttreatment monitoring is essential to identify and retreat severe posttreatment exacerbations. Losses of HBsAg are uncommon during lamivudine therapy but are observed after therapy in those with HBeAg loss.

Resistance. The frequency of HBeAg responses increases with each year of lamivudine therapy, but the downside of long-term therapy is the emergence of viral *resistance*. In 15% to 30% of patients treated for a year and in 50% of those treated for 3 years, a viral variant emerges (e.g., YMDD), reflecting a *mutation* in HBV DNA polymerase. Although YMDD variants are less responsive to lamivudine than wild-type HBV, measures of disease activity remain well below baseline levels, perhaps because variants replicate less effectively than wild-type HBV. Withdrawal of lamivudine results invariably in a return of wild-type HBV and more severe liver injury. Consequently, continued therapy even after the emergence of YMDD variants is recommended, at least until other antivirals are developed. In the future, multidrug regimens will be introduced and will reduce the likelihood of viral resistance. Overall, many authorities rely on lamivudine as first-line therapy for chronic hepatitis B.

Adverse Effects. Lamivudine has no recognized side effects or impact on nonhepatic laboratory values.

Famciclovir and ganciclovir, nucleoside analogues with antiviral activity, have limited activity against HBV.

Monitoring and Followup. *Aminotransferase* levels are *monitored* once a month during therapy. For patients being treated with interferon or lamivudine, monitoring of *HBV DNA* is indicated at intervals of 1 to 3 months; *HBeAg* is checked, at a minimum, at the end of therapy, but an interval HBeAg testing during therapy is helpful. For patients treated with interferon, monitoring of *white blood cell* and *platelet* counts is indicated at weeks 1, 2, and 4 and then monthly to detect any marrow suppression. Aminotransferases are monitored monthly, and bilirubin and albumin are checked periodically. Periodic monitoring of thyroid function (*thyroid-stimulating hormone*) at 1- to 3-month intervals identifies patients with thyroiditis who are candidates for reduction or cessation of interferon or initiation of thyroid hormone-replacement therapy.

Liver Transplantation. Decompensated patients who are refractory to antiviral therapy may be candidates for *liver transplantation* or investigative protocols. The success of liver transplantation for chronic hepatitis B is approximately 75% now that antiviral regimens are offered routinely. The most common approach is a combination of high-dose hepatitis B immune globulin plus lamivudine.

Hepatitis D. *Interferon* achieves reductions in hepatitis D virus RNA and a fall in aminotransferase, but cessation of therapy is followed almost invariably by a return of these markers to pretreatment levels. Long-term high-dose interferon therapy continued for a full year may produce more durable results, and multiyear therapy may be required to control the disease. The benefit of antiviral therapy remains to be demonstrated; corticosteroid therapy is ineffective. Lamivudine is not effective for hepatitis D. *Liver transplantation* has been successful in patients with end-stage disease, with an outcome better than that for hepatitis B alone.

Hepatitis C. Major advances in the treatment of chronic hep-atitis C have been made possible with the advent of interferonalfa and ribavirin. Candidates for antiviral therapy include those with compensated chronic hepatitis C and moderate-to-severe chronic hepatitis on liver biopsy. No consensus exists on treatment of patients with asymptomatic or histologically mild disease; such patients tend to do well without therapy, and therapy has not been shown to have a beneficial impact in this cohort. Decompensated patients are unlikely to respond. Cirrhosis per se is not a contraindication to antiviral therapy, but reports of primarily retrospective studies suggesting that interferon therapy in cirrhotics prevents hepatocellular carcinoma may represent a selection bias favoring treatment in patients with less advanced disease, not a true treatment effect. The role of interferon in preventing complications of cirrhosis and hepatocellular carcinoma needs to be tested in prospective trials. Corticosteroids have never proven useful in treatment of chronic viral hepatitis. *HCV genotype* and quantitative testing for *HCV RNA* ("*viral load*") should be determined before therapy to help determine the duration of treatment (6 months for patients with low viral loads and genotypes other than 1; 12 months for patients with high viral loads and genotype 1).

Interferon Alfa is U.S. Food and Drug Administration approved for treatment of chronic hepatitis C. After receiving a dose of 3 million units three times a week for 24 weeks, 50% of patients with chronic hepatitis C experience a normalization of aminotransferase levels (biochemical response) and approximately 30% have a loss of detectable HCV RNA (virologic response). Histologic improvement occurs in as many as three fourths of patients assessed at the end of therapy. The relapse rate after cessation of therapy is high, yielding a sustained response rate (usually measured at least 6 months after completion of therapy) after 6 months of therapy of only 10%. The frequency of sustained responses can be increased to approximately 20% by increasing the duration of interferon monotherapy from 6 to 12 months; dose escalation has a negligible effect, and switching from one interferon preparation to another is also of limited benefit.

Induction therapy with initial high-dose intensive regimens has been advocated, but they have not improved ultimate sustained response rates. Sustained response rates have been improved with long-acting interferons bound to polyethylene glycol. Pegylated interferons have longer half-lives and are eliminated more slowly, allowing once-a-week administration and achieving a prolonged concentration plateau. In preliminary trials, sustained responses have been observed in more than 30% of patients treated for a year. The likelihood of a response to interferon is increased in patients with low-level HCV RNA (less than 2 million copies/mL) and in those with HCV genotypes other than 1.

Ribavirin. combination interferon–ribavirin therapy is the treatment of choice. Initial responses during therapy and sustained responses after therapy are achieved most frequently by *combining* interferon with the nucleoside analogue ribavirin (1,000 mg by mouth once a day for patients weighing less than 75 kg and 1,200 mg/d for patients weighing 75 or more kg). Although ribavirin monotherapy is ineffective, the combination administered for a year can yield sustained response rates of 40%. Sustained responses are even more likely for patients with low viral loads and HCV genotypes other than 1; in fact, in this subgroup, 6 months of therapy is just

as effective as a year and need not be extended for the full year. Therefore, in the absence of contraindications (coronary artery disease, cerebrovascular disease, anemia, pregnancy, etc.; see below), combination interferon–ribavirin represents first-line therapy for chronic hepatitis C.

Interferon–ribavirin combination therapy is also effective in patients who relapsed after a course of interferon monotherapy, achieving a sustained response rate in 50%. Combination therapy, however, has been disappointing in nonresponders to interferon therapy.

Side effects of combination interferon–ribavirin therapy are similar to those for interferon alone (see above), but ribavirin can cause *hemolysis*, mild in most cases but severe and brisk in an unpredictable proportion of patients. Therefore, combination therapy is *contraindicated* in patients who cannot tolerate anemia, including patients who are already anemic and those with, or with risk factors for, coronary artery disease or cerebrovascular disease, in whom anemia can result in a life-threatening ischemic event. Because ribavirin is renally excreted and teratogenic, the drug is *contraindicated* in patients with renal insufficiency and during *pregnancy* (birth control should be used in fertile patients who take ribavirin).

Monitoring and Follow-up. In patients taking ribavirin, monitoring for hemolysis is carried out by attention to the *complete blood count*, supplemented when suspicion is high by the *reticulocyte count*. During treatment, quantitative HCV RNA should be checked periodically; an undetectable level at 1 month may portend an ultimate sustained response, but most treating physicians will test HCV RNA at 3 months for patients undergoing a 6-month course and at 6 months for patients undergoing a 12-month course. If HCV RNA remains detectable at these landmarks, the likelihood of achieving a response during treatment is low. Whether to continue treatment under these circumstances is still debated. Finally, HCV RNA should be repeated at the end of therapy to document a complete end-treatment response, and in those with an end-treatment response, HCV RNA testing should be repeated intermittently over the next 6 months to document a sustained response. The need for and value of *repeat liver biopsies* at regular follow-up intervals are controversial. After the initial biopsy, which is necessary to initiate therapy, many authorities make subsequent decisions about duration and direction of therapy based on clinical and biochemical responses without reliance on liver histology.

Liver Transplantation is indicated for those with end-stage decompensated chronic hepatitis C. Although reinfection of the allograft is universal, its clinical impact on the new liver is negligible in most cases over the early years after transplantation, and antiviral therapy with interferon and ribavirin has the potential to limit the impact of reinfection considerably.

Nonviral (Autoimmune or Idiopathic) Chronic Hepatitis. Approaches to therapy of nonviral and viral types of chronic hep-atitis are distinctly different. In nonviral disease, histology plays a predominant role in determining prognosis, and immunosuppression is an important treatment modality in severe cases.

In *mild asymptomatic autoimmune* and idiopathic forms of chronic hepatitis, the prognosis is excellent. *No treatment*, beyond simple symptomatic relief, is indicated. Long-term high-dose immunosuppressive therapy (e.g., with prednisone) is not indicated because the high probability of adverse effects (see Chapter 105)outweighs any potential benefit. More randomized controlled trials are needed to better define the efficacy of other forms of immunosuppressive therapy in such patients.

Moderate-to-severe chronic nonviral hepatitis tends to be a more serious and progressive disease. Severe cases have been shown to respond to *immunosuppressive–anti-inflammatory* therapy (*prednisone/azathioprine*). However, only 15% to 20% of patients with autoimmune or idiopathic chronic hepatitis fulfill criteria for severe disease. The need for and efficacy of immunosuppressive therapy in symptomatic patients with less severe disease remains unknown.

Prednisone/Azathioprine. Immunosuppressive–antiinflammatory therapy using *high-dose prednisone* alone or the combination of *reduced-dose prednisone* plus *azathioprine* produces clinical, biochemical, and histologic resolution in 80% of persons with severe disease and significantly reduces mortality. Histologic remission to mild hepatitis or to normal occurs within 6 to 36 months. In the prednisone-only regimen, treatment begins at 60 mg/d, and the dose is reduced over the course of a month to a maintenance level of 20 mg/d. Promising results have been obtained with lower dose corticosteroid-only regimens in which the high-dose phase is omitted, but confirmation is needed. The combination regimen is initiated with 30 mg/d prednisone combined with 50 mg/d azathioprine. The azathioprine dose remains constant, whereas the prednisone dose is reduced over the course of the first month to a maintenance level of 10 mg. Neither azathioprine alone nor alternate-day prednisone therapy has been found to be effective as alternative regimens.

Adverse Effects. About two thirds of patients treated with high-dose steroids alone experience severe steroid complications (see Chapter 105), compared with fewer than 20% of those treated with prednisone plus azathioprine. Azathioprine-induced *bone marrow suppression* may occur in patients receiving the combination-therapy regimen, necessitating close monitoring. Occasionally, unacceptable drug toxicity, intolerable gastrointestinal upset, compression fractures, or failure to respond necessitates premature cessation of therapy.

Duration of Therapy. Therapy is continued until there is objective evidence of remission (i.e., a fall in *aminotransferase activity* to a level under twice normal and improvement in *morphologic features* of chronic hepatitis). Although aminotransferase levels do not always reflect histologic activity absolutely faithfully, such biochemical monitoring has been documented to be valuable and a satisfactory substitute for repeat invasive biopsies. In responsive cases, symptoms improve within 6 months, aminotransferase levels within 12 months, and histology within 24 months. Rarely, more than 36 months are necessary to achieve remission. After 4 years, the likelihood of drug-induced complications becomes greater than the likelihood of beneficial drug effect. Nevertheless, some patients cannot be weaned from maintenance treatment and require indefinite continuation of therapy.

Once remission is achieved, therapy is discontinued by gradual tapering of prednisone over 6 weeks. Patients are monitored closely for signs of relapse, which occur in 50% of patients. Relapse is especially common in patients with cirrhosis, often necessitating prolonged therapy for many years or multiple courses of treatment. Approximately 20% of patients fail to respond to conventional doses but may respond to higher doses. Relapses usually occur early. If remission lasts more than 6 months after cessation of therapy, relapse is less likely. Most cases of relapse are accompanied by symptoms and biochemical abnormalities, but in 10% of cases, the only sign of relapse is a change in histology. After relapse, 80% of patients respond again to reinitiation of therapy. After cessation of therapy, again, the relapse rate is 50%. The likelihood of relapse after combination prednisone-azathioprine therapy may be reduced by maintenance azathioprine monotherapy after steroid withdrawal.

Monitoring and Follow-up. In nonviral disease, patients with *mild* chronic hepatitis may be followed casually, but those who are symptomatic deserve careful monitoring and periodic reassessment to be sure there are no signs of progression. When *severe* chronic disease has been identified, very close follow-up monitoring is vital. If prednisone and azathioprine are used, weekly and later monthly *platelet and white blood cell counts* are required. *Aminotransferase, bilirubin*, and *gamma globulin* levels ought to be obtained at 2 weeks and then every 1 to 3 months to monitor response and to identify treatment failure. Patients with mild-to-moderate chronic disease who do not receive therapy should be monitored in similar fashion and biopsied again if symptoms or biochemical tests worsen.

Transplantation. For patients with end-stage disease who have sustained a life-threatening complication, referral to a liver transplantation center is an appropriate consideration (see below).

INDICATIONS FOR REFERRAL AND ADMISSION

Referral

Prompt consultation is indicated in most patients with fulminant or severe forms of hepatitis, whether viral or nonviral, because treatment decisions are difficult and increasingly effective antiviral and immunosuppressive therapies are becoming available.

Viral Hepatitis. Referral is indicated for consideration of liver biopsy when prognostic information or confirmation of disease severity is needed. Examples include patients with acute viral hepatitis B or C who fail to show signs of recovery within 6 months and who were not treated at the time of initial diagnosis and those with progressive or severe cases of chronic hepatitis B or C who might be candidates for antiviral therapy. It is particularly important to obtain help from a hepatologist, gastroenterologist, or pathologist experienced in interpreting biopsy material obtained from patients with chronic hepatitis; diagnosis depends on histologic appearance and can be difficult.

Autoimmune and Idiopathic Chronic Hepatitis. Referral for biopsy to confirm the diagnosis is indicated for patients with suspected autoimmune or idiopathic chronic hepatitis (e.g., hyperglobulinemia, autoantibodies).

Admission

Admission to the hospital is indicated for *worsening mental status, bleeding, refractory ascites*, or *poor home environment*. When decompensation does not respond readily to medical therapy, then referral to a *liver transplantation center* is indicated. Spontaneous or recurrent hepatic encephalopathy, wasting, refractoryascites, variceal bleeding, and spontaneous bacterial peritonitis are among the indications for transplantation in patients with chronic liver disease. Given the long waiting time for a donor liver, patients should be referred as early as possible for transplantation candidacy evaluation.

PATIENT EDUCATION

Hepatitis often affects previously vigorous people accustomed to full activity. The prolonged course and magnitude of malaise commonly precipitate a reactive depression. Thorough explanation of the disease's course, design of a sensible treatment program that actively involves the patient and family, and close follow-up can maximize compliance and minimize depression.

Instruction concerning diet and activity is central to a comprehensive treatment program. In particular, it is important to prevent unnecessary restriction of activity and to ensure adequate nutrition. Patients can be told to do as much as they feel like doing, as long as they avoid overtiring themselves. Small frequent meals, especially in the morning, are tolerated best. Foods do not need to be restricted, but carbohydrates seem to be the best-tolerated food when nausea is pronounced. Alcohol should be proscribed. Today, many patients with hepatitis take "alternative" therapies of no proven benefit. Most of these preparations are harmless, but some can actually injure the liver. Although patients should be discouraged from taking these substances, such warnings often fall on deaf ears.

Patients and household members have many questions regarding transmissibility of viral hepatitis. Explicit instructions regarding preventive measures are greatly appreciated (see Chapter 57). Of particular concern is sexual activity, especially for young persons who might want to have children. In hepatitis B, the risk of transmission by sexual intercourse is high, but prophylaxis with hepatitis B immune globulin and vaccine reduces the risk in the patient's sexual partner. In hepatitis C, the risk of sexual transmission is negligible, especially between monogamous stable sexual partners, making it possible to allow unprotected intercourse for purposes of conception.

THERAPEUTIC RECOMMENDATIONS(SEE CHAPTER 57 FOR PROPHYLACTIC MEASURES)

Acute Viral Hepatitis

- Maintain adequate caloric intake and a balanced diet. Small feedings are tolerated best, especially in the morning. No foods need to be restricted.
- Ensure adequate rest, but activity does not need to be unduly restricted if the patient feels capable of it.
- Omit potentially hepatotoxic agents, especially alcohol.
- Treat severe pruritus with cholestyramine.
- Treat severe nausea and vomiting with a nonphenothiazine antiemetic, such as trimethobenzamide (Tigan) suppositories.
- Admit the patient to the hospital if signs of marked worsening of hepatocellular function occur (e.g., encephalopathy, bleeding, prolongation of prothrombin time). Also consider admission for maintaining adequate caloric and fluid intake when symptoms are severe or for managing complicated underlying diseases.
- Refer patients with fulminant hepatitis for consideration of liver transplantation. In cases of hepatitis B, a trial of lamivudine may be considered but should not interfere with evaluation for transplantation.
- For patients with acute hepatitis C, therapy with interferon plus ribavirin should be initiated as soon as possible.
- Check aminotransferase, prothrombin time, bilirubin, albumin/globulin, and HBsAg at onset and at 12 weeks; aminotransferase levels should be monitored at 1- to 4-week intervals during acute illness. Retest any patient with evidence of persistent symptoms or laboratory abnormalities every 4 weeks. Refer for liver biopsy those with a combination of failure to resolve infection and inflammation by 6 to 12 months and persistence of disabling symptoms.

Drug-induced Hepatitis

- Stop all drugs that might be responsible and institute supportive measures.
- Avoid rechallenging the patient with the same agent.

Nonviral Chronic Hepatitis

- Follow patients with *mild* chronic hepatitis at regular intervals and rebiopsy if there are signs of marked worsening. Otherwise treat symptomatically. Steroids are not indicated.
- For patients with *severe* chronic hepatitis (multilobular or bridging necrosis, disabling symptoms, and marked aminotransferase and globulin elevations), begin high-dose *prednisone* (60 mg/d) or combination prednisone (30 mg/d) plus *azathioprine* (50 mg/d). Combination therapy is preferred for the elderly, diabetics, and others who cannot tolerate long-term high-dose steroids. Because of the impact of azathioprine on fertility, this drug should be avoided, if possible, in young adults who are planning to raise families.
- Taper prednisone by 5 to 10 mg at a time over the course of a month until a maintenance dose of 10 mg/d (with 50 mg/d azathioprine) or 20 mg/d is established.
- Monitor aminotransferase, bilirubin, and globulins at 2 weeks and then every 1 to 3 months. If the patient is taking azathioprine, obtain platelet and white cell counts at weeks 1 and 2 and then monthly thereafter.
- Continue maintenance therapy for at least 24 to 36 months and then consider attempting discontinuation of therapy with a 6-week period of tapering medication.
- Obtain a consultation if there is failure to achieve clinical improvement within 2 to 8 months of initiating therapy; high-dose treatment may be indicated.
- Treat relapses in the same manner as new cases.

Chronic Viral Hepatitis

- Avoid immunosuppressive therapy in patients with chronic viral hepatitis.
- Consider *interferon alfa* in patients with compensated chronic hepatitis B who demonstrate sustained presence of HBV DNA and HBeAg. If deemed appropriate by a consultant, begin a 16-week course of 5 million units administered subcutaneously daily or 10 million units every other day.
- Most authorities would choose, instead of interferon, to consider lamivudine therapy for chronic "replicative" hepatitis B. Treatment consists of 100 mg daily by mouth for 12 months. Therapy can be stopped in patients who lose HBeAg; in those who retain HBeAg, therapy may need to be prolonged.
- Treat patients with compensated chronic *hepatitis C* who manifest sustained elevations of aminotransferase and detectable HCV RNA with *interferon* at a dose of 3 million units subcutaneously three times a week plus oral ribavirin at a daily dose of 1,000 mg (for those weighing less 75 kg) or 1,200 mg (for those weighing 75 or more kg) for a full year. In patients with genotypes other than 1 and with a low viral load (less than 2 million viral copies), a 6-month course of therapy may suffice. For patients who relapse whenever therapy is stopped and for nonresponder patients, long-term maintenance therapy is a consideration, currently being evaluated in clinical trials.
- Consider *interferon alfa* for patients with *hepatitis D*. Long-term high-dose therapy (as much as 9 million units three times a week for a year) is required. Some patients may benefit from indefinite maintenance therapy.
- Monitor patients receiving interferon by checking leukocyte, granulocyte, and platelet counts at weeks 1, 2, and 4 and monthly thereafter. Check aminotransferase levels monthly and thyroid-stimulating hormone every 1 to 3 months. In patients with hepatitis B treated with interferon or with lamivudine, monitor HBV DNA monthly to every few months and measure HBeAg periodically and at the end of therapy. In patients being treated for hepatitis C, monitor HCV RNA at approximate intervals of 3 months. Those receiving ribavirin need close monitoring of hematocrit/hemoglobin.
- Admit the patient to the hospital when there is evidence of marked worsening of hepatocellular function. Consider liver transplantation for patients with hepatic decompensation.

CHAPTER 71 MANAGEMENT OF CIRRHOSIS AND CHRONIC LIVER FAILURE

Cirrhosis represents an irreversible state of chronic liver injury. The best treatment is *prevention*, detecting and addressing conditions that can lead to it, including *chronic hepatitis, chronic alcohol abuse, hemochromatosis, and primary biliary cirrhosis* (see Chapter 57, Chapter 70, and Chapter 228). Even after its onset, the patient can be kept comfortable, active, and independent if precipitants of further hepatocellular injury are eliminated and complications are prevented or treated promptly. Although consultative help from specialists is often necessary, responsibility for long-term management usually rests with the primary care physician. One needs to be capable of treating etiologies and dealing with such complications as ascites, peripheral edema, encephalopathy, infection, bleeding, renal dysfunction, and electrolyte imbalances.

CLINICAL PRESENTATION AND COURSE

Clinical Presentation. Onset may be rather dramatic if the initial presentation is a late-stage complication such as brisk *variceal bleeding* or *encephalopathy*. In the office setting, the patient may present more subtly with complaints of *fatigue*, easy *bruising*, mild abdominal *swelling*, or new onset of bilateral *ankle edema*. In the setting of portal hypertension, splenomegaly, abdominal distention with *shifting dullness*, and a prominent *abdominal venous pattern* may become significant. Additional signs of chronic hepatic dysfunction include *palmar erythema, Dupuytren's contractures, spider angiomata, parotid and lacrimal gland hypertrophy, gynecomastia, testicular atrophy*, loss of *axillary* and *pubic hair*, and *clubbing*. Although nonspecific abnormalities in routine liver function tests are common, the best measures of hepatocellular synthetic impairment are prolongation of the *prothrombin time* (PT) and decline in the *serum albumin*. PT prolongation occurs first, because of the short serum half-lives of the hepatically synthesized clotting factors (e.g., 7 days) that determine it. The decline in serum albumin follows later because of the longer serum half-life of albumin (28 days).

Most presentations of cirrhosis and chronic hepatic failure are nonspecific, but the initial manifestations of a few treatable etiologies are worth noting because of the potential benefit of early recognition and treatment.

Hemochromatosis. *Primary hemochromatosis* is among the most common of autosomal hereditary conditions, having an estimated prevalence of 1:250 among whites. The mutation causes excessive iron absorption, resulting in iron overload. Decades of chronic iron deposition in parenchymal cells of the liver, heart, pancreas, and gonads eventually produce organ failure as cells suffer peroxidative damage; fibrosis ensues. Initially, the patient may be asymptomatic or incidentally noted to have a mild elevation in serum transaminase level. Mild *fatigue* or *arthralgias* might be the first symptoms. By the fifth or sixth decade, organ failure begins to appear, heralded by *dyspnea, glucose intolerance, arthritis*, and *gonadal dysfunction* and by manifestations of *cirrhosis* and chronic hepatocellular dysfunction. The skin might appear slate gray or *bronzelike* from the chronic iron deposition. Early diagnosis of the homozygous state is achieved by finding a *transferrin saturation* (serum iron/total iron binding capacity) more than 60% in men and more than 50% in women. A ferritin level more than twice normal for age and gender (e.g., more than 300 µg/L in men, more than 200 µg/L in women) indicates iron overload. At this stage, liver biopsy is indicated to determine the extent of iron deposition, degree of hepatic fibrosis, and need for initiation of therapy.

Primary Biliary Cirrhosis. The condition predominates in women aged 30 to 65 years. Autoimmune injury of the intrahepatic biliary tree leads to chronic *cholestasis* and culminates in fibrosis, *cirrhosis, portal hypertension*, and *severe pruritus*. Other autoimmune diseases may coexist with the condition (e.g., *Sjögren's syndrome, Hashimoto's thyroiditis*). *Fatigue* and *itching* are often the initial complaints. *Hepatomegaly* may be the first physical finding, and a markedly *elevated alkaline phosphatase* is the the principal laboratory abnormality before onset of manifestations associated with cirrhosis. *Hyperlipidemia* is common. *Jaundice* with skin excoriations accounts for the initial presentation in about one fourth of patients. The sedimentation rate is markedly elevated; liver function tests reveal a cholestatic pattern. *Steatorrhea* may ensue, compromising absorption of fat-soluble vitamins. *Antimitochondrial antibody* is found in about 90% of cases, and *IgM antibody titers* are elevated. Diagnosis is made by *liver biopsy* with staining for copper that reveals characteristic interlobular ductal inflammation and fibrosis.

Alcoholic Liver Disease. Early hepatic injury may be manifested by mild elevations in aminotransferase levels. A ratio of 2:1 for alanine aminotransferase/aspartate aminotransferase is characteristic of alcoholic liver injury. A palpable liver from *fatty infiltration* is another early presentation. Risk factors for development of cirrhosis include prolonged consumption of *excess alcohol* (e.g., more than 16 oz/d for 10 years or more), *female sex*, and concurrent *viral hepatitis C* infection. Simultaneous use of *acetaminophen* (even at normal doses) and excess alcohol increases the risk of liver injury, especially when the patient is fasting. *Gastritis* and *upper* gastrointestinal (*GI*) bleeding are common consequences of alcohol excess and may be presenting manifestations.

Chronic Hepatitis (see Chapter 70)

Clinical Sequelae. *Portal hypertension, fluid retention*, and *encephalopathy* are the major sequelae of cirrhosis; they lead to *varices, ascites, hypersplenism, peripheral edema*, and *altered mental status*. Variceal bleeding occurs in 20% to 30% of all cirrhotic patients: one third may die during the initial hospitalization, one third rebleed within 6 weeks, and one third survive 1 year or more. The principal causes of death in patients with cirrhosis are variceal bleeding, encephalopathy, and infection. In addition, patients with cirrhosis, especially those with chronic hepatitis B infection, are at increased risk for hepatocellular carcinoma.

Prognosis is determined by the nature, severity, and activity of the underlying illness. The traditional prognostic indicator, the Pugh modification of the *Child-Turcotte prognostic classification*, is widely used to semiquantitatively estimate risk of invasive interventions (Table 71.1). A newer approach to predicting survival uses a discriminant function (DF) based on the serum bilirubin and PT (DF = 4.6 [PT - control] + bilirubin [mg/100 mL]). An ADF greater than 32 indicates a short-term mortality risk of 35%.

CLINICAL FEATURE	CLASS		
	1	2	3
Encephalopathy grade	0	1–2	3
Ascites	None	Slight	Moderate
Bilirubin (mg/dL)	1–2	2–3	>3
Albumin (g/dL)	>3.5	2.8–3.5	<2.8
Prothrombin time prolongation (s)	1–4	5–6	>6

Adapted from Pugh RN, Murray-Lyon IM, et al. Transection of the oesophagus for bleeding oesophageal varices. Br J Surg 1973;60:646-649, with permission.

Table 71.1. Child-Pugh Classification of Hepatic Decompensation

Prognosis in a few common causes of cirrhosis is illustrative of the basic determinants of cirrhosis and survival. Continued alcohol consumption in the context of alcoholic hepatitis is associated with an 80% chance of developing cirrhosis, whereas complete abstinence lowers the risk to 15%. Even after *alcoholiccirrhosis* has developed, survival continues to be affected by alcohol ingestion. Five-year survival is 60% to 85% in those who abstain, compared with 40% to 60% for those who continue to drink. Onset of jaundice or ascites further decreases 5-year survival (to 30% in drinkers). In symptomatic *primary biliary cirrhosis*, the average length of survival from the onset of symptoms is about 12 years, whereas the survival of asymptomatic patients did not differ from that of a control population matched for age and sex. The prognosis of patients with *postnecrotic cirrhosis* is difficult to assess because it is hard to date its onset; the cirrhosis develops insidiously over years

from subclinical chronic active hepatitis.

Irrespective of etiology, development of ascites, encephalopathy, hyperbilirubinemia, variceal bleeding, hypergammaglobulinemia (from bypass of the hepatic reticuloendothelial system), and hypoalbuminemia are poor prognostic signs, as is decreased liver size. Onset of ascites is associated with a 50% 2-year mortality rate, and variceal bleeding has a 35% short-term mortality rate. The 2-year mortality for worsening renal function is 33%.

PRINCIPLES OF MANAGEMENT

Treatment of the underlying etiology and the manifestations and complications of cirrhosis and chronic hepatic failure constitute the basic elements of management. Outcomes can be improved when all elements are addressed in the treatment program.

Treatment of the Underlying Etiology

Alcoholic Cirrhosis requires complete *abstinence* from further alcohol intake (see Chapter 228), because prognosis is markedly worsened by continued drinking (see above). Attention to good nutrition, daily multiple vitamin supplements (including 1 mg of folic acid), and correction of any iron deficiency or electrolyte deficits are important supportive measures. The search continues for agents that might halt hepatic fibrosis and promote hepatocyte regeneration. Glucocorticosteroids and portacaval shunting have failed to demonstrate an improvement in survival, although cortico-steroids do improve short-term survival in patients with acute alcoholic hepatitis. A randomized, placebo-controlled, long-term study of *colchicine* revealed a doubling of 5- and 10-year survival. The drug is an inhibitor of collagen deposition. However, confirmatory data are needed before it or other drugs found experimentally to improve survival (e.g., *propylthiouracil*) can be recommended. *Liver transplantation* is sometimes considered in patients who have become totally and permanently abstinent.

Primary Biliary Cirrhosis used to be thought of as a relentlessly progressive autoimmune disease leading to liver transplantation or death. Medical therapy now appears capable of altering this dismal prognosis. *Ursodiol*, which is well tolerated, may stabilize the disease and even improve survival. *Colchicine* provides some biochemical improvement, but the survival benefit is unclear. *Methotrexate* appears very promising in persons unresponsive to ursodiol or colchicine alone, achieving histologic, biochemical, and clinical remissions when added to the treatment program in selected patients. Corticosteroids and penicillamine do not improve survival and cause serious adverse side effects. *Liver transplantation* has proven to be a viable option.

Severe pruritus associated with this condition can be relieved by *cholestyramine* in a dose of 4 g orally with meals. Refractory pruritus responds to opiate antagonists. Because of decreased fat absorption from low intestinal bile-salt concentrations, these patients are particularly prone to develop deficiencies of the *fat-soluble vitamins*. They may require supplemental vitamin K (10 mg SC every 4 weeks), vitamin D (50,000 U orally two to three times a week or 100,000 U intramuscularly every 4 weeks) with oral calcium (1 g daily), and vitamin A (25,000 U orally per day). Night blindness unresponsive to vitamin A may be due to zinc deficiency, which is treated with oral *zinc sulfate* (220 mg/d). For patients with steatorrhea, *medium-chain triglyceride* preparations often help.

Secondary Biliary Cirrhosis can be halted by relieving or bypassing the obstruction to bile flow (see Chapter 62).

Hemochromatosis is treated with weekly *phlebotomies* of 500 mL until the serum iron and ferritin levels fall to normal; then, phlebotomies are performed as needed based on serum ferritin levels. Early recognition and timely initiation of treatment are essential to minimizing the chance of developing cirrhosis. Repeated studies have shown that iron removal by phlebotomy improves survival and decreases morbidity and may lead to normal life expectancy if started before onset of cirrhosis or diabetes. Unfortunately, delay in diagnosis and treatment are common, underscoring the importance of early recognition (see above).

Chronic Hepatitis of the nonviral variety may benefit from *corticosteroid/azathioprine* therapy; viral hepatitis responds to *interferon alfa* plus *ribavirin* (see Chapter 70).

Wilson's Disease responds to *d-penicillamine* therapy, which should be administered in conjunction with a hepatologist experienced in using the drug, because of its potential for serious side effects.

Treatment of Complications

Ascites and Edema result from increased portal pressure, hypoalbuminemia, secondary hyperaldosteronism, and im-paired free water clearance. Its presence is strongly suggested by the clinical findings of a *fluid wave, shifting dullness*, and *peripheral edema*. Abdominal ultrasound can be used for confirmation and to rule out venoocclusive disease involving the hepatic veins or the hepatic region of the inferior vena cava (Budd-Chiari syndrome). Although ascites is not a hazard, gross ascites can cause abdominal discomfort and respiratory compromise; under such circumstances, it should be treated.

Diagnostic Paracentesis is indicated before treatment is initiated in patients with new onset of ascites, worsening hepatic function, fever, or increasing encephalopathy to exclude infection and malignancy. Although it was once believed that differentiating exudative from transudative ascitic fluid could aid in identifying infection and malignancy, such a differentiation has proven insufficiently sensitive and specific to be reliable. Fluid protein concentrations in excess of 2.5 g/dL are seen not only in conditions causing exudates but also in patients with transudative processes subjected to diuresis. Moreover, the ascitic fluid protein concentration of patients with spontaneous bacterial peritonitis is typically less than 1 g/dL. However, the *serum-to-ascites albumin gradient* (serum albumin concentrationminus the ascites albumin concentration) can help differentiate portal hypertension from other causes of ascites, especially when the ascitic protein concentration is high. A gradient of greater than 1.1 mg/dL is indicative of portal hypertension; ascites in the presence of a gradient less than 1.1 suggests a mechanism other than portal hypertension. Ascitic fluid should also be sent for cytologic examination, cell count, and culture. A leukocyte count in excess of 2,500/mL is strongly suggestive of spontaneous bacterial peritonitis in the patient with abdominal pain and fever. Culture is positive in over 80% of cases when 10-mL aliquots are injected into three blood culture bottles; Gram stain is usually negative.

Salt and Fluid Restrictions. A reduction in daily sodium intake is the first priority in treating ascites due to portal hypertension. One begins with a *2-g sodium diet*, a reasonable compromise between maximizing sodium restriction and dietary palatability. Adequate nutrition is critical. In the absence of encephalopathy, a daily protein intake of at least 50 g is recommended. Excessive water intake should be prohibited, and *free water* should be restricted to 1,500 mL/d if hyponatremia ensues. An effective program of salt and water restriction requires a cooperative patient and a conscientious family. A dietitian can provide invaluable assistance. The patient should be instructed to check weight daily. Measuring abdominal girth is an unreliable index of fluid loss because of variations due to gaseous distention of the GI tract. About 15% of patients will respond to sodium and fluid restrictions alone. Bedrest is of no added benefit.

Diuretic Therapy is indicated if a diuresis has not occurred spontaneously after a full week of salt restriction. *Spironolactone* is the agent of first choice, because it inhibits the hyperaldosteronism of portal hypertension. Being a specific aldosterone antagonist, it counters the hypokalemic alkalosis commonly seen in cirrhotic patients with ascites. Its diuretic action is mild and unlikely to cause rapid intravascular volume depletion. The initial dosage of spironolactone is 100 mg/d orally in divided doses. If diuresis does not follow within 1 week, the daily dosage may be increased by 100 mg every 4 or 5 days to a maximum of 400 mg daily (higher doses may cause hyperkalemic acidosis). It is useful to monitor urinary electrolyte concentrations, because diuresis should follow a significant rise in urinary sodium and a fall in urinary potassium. If natriuresis and diuresis do not occur on a maximal dosage of spironolactone, a loop diuretic such as *furosemide* (starting at 20 to 40 mg/d) may be added. *Bumetanide or metolazone* may be added to the diuretic program, but such potent diuretics must be used with extreme care to avoid precipitating renal failure, hypokalemia, and encephalopathy.

Monitoring blood urea nitrogen, creatinine, and electrolytes is critical during treatment of ascites. However, some cirrhotic patients with renal impairment do not manifest an elevated serum creatinine (believed related to reduced creatine synthesis by the liver). This reduces the sensitivity of the serum creatinine in some cirrhotic patients and can complicate monitoring of their renal status. Other measures of renal function may be required.

The maximum amount of ascitic fluid that can be mobilized in 24 hours is about 700 to 900 mL, although peripheral edema can be mobilized at a faster rate. This translates to a daily weight loss of 0.5 kg in patients with ascites alone and of 1 kg in those with both ascites and peripheral edema. Daily weight loss in excess of these amounts suggests overdiuresis, with its attendant risk of intravascular volume depletion leading to hepatorenal syndrome and encephalopathy. A falling urine output accompanied by orthostatic signs (rise in pulse and fall in blood pressure on change from supine to standing) suggests inadequate intravascular volume. An oral fluid challenge of several hundred milliliters of isotonic fluid can confirm the presence of hypovolemia by inducing a temporary increase in urine output.

Refractory Ascites. Some patients with incapacitating ascites are *truly refractory* to sodium restriction and diuretics. For them, *large-volume paracentesis* and *peritoneovenous (LeVeen) shunting* become therapeutic considerations. Removal of more than 1 to 2 L of ascitic fluid at a time by paracentesis was once considered

to be unwise, because of the risk of precipitating serious intravascular volume depletion from the shift of intravascular fluid into the emptied peritoneal cavity. Moreover, protein depletion and increase in renin activity and aldosterone secretion might ensue. By infusing *albumin* intravenously (6 to 8 g/L of ascitic fluid removed) at the time of paracentesis, large volumes (5 to 6 L) of ascitic fluid can be removed without precipitating adverse reactions. Results are comparable with those achieved by shunting procedures, although admissions for reaccumulation of fluid are more frequent (every 10 to 30 days). The best candidates are those with peripheral edema and relatively well-preserved renal function.

Before the development of large-volume paracentesis, peritoneovenous (LeVeen) shunting was the principal means of dealing with refractory ascites. Although effective in treating ascites, shunt placement does not improve survival. Moreover, insertion can precipitate disseminated intravascular coagulation. Infection and shunt obstruction are common complications. Compared with large-volume paracentesis, LeVeen shunting requires fewer readmissions for treatment of ascites but an overall similar number of hospitalizations due to shunt occlusions. Its potentially serious complications and the advent of large-volume paracentesis has led to a decline in use of Le Veen shunts. Refractory ascites has also been treated with placement of a *transjugular intrahepatic portosystemic shunt (TIPS)*. Although helpful in some persons and successful in decreasing portal pressure, the procedure increases the risk of encephalopathy and carries its own procedural morbidity and mortality (see below).

Spontaneous Bacterial Peritonitis develops in about 10% of ascitic patients per year. Risk is especially great if the total protein concentration of the ascitic fluid falls below 1.0 g/dL. Under such circumstances, primary antibiotic prophylaxis (e.g., *trimethoprim-sulfamethoxazole*, one double-strength tablet every 5 of 7 days/wk) is worth considering. Secondary prophylaxis is indicated in those with a prior episode.

Hepatic Encephalopathy is thought to be produced by one or more intestinally derived toxic substances that escape hepatic detoxification as a result of portasystemic shunting and hepatocellular dysfunction. Candidates include ammonia, benzodiazepine-like substances, mercaptans, phenol, neuroinhibitors, false neurotransmitters, and short-chain fatty acids. Elevations of arterial and venous *ammonia levels* usually, but not always, correlate with the presence of hepatic encephalopathy. Venous levels may be falsely elevated when a tourniquet is left on too long at the time of blood drawing. Ammonia levels are useful in following the clinical state of individual patients. Mild encephalopathy may be managed on an ambulatory basis.Patients should also be monitored with routine mental status examinations that include five-point star and signature testing and examination for asterixis.

Treating Precipitants. The first goal of treatment is to address the major precipitants. Important precipitating factors include GI bleeding; excessive dietary protein intake; hypokalemic alkalosis; infection; constipation; use of sedative, opiate, or hypnotic drugs; surgical procedures; and volume depletion resulting from diuresis or paracentesis. Precipitants are identified in about 50% of patients; the prognosis is usually better in those with an identifiable contributory factor than in those in whom the onset of encephalopathy is associated only with worsening hepatocellular function.

Reducing Ammonia Production. The mainstay of therapy is restriction of dietary protein intake to 30 to 40 g/d while maintaining a daily caloric intake of 1,500 kcal. Controlled trials support dietary protein restriction and substitution of animal protein with vegetable sources; their metabolism produces less ammonia. Sometimes, oral *amino acid supplements* (high in branched-chain varieties and low in aromatic amines) are added to prevent negative nitrogen balance and to reduce production of false neurotransmitters. Their efficacy in treatment of encephalopathy appears to be transient. Simple gut cleansing with enemas or cathartics is effective when bleeding, constipation, or a large dietary protein intake has led to encephalopathy. *Lactulose* (a synthetic nonabsorbable disaccharide metabolized to organic acids by enteric bacteria) causes an osmotic catharsis and also suppresses the growth of ammonia-forming urease-producing bacteria in favor of lactose-fermenting organisms. The initial dosage for patients with mild encephalopathy is 15 to 30 mL orally every 4 to 6 hours, with adjustments thereafter to produce two to three loose stools a day. Side effects of oral lactulose include diarrhea and abdominal distress, which usually resolve after a reduction in dosage.

Use of poorly absorbed antibiotics to decrease the intestinal concentration of ammonia-forming bacteria is a proven approach to treating encephalopathy. *Neomycin*, a poorly absorbed broad-spectrum aminoglycoside antibiotic, is about as effective as lactulose, but prolonged use of doses in excess of 4 g/d (especially in patients with renal insufficiency) may lead to ototoxicity and nephrotoxicity. The recommended maximum oral dose is 1 g twice daily. The drug also causes malabsorption. In patients who fail to respond to either lactulose or neomycin, the two may be given together; in some patients, the effect appears to be additive. *Metronidazole* (800 mg/d for 1 week) may be used instead of neomycin; when used for short periods, it is less toxic. Eradication of *Helicobacter pylori* is meeting with some initial success in uncontrolled studies, presumably because of its contribution to ammonia production (being a urea-splitter). Repopulating the colon with nonurease-producing organisms, such as *Lactobacillus acidophilus*, has been tried with variable success; *Enterococcus faecium* use has been more promising.

Improving Ammonia Metabolism. Dietary supplements of *ornithine aspartate, benzoate, and phenylacetate* are thought to increase ammonia metabolism, and available studies are encouraging, with benefits approaching those seen with lactulose in persons with mild encephalopathy. Zinc, a required cofactor of several enzymes of the urea cycle, is often deficient in cirrhotics. Treatment of zinc deficiency with 600 mg/d of zinc supplement has been helpful in some but not all controlled trials of this element.

Reducing False Transmitters. The restriction of aromatic amino acids and use of preparations rich in branched-chain amino acids is based on the hypothesis that such an approach reduces production of false neurotransmitters. Results of controlled trials are equivocal at best. Nitrogen balance may improve, but improvement in encephalopathy may be hard to come by.

Inhibition of GABA-Benzodiazepine Receptors. Although binding of ligands to this receptor is believed to be pathophysiologically important in hepatic encephalopathy, receptor antagonist therapy with flumazemil has not produced significant benefit.

Variceal Bleeding. Primary and secondary prophylaxis against bleeding are the principal concerns of the primary care physician. In patients with known varices, risk of bleeding is high. Independent risk factors include marked hepatocellular dysfunction, ascites, encephalopathy, large varices, and presence of dilated venules on the varices. Risk of a first bleed is as high as 65% in the first year. Because clinical and endoscopic risk factors are independent and therefore not predictive of one another, some authorities recommend endoscopic assessment of all cirrhotic patients to determine risk and candidacy for treatment.

Beta-blockers are useful in patients at high risk for variceal bleeding. When prescribed in dosages that produce beta-blockade (a reduction in heart rate of about 25%), these agents can lower portal venous pressure and decrease the risk of variceal bleeding by about 50%. The rate of death from hemorrhage is also reduced, but all-cause mortality is not. Although disappointing for secondary prophylaxis, beta-blockers have demonstrated efficacy for prevention of a first variceal bleed and should be considered for use in high-risk patients (large varices). Other agents are being investigated for their ability to further reduce portal pressure.

Endoscopic Injection Sclerotherapy is used to control acute variceal bleeding and, when repeated several times over 2 to 3 months, to prevent recurrences. Controlled trials have shown it to be superior to placebo in preventing repeat variceal hemorrhage but having little impact on the risk of all-cause upper GI bleeding, which remains at close to 40%. The procedure is not effective in preventing a first bleed. Addition of *octreotide* infusion to sclerotherapy reduces the short-term risk of rebleeding and transfusion requirements. The procedure has a high complication rate (up to 20%) and a mortality risk of nearly 5%. Like portasystemic shunt surgery (see below), sclerotherapy may only substitute one form of morbidity and mortality for another. Sclerotherapy largely replaced portasystemic shunt surgery, which is reserved for those who bleed despite repeated sclerotherapies and other approaches to treating varices.

Endoscopic Band Ligation of varices has been used to improve upon injection sclerotherapy. It requires fewer treatments than sclerotherapy and causes fewer complications. Outcomes are about the same; consequently, it is replacing sclerotherapy.

TIPS involves angiographic placement of a stent from a branch of the hepatic vein through the liver parenchyma and into a branch of the portal vein. It represents an increasingly effective option in persons who fail endoscopic therapy. TIPS decompresses the portal system and reduces the risk of bleeding. Stent failure occurs in up to 50% of cases and represents theprincipal cause of rebleeding. Improvements in stent design are lowering the failure rate. The procedure has a 5% mortality risk, similar to that for sclerotherapy. In a randomized controlled trial comparing TIPS with endoscopic sclerotherapy, TIPS produced a dramatic decrease in portal pressure and was superior in preventing rebleeding; however, there was no difference in survival, although a positive trend toward improved survival was noted. The major drawback to stent placement is encephalopathy or its worsening, which can be especially problematic if present before the procedure.

Portasystemic shunt surgery remains the final treatment option for patients with recurrent variceal hemorrhage due to portal hypertension. Although reducing the risk of hemorrhage, shunt surgery increases the risk of encephalopathy. The likelihood of recurrent variceal bleeding is significantly reduced after portasystemic shunting, but long-term survival is not. Reasons for lack of improvement in survival include high operative mortality rates and no benefit to hepatic function, the principal determinant of survival. Consequently, portasystemic shunt surgery is not indicated in patients with varices who have never bled. Selective shunt procedures were developed to reduce the risk of encephalopathy, a common consequence of shunt surgery. For example, the selective *distal splenorenal shunt* attempts to preserve

portal blood flow in patients with demonstrable preoperative portal perfusion. Its incidence of postoperative encephalopathy is lower than with conventional portacaval shunting, but long-term benefit is reduced as collateral channels develop. *Side-to-side portacaval or proximal splenorenal shunts* are the most effective operations for decompressing hepatic sinusoids and reducing ascites, but they still risk precipitating encephalopathy. For patients awaiting liver transplantation, TIPS can be used to bide time.

Coagulopathy results from reductions in vitamin K–dependent clotting factors (II, VII, IX, and X) secondary to decreased hepatic protein synthesis and increased plasma proteolytic activity. In addition, bile-salt deficiency, neomycin therapy, and malnutrition may contribute to malabsorption of *vitamin K*, and hypersplenism may account for thrombocytopenia. If a patient with cirrhosis is discovered to have a prolonged PT, a trial of *vitamin K*, 10 mg subcutaneously daily for 3 days, will correct hypoprothrombinemia caused by bile-salt deficiency, neomycin, or malnutrition but not hypoprothrombinemia related only to hepatocellular disease. In the absence of bleeding, measures to correct abnormal coagulation parameters are generally not indicated.

Role of Liver Transplantation. In the face of terminal hepatocellular failure, liver transplantation becomes a consideration. In properly selected patients, 5-year survival may be as high as 85%. The best candidates are those who are highly motivated, emotionally stable, and willing to comply with a medical program. Postnecrotic cirrhosis, primary biliary cirrhosis, and primary sclerosing cholangitis are among the primary indications. Alcohol-induced liver disease associated with continued drinking is a strong relative contraindication, as is hep-atitis B liver disease, hepatocellular carcinoma, and renal failure. Absolute contraindications are AIDS, extrahepatic sepsis, metastatic cancer, and severe cardiopulmonary disease. Advanced age is not a poor prognostic factor, nor is alcoholic liver disease in a person who abstains from drinking for 6 months before transplantation.

THERAPEUTIC RECOMMENDATIONS AND MONITORING

General Measures

- The patient should maintain a caloric intake of at least 2,000 to 3,000 kcal/d.
- Use of alcohol or other hepatotoxic agents must be prohibited.
- The patient should avoid tranquilizers and sedatives.
- Monitor PT, serum albumin, and bilirubin to assess the severity and progression of hepatocellular dysfunction.
- Have the patient keep a record of daily weights.
- Check stools at each visit for evidence of occult bleeding.
- Check for asterixis and other signs of encephalopathy at each visit.
- Check the abdomen for evidence of ascites (shifting dullness, fluid wave, bulging flanks). Ultrasound examination is useful to confirm the presence of ascites and rule out venoocclusive disease.

Management of Ascites

- Perform a diagnostic paracentesis in patients with the new onset of ascites or clinical deterioration in the setting of preexisting ascites. The fluid should be sent for cell count and differential, total protein and albumin concentrations, culture, and cytologic examination.
- Instruct patients with ascites to restrict daily sodium intake to no more than 2 g and to consume at least 50 g protein/d. Consult with a dietitian and provide patient and family with specific menus and food lists.
- Restrict fluid intake to 1,500 mL when there is marked hyponatremia (serum sodium concentration less than 125 mEq/L).
- If salt restriction does not result in diuresis, begin spironolactone 100 mg daily in divided doses. If natriuresis and diuresis do not occur after 1 week, increase the daily dose of spironolactone by 100 mg every 4 to 5 days to a maximum of 400 mg/d.
- If spironolactone alone is ineffective in causing diuresis, add furosemide 20 to 40 mg/d to the regimen and cautiously increase dosage as necessary.
- Adjust diuretic dose so that no more than 0.5 kg of fluid (approximately 1 lb) is lost per day in patients with ascites alone, and no more than 1 kg/d (2 lb) in those with both ascites and peripheral edema. Halt diuretics at the first sign of intravascular volume depletion.
- Consider daily potassium supplementation (20 to 40 mEq KCl elixir) in patients receiving furosemide; administer cautiously, if at all, to patients concurrently taking a potassium-sparing diuretic such as spironolactone.
- Monitor serum potassium, blood urea nitrogen, creatinine, daily weight, and postural signs to avoid inducing intravascular volume depletion, renal failure, hypokalemia, and encephalopathy. Be aware that in some patients the serum creatinine may be falsely normal and remain within normal limits despite worsening renal function.
- Consider large-volume paracentesis (5 to 6 L) with concurrent intravenous albumin infusion (6 to 8 g/L of fluid removed) for patients with refractory ascites that is disabling. Admit for the procedure.

Encephalopathy

- At the first sign of encephalopathy, restrict dietary protein intake to 20 to 30 g/d. Obtain dietary consultation to construct a diet emphasizing plant protein over animal protein. Consider use of an oral supplement rich in branched-chain amino acids if protein intake is insufficient.
- Monitor mental status and check for asterixis; use five-point star or signature testing. Monitoring venous ammonia levels is less useful; in drawing blood for a determination, avoid prolonged tourniquet application.
- When protein restriction fails to control encephalopathy, begin oral lactulose, 15 to 30 mL every 4 to 6 hours, with subsequent adjustments in the dosage to allow two to three soft stools a day. Add oral *neomycin* 1 g twice daily or *metronidazole* 250 mg three times a day if lactulose alone does not suffice. Metronidazole is probably the better tolerated for short-term use.
- Consider dietary supplementation with *ornithine aspartate, benzoate,* or *phenylacetate* in patients with mild encephalopathy.

Prevention of Variceal Bleeding and Bleeding Due to Clotting Factor Deficiency

- Begin a beta-blocker (e.g., propranolol 80 mg/day) for primary prevention in patients with risk factors for variceal bleeding (marked hepatocellular dysfunction, ascites, encephalopathy, large varices, and presence of dilated venules on the varices).
- Consider endoscopic sclerotherapy, endoscopic variceal banding, and shunt procedures (e.g., TIPS) for prevention of recurrent variceal bleeding.
- Monitor PT and platelet count. Administer vitamin K (10 mg SC daily for 3 days) if there is prolongation of PT due to drug-induced bile-salt malabsorption, neomycin, or malnutrition. Platelet transfusions are unwarranted unless there is active bleeding in the context of a very low platelet count (see Chapter 81).

INDICATIONS FOR REFERRAL AND ADMISSION

Prompt hospitalization is required for patients with GI bleeding, worsening encephalopathy, increasing azotemia, signs of peritoneal irritation, or unexplained fever. Intractable ascites may respond to elective admission for large-volume paracentesis. Decisions about the management of refractory ascites, encephalopathy, variceal bleeding, and uncommon etiologies of cirrhosis (e.g., primary biliary cirrhosis, Wilson's disease, hemochromatosis) are best made in consultation with a gastroenterologist skilled in treating liver disease. The same pertains to candidacy for liver transplantation. When urine output falls in the absence of a clearcut explanation, a nephrologic consultation may be of considerable help, especially because creatinine level may not adequately reflect renal function.

PATIENT EDUCATION AND SUPPORT

It should be emphasized to the patient and family that prognosis can often be greatly improved and symptoms lessened by careful adherence to the prescribed medical program. In particular, dietary discipline and omission of alcohol are central to a successful outcome and should be stressed. Many of these patients are chronic alcoholics with low self-esteem. A nonjudgmental sympathetic physician can be instrumental in providing support, raising self-esteem, and improving the chances of compliance (see Chapter 228). Depression is a frequent accompaniment of the later stages of chronic liver disease and is manifested by failure to comply with the medical regimen and outright expressions of wanting to die. Treatment is very difficult. Antidepressant drugs may cause oversedation and thus are risky. There are no simple measures, but the physician's concern and support can help enormously (see Chapter 227).

CHAPTER 72 MANAGEMENT OF PANCREATITIS

JAMES M. RICHTER

The primary physician encounters pancreatitis in three forms that lend themselves to ambulatory management: 1) recovery phase of acute pancreatitis; 2) chronic mild relapsing pancreatitis presenting as recurrent abdominal pain; and 3) pancreatic insufficiency, with steatorrhea and weight loss.

In the United States, most cases of pancreatitis are a result of excess ethanol ingestion or biliary tract disease, chiefly among middle-aged alcoholic men and elderly women with gallstones, respectively. A penetrating duodenal ulcer, trauma, hypercalcemia, hypertriglyceridemia, vascular insufficiency, tumor, heredity, ampullary stenosis, and drugs such as thiazide diuretics, glucocorticosteroids, azathioprine, and sulfasalazine are also associated with pancreatitis. In patients with AIDS, the risk of acute pancreatitis increases by 35 to 500 times, due in part to some of the drugs used to treat the condition and to increased risk of infection. In some cases of acute pancreatitis, no etiology is found. The course, response to therapy, and prognosis are largely functions of the etiology.

The primary physician must be able to distinguish acute pancreatitis from other causes of acute upper abdominal pain (see Chapter 58), pancreatic insufficiency from other causes of steatorrhea (see Chapter 64), and chronic abdominal pain due to pancreatitis from that due to pancreatic carcinoma and other important etiologies (see Chapter 58) and Chapter 76). Objectives of management include relief of pain, removal of precipitants, and assurance of adequate nutrition.

DIAGNOSIS, CLINICAL PRESENTATION, AND COURSE

Acute Pancreatitis

The manifestations of acute pancreatic disease are produced by inflammatory breakdown of pancreatic architecture, with release of digestive enzymes into the interstitium of the gland, leading to autolysis. Typically, acute pancreatitis produces constant epigastric, periumbilical, or left or right upper abdominal pain radiating to the back, often increased by food and decreased by upright posture. Vomiting can be persistent. Examination reveals abdominal tenderness and may include decreased bowel sounds, distention, and fever. The clinical presentation in HIV-infected patients is similar to that in immunocompetent patients but often obscured by other concurrent illnesses.

Diagnosis. The diagnosis of acute pancreatitis is supported by increases in the serum amylase and serum lipase. The *serum amylase* is elevated principally in pancreatic disease but may also be high in renal insufficiency, salivary gland disease, biliary tract obstruction, aortic dissection, and such other intraabdominal conditions as perforated peptic ulcer, mesenteric infarction, and small bowel obstruction without detectable pancreatitis. Patients with AIDS may have hyperamylasemia from salivary gland pathology or macroamylasemia. Macroamylasemia is also seen in connective tissue diseases, lymphoma, and liver disease. The *serum lipase* is more specific but less sensitive; it is a good confirmatory test. Assays of *amylase isoenzymes* have also been developed as confirmatory tests, especially useful when nonpancreatic sources of hyperamylasemia need to be ruled out (e.g., as in AIDS). An *amylase-creatinine clearance ratio* greater than 5 was thought to convey added specificity, but further study found it to be merely a nonspecific consequence of decreased renal amylase clearance that can occur in the setting of any severe acute stress, including diabetic ketoacidosis and cutaneous burns.

Improved rapid screening methods for diagnosis acute pancreatitis continue to be sought. *Trypsinogen-2 dipstick testing* of the urine is being studied as a means of quickly ruling out acute pancreatitis in the urgent care/emergency room setting. The qualitative version of the test has a sensitivity of 94% and a specificity of 95% for acute pancreatitis. When applied to patients with acute abdominal pain, a negative result effectively rules out acute pancreatitis; a positive result needs confirmation because the test has a 5% false-positive rate.

At present, the serum amylase remains the best initial diagnostic study. At times *ultrasonography* can be used for diagnostic purposes; it shows edema of the gland and any biliary tract pathology. Contrast-enhanced *computed tomography (CT)* of the abdomen can also be used to detect such findings and to provide an estimate of severity. Intraglandular necrosis, surrounding edema, and fluid collections can also be detected. The test is considered the gold standard for severe cases of acute pancreatitis but is less sensitive for mild disease. The disadvantages of CT include high cost and need for potentially injurious contrast agents.

Clinical Course. The course of acute pancreatitis depends on the severity of the disease and the underlying etiology. Patients with HIV infection or frank AIDS have particularly poor prognoses. In a patient recovering from acute pancreatitis, symptoms are reliable indicators of disease activity. Elevated enzymes in an otherwise asymptomatic patient are usually of no significance. The serum amylase routinely falls to normal within several days but may remain elevated for weeks after an uncomplicated illness. In other instances, persistently elevated enzymes in an asymptomatic person may be a clue to the presence of a silent pseudocyst. If a mass is palpable or pain recurs, a *pseudocyst* should be ruled out by ultrasonography of the upper abdomen. Pseudocysts arise in about half of patients with severe pancreatitis, mostly in those with alcohol-induced disease or AIDS. Spontaneous resolution occurs over 3 months in about 50% of patients; those with persistent lesions over 5 cm usually require surgical drainage.

Chronic Pancreatitis characteristically presents and proceeds as bouts of mild to severe recurrent epigastric pain, often occurring in *alcoholic patients* after years of excessive drinking. Sometimes chronic pancreatitis is heralded by a severe attack of acute pancreatitis. At other times, there may be mild pain or simply the painless insidious onset of exocrine insufficiency and diabetes. The pain of chronic pancreatitis is not entirely constant and often varies in intensity over days to weeks. There may be exacerbations of pain, nausea, and vomiting after eating or drinking alcohol. Elevated serum *amylase* and *lipase* levels are helpful, but the sensitivity of these tests is lower in acute pancreatitis.

Diagnosis. Individuals who present with chronic recurrent abdominal pain and a history of relapsing pancreatitis usually do not present difficult diagnostic problems, but the patient without such a history requires more extensive assessment. A *plain film of the abdomen* may reveal *pancreatic calcification*, a late finding in alcoholic pancreatitis. *Ultrasonography* may demonstrate a diffusely enlarged gland, local mass, or pseudocyst. If ultrasound evaluation is normal and pancreatic disease is strongly suspected on clinical grounds, *CT* of the upper abdomen should be performed. If a solitary mass is found, *needle biopsy* should be performed to help diagnose cancer. If uncertainty about cancer or chronic pancreatitis persists, *endoscopic retrograde pancreatography* may prove diagnostically useful. *Abdominal angiography* can be substituted for retrograde pancreatography, if the latter is unavailable or fails.

Clinical Course. The clinical course of chronic pancreatitis is variable and depends on elimination of precipitating factors. Gallstones, particularly common bile duct stones, should be promptly removed, either surgically or endoscopically. Successful and early removal greatly reduces the risk of recurrent or chronic pancreatitis. With recurrent disease, *pancreatic insufficiency* may gradually develop over years, manifested by weight loss and steatorrhea. Although mild glucose intolerance may occur early in the disease process, the onset of clinical *diabetes* is a late complication and a sign of advanced disease. There appears to be an increased risk of pancreatic cancer.

Pancreatic Insufficiency. Patients with pancreatic exocrine insufficiency complain of *weight loss* and frequent greasy bowel movements (i.e., steatorrhea). Weight loss is often striking but nonspecific in this population, which tends to substitute alcohol for other forms of nourishment. Steatorrhea is a late development, not seen until more than 80% of pancreatic exocrine function has been lost. Objective evidence of maldigestion may be obtained by a *qualitative examination for stool fat* with Sudan stain. Where this is not available, a 72-hour *quantitative stool fat analysis* can also be used to establish the presence of steatorrhea and a *d-xylose test* to exclude small bowel mucosal disease. The *bentiromide test* is a simple outpatient study for detecting pancreatic exocrine insufficiency. When bentiromide (500 mg) is given orally, it normally is acted on by pancreatic chymotrypsin to produce para-aminobenzoic acid, which is absorbed by the small bowel and excreted in the urine. In normal persons, greater than 50% is excreted in 6 hours. This test appears to have a sensitivity of 80% and a specificity of 90% for exocrine insufficiency. A trial of pancreatic enzyme replacement may be valuable diagnostically.

When significant uncertainty persists, direct pancreatic function tests, such as secretin stimulation, may be needed to demonstrate exocrine insufficiency objectively.

A small group of patients with pancreatic insufficiency who do not give a history of alcoholism or recurrent abdominal pain should be evaluated for hemochromatosis and cystic fibrosis.

PRINCIPLES OF MANAGEMENT

Acute Pancreatitis. About 50% of patients have mild self-limited disease and will recover spontaneously. Such patients with mild pain and no vomiting may be treated on an ambulatory basis with restriction of fat and protein and careful monitoring. Patients with more severe disease who require hospitalization generally tolerate a full diet before discharge from the hospital, although a *diet moderately restricted in fat* is often recommended to lessen the degree of pancreatic stimulation. H_2-receptor antagonists, antacids, and anticholinergics are frequently given with the hope of reducing the stimulus to pancreatic secretion but are of no proven benefit. A patient who returns with severe pain and vomiting should be readmitted.

Identification and treatment or removal of precipitants, such as alcohol abuse, hypercalcemia, gallstones, and hypertriglyceridemia, are essential to successful therapy. Of the conditions associated with pancreatitis, alcoholism is the most difficult to deal with. Even the pain of pancreatitis often does not dissuade the dedicated drinker from abusing alcohol. Nevertheless, the *treatment of alcoholism* should be undertaken with considerable effort (see Chapter 228), because there is much to gain by the cessation of drinking. A check for drugs associated with pancreatitis is indicated (thiazides, corticosteroids, estrogens, azathioprine). In the *HIV-infected patient*, treatment of potentially etiologic opportunistic infections (e.g., toxoplasmosis, cytomegalovirus) and elimination of inciting medications (e.g., didanosine, pentamidine, sulfonamides, corticosteroids) are priorities in addition to the standard approaches to treatment.

All patients should undergo evaluation of the biliary tract by *ultrasonography* to rule out gallstone disease, a treatable cause of pancreatitis. However, in acute pancreatitis, early stone removal by *endoscopy retrograde cholangiopancreatography* in the absence of obstructive jaundice is no better than conservative therapy and fraught with more serious complications. After an acute episode, the serum calcium should be repeated, because *hypercalcemia* can be masked by the decrease in calcium that may result from an attack. Repeatedly marked elevations in *fasting triglyceride* concentration suggest the diagnosis of hypertriglyceridemia, which responds to gemfibrozil (see Chapter 27).

Chronic Pancreatitis. Patients with chronic pancreatitis may develop recurrent bouts of pain and vomiting indistinguishable from acute pancreatitis. Those with severe pain and inability to maintain hydration orally should be admitted. Others with less severe exacerbations may be managed on an outpatient basis. Many are bothered by chronic pain.

Initial treatment consists of eliminating causative factors (see above) and attempting to control the often disabling pain. Pancreatic enzymes and low-fat diets may decrease pancreatic secretion but do not reliably lessen the pain. Nonnarcotic analgesics (aspirin, ibuprofen, acetaminophen) should be tried but are usually inadequate, necessitating use of more potent agents. *Methadone* and *sustained-release morphine* are the narcotics best suited for long-term outpatient use. Sometimes, *tricyclic antidepressants* are useful adjuncts for pain control (see Chapter 227). The establishment of a *supportive doctor–patient relationship* complements pharmacologic pain control efforts.

Numerous *surgical procedures* have been designed to alleviate the pain of chronic pancreatitis; none is totally effective. Patients with persistent pain in the absence of gallbladder disease or alcoholism should have an endoscopic *retrograde pancreatogram* to search for a surgically treatable anatomic abnormality, such as pancreas divisum. If a markedly dilated duct is found, a modified *Puestow sphincteroplasty procedure* can be performed to improve drainage of pancreatic juices into the small bowel. The operation may provide reasonable pain relief without removal of pancreatic tissue. Large persistent pseudocysts should be drained internally; however, reduction in pain is not consistently achieved. Sometimes partial or even subtotal pancreatectomies are attempted for control of pain; at best, results are equivocal.

In patients with severe active disease, the pancreas is progressively destroyed, and eventually the pain subsides as the disease "burns" itself out. Then the management priority shifts to treatment of pancreatic insufficiency.

Pancreatic Insufficiency. Management of pancreatic insufficiency begins with a therapeutic trial of oral pancreatic enzymes to judge efficacy of therapy. The patient who benefits from use of exogenous enzymes will tolerate the unpleasant taste and mild discomfort they cause. *Pancreatin* contains trypsin, amylase, and some lipase, whereas *pancrealipase* contains trypsin, amylase, and extra amounts of lipase. The usual dose is 0.5 to 2.5 g with each meal. Because enzyme preparations are partially inactivated by gastric acid or require increased alkalinity in the duodenum, they may work better when given with antacids, bicarbonate, or H_2-receptor antagonists. *Medium-chain triglycerides* are often helpful because they can be absorbed in the absence of lipase. Therapy can be assessed by monitoring symptoms, weight, and qualitative stool fat determinations. Clinically significant fat-soluble vitamin deficiencies are uncommon, perhaps because intact bile secretion prevents complete fat malabsorption.

Most patients with chronic pancreatitis have abnormal glucose tolerance tests. Mild glucose intolerance can be watched, but insulin dependence may occur. Hypoglycemia may be a problem, because loss of glucagon secretion leads to a "brittle" diabetic state, but ketoacidosis is rare. The vascular complications of diabetes are infrequent but eventually occur if severe pancreatic insufficiency persists.

PATIENT EDUCATION

Most patients know little about the pancreas and its role in digestion. Moreover, few are aware of the connection between alcohol abuse and pancreatitis. Patient cooperation regarding diet, alcohol intake, and use of enzyme extracts may be facilitated by a better understanding of the function of the pancreas and the nature of pancreatitis. Also, patients with acute pancreatitis who are making good recoveries can be comforted by the fact that recurrence is not common when the underlying cause is treated.

The patient with intractable pain and narcotic dependence poses one of the most difficult problems encountered in clinical medicine. A major pitfall is the development of an adversarial relationship between patient and physician concerning the need for narcotics. Although there are no simple solutions, it is essential to elicit, understand, and respond to patient concerns, fears, and needs at the outset. A well-informed patient who has confidence in the physician and in him- or herself requires less pain medication than one who is scared, feels abandoned, and is in conflict with the physician.

INDICATIONS FOR ADMISSION AND REFERRAL

Some patients present with rather mild symptoms but later develop a fulminant illness. Patients over age 55 are at risk for a serious progression, as are those who manifest fever, tachycardia, hyperglycemia, serum calcium below 8.0 mg/dL, or amylase over 1,000 mg/dL at the time of initial presentation. Such individuals deserve admission for careful monitoring, even if they do not appear seriously ill at the outset. Patients who cannot maintain oral hydration also require admission. Patients with refractory pain might benefit from evaluation by a gastroenterologist skilled in endoscopic retrograde pancreatography. Surgical consultation is indicated if an anatomic abnormality, pseudocyst, or obstructive lesion is detected on workup of the pancreas and biliary tract. Patients with chronic refractory pain may benefit from a psychiatric or pain management assessment, supplemented by tricyclic antidepressant therapy.

MANAGEMENT RECOMMENDATIONS

Recovery Phase of Acute Pancreatitis

- Begin feedings with foods rich in carbohydrates and low in protein and fat. Gradually increase the amount of protein in the diet as tolerated, followed by slow resumption of fat intake.
- Check for and treat any underlying alcohol abuse (see Chapter 228), hypertriglyceridemia (see Chapter 27), or hypercalcemia (see Chapter 96).
- Eliminate, if possible, use of drugs associated with pancreatitis (azathioprine, estrogens, thiazides, corticosteroids). In the HIV-infected patient, check for and treat any toxoplasmosis or cytomegalovirus infection and eliminate any potentially inciting medication (e.g., didanosine, pentamidine, sulfonamides, corticosteroids).
- Obtain ultrasound examination of the gallbladder and biliary tract; refer the patient for consideration of surgery if stones are found. There is no benefit to early endoscopic retrograde cholangiopancreatography and stone removal in persons with biliary pancreatitis who are not jaundiced.

Chronic Pancreatitis

- Check for and treat any inciting cause, such as alcoholism, biliary tract disease, hypercalcemia, or hyperlipidemia (see above).
- Readmit the patient if severe recurrent acute pancreatitis develops.
- Temporarily limit fat intake during flare-ups.
- Begin with mild analgesics for pain control, such as aspirin or acetaminophen 600 mg every 4 hours.
- Pain unrelieved by mild analgesia is an indication for a course of narcotic analgesics, such as methadone 5 or 10 mg every 6 or 8 hours.
- Further evaluation is needed to rule out carcinoma, pseudocyst, and biliary tract disease. Begin with ultrasonography and proceed to CT if ultrasonography is technically unsatisfactory.
- Refer the patient for surgery if a treatable lesion is found.
- Aggressive surgical procedures other than sphincteroplasty aimed at relieving ductal obstruction do not reliably relieve pain.
- Consider a trial of tricyclic antidepressant therapy (see Chapter 227) for patients with refractory pain. Psychiatric or pain management consultation may also help.

Pancreatic Insufficiency

- Give oral pancreatic extract with each feeding in doses of 0.5 to 2.5 g (two to eight tablets) with full meals and 0.5 g with snacks. Lack of effect may require addition of an antacid (e.g., 60 mL of Mylanta with each meal) or H_2-receptor antagonist (e.g., ranitidine, 150 mg twice daily) to neutralize gastric acid and prevent enzymes from becoming inactivated.
- Provide a high-calorie diet rich in carbohydrate and protein.
- Supplement the diet with a medium-chain triglyceride preparation. Restrict fat in symptomatic steatorrhea.
- Monitor glucose tolerance and treat clinical diabetes, if present, with insulin, cautiously; these patients often exhibit brittle disease.

CHAPTER 73 MANAGEMENT OF INFLAMMATORY BOWEL DISEASE

JAMES M. RICHTER

Ulcerative colitis and Crohn's disease account for most inflammatory bowel disease seen in primary care practice. Abdominal pain, diarrhea, and bleeding are among the presenting manifestations. The first priority is to distinguish inflammatory bowel disease from other causes of diarrhea (see Chapter 64). The chronicity, potentially disabling symptoms, risk of malignancy (in the case of ulcerative colitis), and occasional refractoriness to medical therapy make management a major challenge. The primary care physician needs to know how to treat exacerbations, maintain remissions, and psychologically sustain these patients through difficult times. Competent care is based on a thorough understanding of the roles for medical and surgical therapy and skill in providing psychological support. Although patients with severe or refractory disease may need to be referred to the gastroenterologist, most others can be well managed by the primary care physician.

PATHOPHYSIOLOGY, CLINICAL PRESENTATION, AND COURSE

Ulcerative Colitis

Ulcerative colitis is an idiopathic diffuse inflammatory disease of the bowel mucosa. Although pathogenesis remains poorly understood, there is growing evidence of a primary immune mechanism (e.g., high prevalence of antibodies to intestinal epithelial antigens in asymptomatic relatives of patients and in patients themselves). The disease typically begins in adolescence or young adulthood but may occur at almost any age. Whites are affected more often than African-Americans. Prevalence is highest among Jews of Eastern European descent, and there is a 10-fold increase in risk for having the disease among first-degree relatives of patients.

Clinical Presentation. The cardinal symptoms are *bloody diarrhea* and *abdominal pain*; in severe cases, *fever, anorexia*, and *weight loss* are present as well. The variability of presentations is remarkable, ranging from malaise and no symptoms referable to the colon, to fever, prostration, abdominal distention, and passage of large volumes of liquid stool. The disease need not be confined to the bowel; extracolonic manifestations include *arthritis, uveitis, jaundice*, and *skin lesions*. The course is characteristically chronic, recurrent, and unpredictable. An insidious presentation does not predict a benign course, and a fulminant onset may be followed by long relatively asymptomatic periods.

Ulcerative colitis almost always involves the *distal colon* and *rectum*, making diagnosis possible by sigmoidoscopy. The mucosa becomes edematous, obscuring the fine network of submucosal vessels. The moist glistening mucosal surface is lost, and a *granular* appearance develops. The bowel wall is friable, bleeding spontaneously or when touched with a swab.In advanced cases, *pseudopolyps* and discrete *ulcers* may be seen. Smears of mucus from the bowel wall show polymorphonuclear leukocytes. Barium enema documents the extent of disease. Radiologic findings range from mucosal denudation to frank ulceration, with loss of haustral markings and a tubular appearance. There are *no skip areas*. Liver involvement occurs in the form of *pericholangitis* and *fatty infiltration*; these are common histologic findings in ulcerative colitis but are seldom symptomatic. Much less frequently, *chronic active hepatitis, cirrhosis*, or sclerosing cholangitis is seen. A migratory *monoarticular arthritis* affecting the large joints develops in 10% of patients. This arthritis often coincides with an exacerbation of colitis and resolves with control of the underlying disease. *Ankylosing spondylitis* also occurs but runs a course independent of the colitis. Uveitis or episcleritis may be seen at any time during the course of the disease. *Erythema nodosum, pyoderma gangrenosum*, or *oral aphthous ulcerations* are found in about 5% of patients, usually during active colitis.

Course. The prognosis for patients with ulcerative colitis seen in the primary care setting is far better than that for patients studied in referral centers who are likely to have more severe disease. Long-term community-based studies find that nearly 90% go into complete remission after the first attack and less than 10% develop chronic persistent disease. Among those with chronic disease, nearly three fourths have disease limited to the distal bowel (rectum or rectosigmoid). Overall mortality in community-based populations of ulcerative colitis patients is no different from that of the general population, although it is increased in patients with severe first attacks or extensive disease.

There is an increased *risk of cancer* that correlates with the extent and duration of disease and age at diagnosis. Risk begins to increase substantially after 8 years of illness. Absolute risk of colon cancer in the setting of pancolitis has been found to be 30% after 35 years from time of diagnosis. Those with pancolitis diagnosed before the age of 15 manifest an absolute risk of 40%. These figures are slightly lower than traditional risk estimates of 1% to 2% per year derived from referral center cohorts.

Ulcerative Proctitis

Typically, the patient with ulcerative proctitis is a young adult who presents with rectal bleeding and tenesmus. The bleeding is usually not severe; it is sometimes mistakenly attributed to hemorrhoids. Diarrhea or constipation may accompany the bleeding, but often there are only small frequent bowel movements associated with a small amount of mucus. On sigmoidoscopy, an edematous friable rectal mucosa is observed; the bowel above the rectosigmoid is uninvolved. On barium enema or colonoscopy, the remainder of the large bowel is normal. The clinical presentation of ulcerative proctitis is not pathognomonic; the condition must be distinguished from infectious forms of proctocolitis, including AIDS-related etiologies (see Chapter 13) and Chapter 66).

Ulcerative proctitis is a variant of ulcerative colitis, distinguished by the limited extent of inflammation, its good prognosis, and paucity of serious complications. However, relapses are common. Fewer than 15% progress to generalized ulcerative colitis. The distant complications of ulcerative colitis are rare, and carcinoma of the rectum develops no more often than in unaffected individuals.

Crohn's Disease

Pathophysiology. Crohn's disease is a chronic relapsing inflammatory disorder of the alimentary tract that appears to have an autoimmune pathophysiology. There are high levels of selected T-cell populations and high prevalence of antibodies to intestinal epithelial antigens in patients and in their asymptomatic relatives. Of therapeutic interest is the role of inflammatory mediators. T helper cells in the bowel mucosa of patients with Crohn's disease appear to produce increased amounts of tumor necrosis factor-a. Infusion of monoclonal antibodies directed against these cytokines can produce remission of otherwise refractory disease (see below). Other potentially important cytokines include interleukin-12 and interferon-g. There may also be inadequate production of counter-regulatory substances. Pathologically, the distribution of bowel inflammation is *discontinuous*, with diseased segments of bowel separated by normal areas. Because the granulomatous inflammatory process may extend through *all layers* of the bowel wall, it has a tendency to cause *strictures, fistulas*, and *abscesses*.

Clinical Presentation. Peak incidence is in the second and third decades. The condition often affects the distal ileum and right colon, but frequently it involves only the small bowel or colon. It may occur in any portion of the alimentary tract, from the buccal mucosa to the anus. Extraintestinal involvement occurs in 15% to 20% of cases, with *arthritis, ankylosing spondylitis, uveitis, erythema nodosum, aphthous oral ulcers*, and *pyoderma gangrenosum* being the predominant manifestations of disease outside the bowel. In addition, *cholelithiasis* and *nephrolithiasis* have a higher incidence in these patients than in the general population.

Symptoms vary, depending on the location and extent of disease. *Diarrhea* and *abdominal pain* (particularly in the right lower quadrant) are cardinal symptoms, occurring in almost 80% of patients. *Weight loss, vomiting, fever, perianal discomfort*, and *bleeding* are also common complaints. *Constipation* may be an early manifestation of obstruction. Symptoms can develop subtly or can present in fulminant fashion with the patient systemically toxic.

Physical examination may reveal a discrete abdominal mass, especially in the right lower quadrant, but usually a normal abdomen or doughy loops of bowel are found. Abdominal or perianal fistulous tracts are noted on examination in up to 10% of patients. Extraintestinal findings include inflamed joints, spinal deformities, erythema nodosum, pyoderma, uveitis, and aphthous ulcers.

Sigmoidoscopy is abnormal in fewer than 20% of cases; fistulous tracts and discrete inflammatory ulcers are sometimes encountered in the rectosigmoid. *Barium enema and upper gastrointestinal series* often show segmental involvement of large and small bowel, often with strictures, fistulas, and ulcers. The primary abnormality in Crohn's disease is submucosal, causing radiologic studies to sometimes appear normal. In such cases, *colonoscopy* aids diagnosis by demonstrating segmental disease and ulceration that may be missed on barium enema.

Prognosis. Although it is difficult to extrapolate from referral center data to patients seen in primary care settings, a pattern emerges of disease activity that waxes and wanes over many years. Disease-free intervals may last as long as several years or even decades, but recurrences are the rule. Several years of relief from symptoms may be afforded by surgical resection, but there is no evidence that any medical and surgical therapy alters the ultimate course of the illness. In referral center series, as many as 70% of patients ultimately require surgical resection.

WORKUP

Proper management requires confirming the diagnosis and determining the extent of disease. One proviso should be kept in mind: Because these illnesses often occur in women of childbearing age, attempts should be made to minimize their x-ray exposure and carefully select only the most necessary radiologic studies.

Ulcerative Colitis

Diagnosis. The diagnosis is usually based on the clinical presentation, sigmoidoscopic demonstration of inflammation, and the exclusion of bacterial and parasitic infections by culture and examination for ova and parasites (see Chapter 64). Because the disease almost invariably affects the distal colon and rectum, *sigmoidoscopy* is an essential component of the workup. The procedure is best performed without cleansing preparations, so as not to distort the appearance of the bowel mucosa (see Appendix in Chapter 56). In acute phases of the illness, the mucosa appears *friable* and inflamed; there is loss of the normal vascular pattern. As the disease progresses, a *purulent exudate* and discrete small *ulcers* may form. With severe colitis, there may be pus and spontaneous bleeding and large ulcers. Chronic phases of the disease are characterized by a granular mucosa and inflammatory *pseudopolyps* (tags of damaged mucosa and granulation tissue).

When the sigmoidoscopic picture is nonspecific, one should *culture* and examine the stool for *Clostridium difficile, Entamoeba histolytica, Campylobacter, Shigella, Salmonella*, and *Neisseria gonorrhea* (see Chapter 64 and Chapter 66). Rectal biopsy is indicated when one needs to confirm the diagnosis and exclude conditions such as Crohn's disease of the rectosigmoid, amoebic colitis, pseudomembranous colitis, cytomegalovirus infection, and herpetic pancolitis. *Barium enema* or *colonoscopy* can be used to provide supportive evidence when the diagnosis is in doubt and helps document the extent of disease. However, they should not be performed during a flare-up because there is a small risk of perforation when the procedure is performed on an acutely inflamed bowel.

Estimating Disease Activity and Severity. The appearance of the bowel mucosa on *colonoscopy* remains the mainstay of assessment of disease activity. Scoring systems based on clinical parameters are sometimes used in research settings but have little utility in clinical practice. A host of radionuclide imaging methods has been tried, but they lack specificity. Disease severity is defined more clinically. *Mild disease* is defined as less than four bowel movements a day and no signs of toxicity (i.e., no fever, tachycardia, anemia, or elevation of sedimentation rate). *Moderate disease* is characterized by four or more bowel movements a day plus minimal toxicity. *Severe disease* is manifested by six or more bowel movements a day and/or signs of toxicity.

Crohn's Disease

Diagnosis. Crohn's disease of the colon may mimic ulcerative colitis clinically. Differentiating features include *skip areas* in the colon, significant *small bowel* involvement, *fistulas*, and *granulomas* on biopsy. The diagnosis is suggested by a history of recurrent postprandial lower abdominal pain and altered bowel habits in a young person; it is reinforced by finding on physical examination a mass or tenderness in the right lower quadrant. Radiologic contrast studies are needed for a more definitive assessment. The small bowel phase of an upper gastrointestinal series shows *segmental narrowing*, areas with loss of the normal mucosal pattern interspersed with areas of normal mucosa, fistula formation, and the "*string sign*" (a narrow band of barium flowing through an inflamed or scarred area) in the terminal ileum.

Colonic disease may be documented by *air contrast barium enema*, with asymmetric segmental changes distinguishing Crohn's disease of the large bowel from ulcerative colitis. Disease of the terminal ileum can often be detected on barium enema; however, radiologic involvement of the terminal ileum is not unique to Crohn's disease. Some ulcerative colitis patients also demonstrate inflammatory changes in the terminal ileum ("backwash ileitis"), but they lack the skip pattern characteristic of Crohn's disease.

Sigmoidoscopy demonstrates rectosigmoid inflammation in the 20% to 50% of patients with disease in this area; however, the findings are often nonspecific (mild erythema). *Colonoscopy* is needed in difficult cases and helps in judging the extent and severity of disease. *Biopsy* can be diagnostic but is usually unnecessary unless the diagnosis remains unsubstantiated; it should be avoided when acute inflammation is present.

Estimating Disease Activity and Severity. Disease activity in the colon is best assessed by *colonoscopy* and in the small bowel by *barium contrast study*. Disease severity is categorized clinically. *Mild-to-moderate disease* is defined as having symptoms but functioning adequately on an ambulatory basis, maintaining oral intake of food and fluids, and showing no signs of toxicity or complications. In *moderate-to-severe disease*, symptoms are more severe, sometimes interfering with daily activity and not responding fully to treatment. In *severe disease*, there may be toxicity, complications, and failure to respond to full doses of oral corticosteroids.

PRINCIPLES OF MANAGEMENT

The inflammatory bowel diseases are chronic illnesses that require long-term comprehensive management. Such management entails attention to the patient's medical, psychological, and nutritional needs and support for the family. For the most part, treatment is empirical and directed at providing symptomatic relief; however advances in the understanding of inflammatory bowel disease pathophysiology are leading to a host of new treatments that have the potential to improve treatment outcomes.

Ulcerative Colitis

Because the disease typically follows a relapsing course with acute exacerbations and intervals of remission, the approach to treatment depends on the patient's current clinical status. During remission, treatment is prophylactic; during flare-ups, the goal is control of the inflammatory process. Surgery is a consideration for those with refractory disease, especially when it is widespread.

Dietary and Nutritional Measures. No specific diet improves or exacerbates ulcerative colitis. However, reduction in dietary *fiber* may be of some benefit during periods of active disease. In patients with inactive disease, 1 or 2 teaspoons of *psyllium* hydrophilic colloid (Metamucil) in water daily often helps to bind the stool. There is an increased incidence of lactase deficiency in these patients; an empirical trial of a *milk-free diet* is reasonable when diarrhea persists despite other evidence of clinical remission. Those who are anemic from blood loss need oral or parenteral *iron* supplementation (see Chapter 82). Oral iron may be poorly tolerated, necessitating parenteral administration. Anemia may also be due to folic acid deficiency. *Folic acid* supplementation is indicated when intake of leafy vegetables and fresh fruits is poor or when sulfasalazine is being taken (see below). Anemia may also be due to chronic disease and may not respond to dietary and nutritional measures.

Sulfasalazine. The drug is recommended as initial treatment for mild to moderate disease and for prevention of relapses. After oral administration, about 70% reaches the colon, where it is metabolized by intestinal bacteria, resulting in the local release of sulfapyridine and the salicylate analogue *5-aminosalicylate (5-ASA)*, which is believed to be the active moiety. Sulfasalazine's precise mechanism of action remains speculative. Hypotheses include effects on prostaglandin synthesis (particularly arachidonic acid metabolism) and inhibition of migration of polymorphonuclear leukocytes.

Efficacy. Randomized controlled studies have shown the drug to be effective as *initial treatment* for patients with mild to moderate symptoms when given in doses of 4 g/d for 2 to 4 weeks. About 80% of patients respond. Because sulfasalazine is less effective than corticosteroid therapy, it is reserved for relatively mild cases; however, combined use with steroids has been suggested for early treatment of severe disease.

Controlled studies have also documented the drug's efficacy for *prophylaxis* and maintaining remissions. In one major study, more than 65% of patients given maintenance doses of 2 g/d remained symptom-free for at least 1 year compared with 25% of patients given placebo. The prophylactic effect of maintenance therapy persists when the drug is continued beyond 1 year. The optimum dose is 2 g/d (4 g/d provides even better protection, but the frequency of side effects is markedly increased).

Adverse Effects. Sulfasalazine is usually well tolerated (being safe enough to use during pregnancy and when breastfeeding), but up to 20% experience adverse effects, mostly due to the sulfapyridine moiety. These range from common forms of dose-related gastrointestinal upset (*nausea, vomiting, anorexia, heartburn*) and mild *hypersensitivity* reactions (*rash, fever*) to uncommon but potentially serious idiosyncratic reactions such as *agranulocytosis, hepatocellular injury, and lupuslike phenomena*. Patients unable to tolerate full doses of sulfasalazine because of gastrointestinal upset often do better when reintroduced to the drug more gradually. Taking it with meals also helps. Other potential hematopoietic effects include *anemia* (from folic acid deficiency, hemolysis, or marrow suppression), *granulocytopenia*, and *thrombocytopenia. Low sperm counts* and qualitative sperm abnormalities have been noted in men taking the drug, usually after about 2 months of therapy; these conditions reverse when the medication is stopped. *Desensitization* (starting with fractions of a tablet and slowly advancing over 2 to 4 weeks to therapeutic doses) can overcome minor allergic reactions (rash, fever), but most often sulfa-intolerant patients are now switched to a sulfa-free 5-ASA preparation (see below).

Drug interactions associated with sulfasalazine include inhibition of *folic acid* absorption (usually not clinically significant) and a 25% reduction in *digoxin* bioavailability. Sulfasalazine's metabolism is slowed when *cholestyramine* or *broad-spectrum antibiotics* are used concurrently, an effect of uncertain clinical significance. *Ferrous sulfate* appears to have a similar effect on sulfasalazine, although iron absorption is not appreciably hindered; these drugs should not be taken at the same time. Because of the risk of neutropenia, any concurrent use with azathioprine or 6-mercaptopurine (6-MP) requires extreme caution and close monitoring.

Sulfapyridine-free 5-Aminosalicylate Agents. These agents were developed to provide a sulfapyridine-free means of delivering 5-ASA to affect bowel and in doing so eliminate most the adverse effects seen with sulfasalazine. The first developed was *olsalazine*, which is just two 5-ASA molecules bound by an azo bond that is cleaved by bacteria in the colon, releasing the active 5-ASA moiety. It is useful for achieving control of mild-to-moderate disease and for maintaining remissions. Diarrhea is the most common side effect, is dose related, and is diminished by increasing dose gradually and by giving the drug with meals.

Mesalamine is 5-ASA specially coated to produce delayed release. The oral tablet formulation (Asacol) dissolves at a pH of 7, the lumenal pH of the terminal ileum and colon. The methylcellulose capsule formulation (Pentasa) releases 5-ASA into the small bowel and the colon. In controlled trials, oral 5-ASA agents perform at least as well as sulfasalazine in the treatment of active mild-to-moderate ulcerative colitis and in maintaining remissions. Benefit appears to be dose related. Side effects are nil, but 5-ASA–related interstitial nephritis (seen in animal studies and case reports) is a concern with long-term high-dose use. Idiosyncratic reactions include pleuropericariditis, pancreatitis, and nephrotic syndrome. Those with very active disease should probably take mesalamine with meals if they note that the coated tablet is being passed undissolved, because taking the pill with food can slow transit and allow more time for dissolution.

Although these oral 5-ASA agents appear better tolerated than sulfasalazine, they are considerably more expensive. Nonetheless, patients who do not tolerate sulfasalazine deserve a trial of a sulfapyridine-free agent.

Topical 5-ASA enemas were also developed as an alternative to sulfasalazine and represent a reasonable option in patients with distal colitis. At maximum dose, they are more effective than hydrocortisone enemas and useful for persons with mild-to-moderate disease limited to the distal large bowel. Relapse is common with cessation of enema therapy; however, unlikehydrocortisone enemas, a maintenance program (alternate-day dosing) of topical 5-ASA therapy helps to maintain remission. The safety profile is excellent; adverse effects are nil other than idiosyncratic reactions, and the only common side effects are local itching and mild rectal irritation. Cost is considerably higher than that of a hydrocortisone enema. However, unlike steroid enemas, there is no concern about systemic steroid absorption.

Glucocorticosteroids. Steroids suppress the inflammatory process of ulcerative colitis and have important roles both as systemic agents in severe disease and as topical agents in disease confined to the rectosigmoid. When uveitis and colitis flare simultaneously, oral steroids are often effective for both. (In the absence of active colitis, the uveitis may be treated with topical steroids and mydriatics.) The best means of treating other systemic manifestations (erythema nodosum, pyoderma gangrenosum, oral aphthous ulcerations) is to control the underlying disease with systemic steroids. Patients with severe disease requiring daily steroids should receive calcium and vitamin D supplementation, because absorption may be impaired.

Systemic preparations are used in moderate-to-severe and severe disease, especially in markedly symptomatic patients with extensive bowel involvement. Those without systemic toxicity can be treated on an outpatient basis starting with the equivalent of 60 mg/d of *prednisone*. Patients too ill for oral therapy (i.e., those with vomiting, high fever, or signs of bowel distention) should be admitted to the hospital. Once symptoms lessen, steroids are gradually tapered over 4 to 8 weeks to the lowest dose that maintains control. Whenever possible, every effort should be made to taper and terminate systemic steroid therapy, both because only some ulcerative colitis patients benefit from chronic steroid use and because the adverse effects of chronic steroid therapy can be disabling (see Chapter 105). *Alternate-day* steroid administration often suffices after a flare-up has been brought under control and poses much less risk of steroid side effects. Newer corticosteroids with fewer systemic side effects are under development. The best studied is a slow-release oral preparation of *budesonide*, which provides release in the colon with minimal systemic side effects.

Topical preparations are useful for disease confined to the rectosigmoid area. *Hydrocortisone* enemas as widely prescribed and effective, but prolonged high-dose use can lead to systemic steroid side effects (some hydrocortisone does get absorbed). The topically active steroid *beclomethasone* has been found equally efficacious to topical hydrocortisone but with less systemic absorption and no effect on serum cortisol levels; however, cost is greater.

Immunosuppressive Agents. Patients who require chronic high-dose steroid therapy might benefit from a trial of steroid-sparing immunosuppressive therapy with *6-MP* or *azathioprine*. Because onset of action can be slow (up to 6 months), concurrent therapy with a second agent is necessary until the drug's effect sets it. Side effects are less frequent than with systemic steroids, but these can be serious (see below). Intravenous administration of *cyclosporine* is sometimes used in very ill patients not responding to intravenous steroids. Results from controlled trials are variable and risk of toxicity is high.

Opiates are useful for providing symptomatic relief of diarrhea during acute phases of illness and chronic active colitis. They must be used with caution in acutely ill patients because of the risk of precipitating *toxic dilatation*. Diphenoxylate, codeine, tincture of opium, paregoric, and loperamide all limit the number of bowel movements. They are given before meals and at bedtime. *Loperamide* is among the most effective and least addicting but is considerably more expensive. *Codeine* is excellent for short-term use and superior to diphenoxylate in efficacy. *Tincture of belladonna* and other anticholinergics help to control cramps.

Psychological Support. Although psychological disturbances are more prevalent in patients with inflammatory bowel disease than in control subjects, there is little evidence that psychiatric disease is etiologically linked to the development of ulcerative colitis. However, recent data suggest a correlation between stress, immunologic dysfunction, and onset of symptoms. Formal psychotherapy directed at uncovering intrapsychic conflict has not proven useful, but a close, supportive, and empathetic patient–doctor relationship is invaluable to psychologically sustaining the patient through this illness (see below). Fears and worries about debility, surgery, colostomy, and body image contribute markedly to the psychosocial impairment and disability associated with this illness.

Surgery. Total colectomy offers the potential for complete cure of bowel disease and remission of most peripheral manifestations. As such, it represents an important therapeutic consideration, albeit a difficult one. Indications include *high-grade dysplasia, suspected cancer*, and *unresponsiveness* of bowel or systemic symptoms to maximal medical management. Patients with severe persistent disease requiring continuous *high-dose corticosteroids* that cannot be tapered after 6 to 12 months also warrant serious consideration for surgery, as do those with frequent severe *relapses* or *complications* from prolonged exposure to systemic steroids.

The traditional procedure is *proctocolectomy with Brooke ileostomy*. It has the advantage of being the fastest and safest procedure. The disadvantages of an ileostomy include incontinence, need to frequently empty an external ileostomy appliance, skin excoriations, and potential need for stomal revision (in about 10% to 20%). *Total proctocolectomy with continent ileostomy* (Koch pouch) creates a continent ileostomy that does not require wearing an appliance; it is best suited for those who desire control of stomal output. *Park's procedure* (total colectomy, rectal mucosectomy, ileal reservoir, and ileoanal anastamosis) provides the opportunity to retain continence and avoid a stoma. Although there is likely to be some incontinence initially, this usually passes. About four to eight bowel movements per day are common, helped by chronic use of low-dose antidiarrheal therapy (e.g., loperamide). Potential complications include pelvic infection, strictures, small bowel obstruction, and "pouchitis." Although complications occur in up to 30%, most patients are pleased with the procedure and its outcomes.

Regardless of the surgical procedure chosen, the morbidity of active disease and the threat of cancer must be weighed against the risks of major surgery. The

mortality of elective colectomy is 1% to 3%, with most patients having no postoperative complications. Stoma revision is necessary in 10% to 20% of cases.

Screening for Cancer.

All patients with clinical or radiologic evidence of *pancolitis of 7 or more years* should be considered for colon cancerscreening. At this point, cancer risk begins to rise substantially. Because the bowel cancer is often multicentric, the best method of screening is *colonoscopy* with multiple biopsies. Cancer screening should begin at 7 years with 3-year intervals until 20 years, when it should become more frequent. Worrisome findings include *stricture* and *dysplasia*. Mild dysplasia is an indication for repeat study in 3 months. Severe dysplasia and stricture formation require consideration of colectomy; the risk of cancer is very high in the presence of such findings.

Crohn's Disease

Most patients can be treated on an outpatient basis by judicious use of medications and careful follow-up. A strong working alliance between the patient and primary physician is essential, because the disease is chronic, relapsing, and incurable.

Diet. Adequate nutrition is critical to the promotion of healing. Sufficient protein and calories must be provided but in a manner that limits the stress put on an inflamed and often strictured bowel. Patients with cramps and diarrhea should have the *fiber* content of their diet *reduced*; those with steatorrhea will benefit from a *decrease in fat intake* to less than 80 g/d. An empiric trial of *restricting milk products* may terminate diarrhea due to lactase deficiency, which often accompanies the illness. More severely ill patients require partial *bowel rest*, which removes the stimulus that food has on bowel motility and secretion. *Elemental diet preparations* (e.g., Magnacal, Ensure, Sustacal, Isocal) have been found to induce remission, improve symptoms, and decrease disease activity in patients with acute disease. They are convenient and usually well tolerated sources of the extra nutrition needed during exacerbations. *Total parenteral nutrition* should be used in patients whose oral intake is not adequate or in whom surgery is indicated.

Vitamin and mineral deficiencies are common and must be corrected for proper healing and avoidance of such complications as anemia and bone disease. *Folic acid* supplementation is particularly important in patients taking sulfasalazine, which impairs its absorption. Patients who have had ileal surgery may need extra *vitamin B12*. *Vitamin D* levels are likely to be low when intake is poor or steatorrhea is a problem. An oral supplement of 4,000 IU or more usually suffices. Most vitamin and mineral deficiencies can be overcome by taking a multiple vitamin containing about five times the normal daily vitamin requirements and such minerals as iron, calcium, magnesium, and zinc.

Antidiarrheal Agents. The use of these agents in Crohn's disease is similar to that in ulcerative colitis (see above). The risks include addiction and exacerbation of obstructive symptoms.

Sulfasalazine and Other 5-Aminosalicylate Preparations. The National Cooperative Crohn's Disease Study demonstrated modest efficacy of sulfasalazine in patients with disease of the colon and no benefit in those with disease limited to the small bowel. Doses of 2 to 4 g/d are used to treat acute exacerbations of abdominal pain and diarrhea in patients with colonic involvement. Improvement typically occurs within 4 to 8 weeks. Patients who respond to sulfasalazine but experience an adverse effect attributable to the sulfa moiety are candidates for a *sulfa-free 5-ASA* preparation (e.g., *mesalamine* or *olsalazine*). Olsalazine delivers 5-ASA exclusively to the colon, making it useful only for those with disease confined to the large bowel. Mesalamine tablets (Asacol) are formulated to deliver 5-ASA to the cecum and large bowel; mesalamine capsules (Pentasa) release 5-ASA to the entire small bowel and colon. Because they are costly, the 5-ASA preparations should not be used before sulfasalazine for treatment of active disease. Sulfasalazine does not sustain remissions, but meta-analytic data and subsequent controlled trials suggest that mesalamine may reduce risk of recurrence by up to 40%, with benefit most notable for disease of the small bowel and for sustaining remission and after surgery. Nonetheless, the safety and efficacy of routine long-term prophylactic use of mesalamine in Crohn's disease is not established. Combination of sulfasalazine with corticosteroids has not been shown to have a steroid-sparing effect or allow more rapid tapering of steroids once a remission has been induced.

Adverse Effects ([see above](#), under Ulcerative Colitis)

Metronidazole, in doses of approximately 10 to 20 mg/kg/d (e.g., 250 to 500 mg three times a day), is effective in the treatment of patients with Crohn's ileocolitis or colitis and is a reasonable next step in patients who fail to respond adequately to a 5-ASA agent. In addition, uncontrolled studies have demonstrated healing of rectovaginal fistulas, abscesses, and proctocolectomy wounds. It appears that *maintenance* therapy at a lower dose can minimize recurrence of perineal disease. Patient acceptability is sometimes limited by gastrointestinal upset, metallic taste, and paresthesias (a manifestation of peripheral neuropathy associated with chronic use). There is a small risk (1% to 2%) of an *Antabuse-like reaction* occurring with concurrent alcohol use. Persons on long-term therapy who would like to have an occasional drink can conduct a trial of modest alcohol intake at home (where any vomiting will not be embarrassing) to see if they are at risk.

Other Antibiotics. The fluoroquinolone antibiotics (e.g., ciprofloxacin) have also demonstrated efficacy in very ill patients with fistulas and abscesses.

Glucocorticosteroids. If a patient is acutely ill or has moderate-to-severe disease not responding to 5-ASA therapy, then systemic steroids are indicated. Patients with small bowel involvement are especially responsive. *High doses* (e.g., the equivalent of 60 mg prednisone/d) should be used initially. Steroids plus sulfasalazine are more effective than sulfasalazine alone in bringing an acute flare-up under control, but, like sulfasalazine, they are ineffective in preventing a relapse. Sulfasalazine has no steroid-sparing effect.

As acute disease activity subsides, the steroid dose is empirically tapered to the minimum necessary to control symptoms. Sometimes, *alternate-day regimens* will suffice to control disease activity; they have the advantage of minimizing the steroid side effects (see [Chapter 105](#)). As long as 4 months of steroid therapy may be necessary to treat an exacerbation.

Newer oral steroid preparations are being developed, such as controlled-release *budesonide*, which is topically active in the terminal ileum and proximal small bowel yet much less likely to cause systemic side effects because it is 90% inactivatedafter the first pass through the liver. It has proven more effective than mesalamine in persons with active mild to moderate disease yet relatively free of adverse systemic effects. Its full role in treatment of Crohn's disease (including use as maintenance therapy) is being actively explored; it should soon be available in the United States.

Although steroids occupy a central place in the treatment of Crohn's disease, they are *ineffective for maintaining remissions* or preventing exacerbations. Prophylactic steroids are not indicated in Crohn's disease. Moreover, some extraintestinal manifestations and perianal disease do not respond well to glucocorticoids. An important goal of treatment is discontinuation of steroids, necessitating consideration of maintenance mesalamine, metronidazole, immunosuppressive therapy, and the newly developed monoclonal antibody preparations.

6-Mercaptopurine, Azathioprine. These closely related *immunomodulators* are especially useful for their steroid-sparing effects, providing an option for maintenance therapy that is considerably less toxic than chronic steroids. In controlled studies, these agents achieve or maintain control and allow a reduction or discontinuation of steroids in two thirds to three fourths of patients. Treatment is initiated at low doses and increased if no response is noted. There can be a delay in onset of effect of weeks to months, necessitating continuation of concurrent therapy until the effect sets in. Treatment is typically continued for about 12 months and then cessation is attempted. Unlike other forms of medical treatment for Crohn's disease, chronic immunosuppressive therapy has been shown to be capable of maintaining remission, especially in patients with fistulas or frequent relapses.

Limitations to immunosuppressive therapy include slow onset of action and potentially serious side effects. Onset of action may take as long as 3 to 6 months in some patients, necessitating a 6-month trial that includes a doubling of the starting dose. In addition, immunosuppressive therapy may induce infection, pancreatitis, bone marrow suppression, or drug-induced hepatitis. Monitoring of blood counts is essential. Despite the potential for such adverse effects, 6-MP and azathioprine have a good safety profile, especially if the dose is 50 mg/d or less. A total dose of 1.5 to 2.0 mg/kg/d should not be exceeded. Initiation of immunosuppressive therapy should not done without first consulting a gastroenterologist familiar with use of these agents.

Other Immunomodulating/Anti-inflammatory Agents. A host of other agents have been examined for use as steroid-sparing therapy. They should used only in consultation with a gastroenterologist familiar with their use in inflammatory bowel disease.

Methotrexate, the folic acid antagonist with anti-inflammatory effects, has been found in a double-blind placebo-controlled trial of Crohn's disease patients requiring chronic steroid therapy to reduce steroid needs and improve disease control. However, elevations in transaminases and nausea caused nearly a fifth of patients to withdraw from therapy. More study is needed to fully determine the role of methotrexate in Crohn's disease and to develop guidelines for its safe use. Some speculate

that its efficacy in achieving short-term control may make it useful as a complement to azathioprine or 6-MP.

Monoclonal Antibody cA2 (infliximab) directed against *tumor necrosis factor-a* has demonstrated efficacy and minimal toxicity in well-designed short-term trials in patients with moderate-to-severe disease resistant to other forms of therapy. Patients with refractory fistulas treated with one to three intravenous infusions over 6 weeks achieve a marked clinical response, with some fistulas healing completely. However, relapse is common, and safety and efficacy of maintenance infusions remains to be established. Serum sickness–like reactions have occurred with repeat infusions and some lymphomas, and antinuclear antibody positivity has been noted in patients receiving cA2 therapy. Cost is very high (in the thousands of dollars) for a single infusion. Whether these impressive short-term results will hold up in long-term study remains to be determined. Consultation is required for cA2 use.

Omega-3 Fatty Acids, found in fish oil and believed to suppress inflammatory mediators such as the leukotrienes and prostaglandins, have produced modest improvements in acute disease and in maintenance of remission.

Cyclosporine A, an immunomodulator with a faster onset of action than that of azathioprine and 6-MP, has produced promising results in uncontrolled studies but unimpressive findings in placebo-controlled trials. Risk of toxicity is high.

Surgery. Unlike ulcerative colitis, surgery in Crohn's disease does not cure the patient. It is therefore best reserved for patients who have intractable disease, perforation, obstruction, or severe bleeding. It has been estimated that the probability of surgery is 78% at 20 years and 90% at 30 years from the onset of Crohn's disease symptoms. The objective of surgery is to remove grossly involved bowel and spare as much normal-appearing bowel as possible. Postoperative recurrence rates have been estimated to be 30% to 50% per decade and are inversely related to preoperative disease duration. The most common operation is removal of a diseased portion of the terminal ileum with an end-to-end ileocolonic anastomosis. For patients with colonic involvement, colectomy with an internal anastomosis connecting the ileum to the sigmoid or total proctocolectomy with Brooke ileostomy is the procedure of choice. Ileostomy is necessary in patients with marked rectosigmoid disease. Twenty percent to 40% of ileostomies need revision within 5 years because of disease in the stomal area.

Surgical treatment is undertaken with reluctance and only in the setting of severely disabling disease or serious complications. The patient presenting with obstruction may respond sufficiently to bowel rest, nasogastric suction, steroids, and other conservative measures, avoiding the need for immediate surgery, unless the obstruction persists or recurs quickly. In patients with multiple surgeries and much bowel already resected, stricturoplasty might be considered in lieu of yet another resection of bowel. All attempts should be made to use a conservative surgical approach to preserve functional bowel. Loss of bowel, especially right colon, can lead to disabling postsurgical diarrhea.

Management of the Pregnant or Nursing Patient with Inflammatory Bowel Disease

For patients with a flare-up of inflammatory bowel disease during nursing or pregnancy, both sulfasalazine and steroids aresafe and effective. To maintain remission throughout pregnancy in ulcerative colitis, sulfasalazine should be continued in conjunction with folic acid supplementation. Metronidazole and immunosuppressive agents may be injurious to the fetus or nursing child and should be avoided. Women with ulcerative colitis are prone to suffer new attacks or exacerbations during the first trimester of pregnancy and have a spontaneous abortion rate of about 10%. Pregnancy seems to inhibit relapses during later trimesters. Women with active ulcerative colitis should be counseled to postpone getting pregnant until they have been in remission for about a year.

PATIENT EDUCATION

The education and support of the patient and the family are essential. Fears abound when patients are told they have ulcerative colitis or Crohn's disease. These diagnoses conjure up images of colostomy, recurrent hospitalizations, invalidism, and social isolation. It is important to emphasize that the vast majority of patients lead fully functional lives and many obtain satisfactory control of their disease through medical therapy.

Because these are chronic diseases that affect young adults, the questions of *conception, pregnancy, and childbearing* will arise. Although there is some familial pattern to the occurrences of the inflammatory bowel diseases, transmission is not purely genetic, and there is ample evidence that when the disease is in remission, fertility is essentially normal, and healthy full-term infants can be delivered. However, conception might be a problem when the male patient is taking sulfasalazine (see above).

The issue of *cancer risk* in patients with long-standing and extensive ulcerative colitis can be addressed directly and clearly, reassuring those with minimal disease that their risk is no greater than that of the general population. Even those with extensive disease appreciate knowing the magnitude of the risk.

The primary physician can do much to prepare the patient who requires *colectomy* and subsequent *ileostomy*. Thorough patient education combined with a caring approach that includes a willingness to listen to concerns and fears is invaluable and greatly appreciated. Many patients have fears and anxieties that they will not discuss unless they are broached by the physician. Also helpful in preparation for ileostomy is to have an ileostomy patient of the same age and sex discuss the procedure and its consequences with the surgical candidate. Seeing that one can go on to lead a fully active life is comforting. Where available, a local association of ostomates is a valuable resource. Finally, the more widespread use of ileoanal anastomosis in carefully selected patients may increase the acceptability of surgery.

Many patients can be taught to *adjust their medication* within a prearranged set of guidelines and limits. Dosages of sulfasalazine to be used for mild exacerbations can be specified and extra supplies of medication can be provided, allowing the patient to play an active role in his or her care and ensuring prompt treatment of a flare-up. Antidiarrheal agents can also be provided for as-needed use but only to reliable patients who are not likely to abuse them. Patients should be *instructed to call* if fever develops, diarrhea worsens, bleeding occurs, or abdominal pain becomes marked.

The need for a steady exchange of information with the patient, including careful explanation of procedures and therapies, and the importance of close follow-up and availability cannot be overemphasized. Attentiveness and responsiveness alleviate much of the fear and worry that accompany inflammatory bowel disease and support the development of an effective therapeutic alliance. Additional information and support is available to the patient from the local Chapter of the National Ileitis and Colitis Foundation.

INDICATIONS FOR REFERRAL AND ADMISSION

Referral for gastroenterologic consultation is indicated when full dosages of sulfasalazine in combination with oral corticosteroids (± metronidazole in patients with Crohn's disease) fail to control symptoms. In addition, Crohn's disease patients who require high doses of chronic daily steroid therapy should be referred for consideration of immunosuppressive therapy. Ulcerative colitis patients with disabling, chronic, refractory disease ought to have a surgical consultation. The pancolitis patient with long-standing disease who is at increased risk for cancer needs referral for periodic colonoscopy and biopsy. Patients with extraintestinal disease should undergo an ophthalmologic consultation that includes a slit-lamp examination to check for uveitis.

Prompt hospitalization for parenteral management is indicated for patients who are toxic, bleeding heavily, in severe pain, or too sick to obtain adequate nutrition orally. Bowel rest, nasogastric feeding of elemental diets, and parenteral steroids are prescribed, and surgical consultation is obtained, especially if there is severe bleeding, toxicity, distention, or evidence of peritoneal irritation. Home nasoenteric feeding has been demonstrated for carefully selected patients with malabsorption and weight loss refractory to conventional outpatient therapy. Nocturnal tube feedings of a low-fat elemental diet can correct such nutritional problems, but the program requires patients who can insert their own feeding tubes at night.

MANAGEMENT RECOMMENDATIONS

Ulcerative Colitis

General Measures

- Document mucosal inflammation with sigmoidoscopy.
- Reduce dietary fiber during an exacerbation.
- Advise adequate rest and sleep.

- Prescribe a *folic acid* supplement (1 mg/d) when leafy vegetables are restricted or sulfasalazine is being used.
- Add oral *iron* supplementation (300 mg ferrous sulfate three times daily) when there is considerable rectal bleeding and documented iron-deficiency anemia.
- Schedule visits frequently in the early phases of the illness to provide psychological support and close monitoring. Phone checks are helpful.
- Prescribe a short course of opiate therapy (e.g., *loperamide* 2 to 4 mg or codeine 15 mg before meals and at bedtime) for temporary symptomatic control of troublesome diarrhea in patients with mild to moderate disease; avoid prolonged use and use in patients with severe disease (high risk of toxic dilatation).
- If mild diarrhea persists during remissions, initiate a trial of psyllium hydrophilic colloid (1 teaspoon in 8 oz of water once or twice daily); if this is still unsuccessful, try restricting milk products.
- Refer for consideration of periodic colonoscopy and biopsy those patients who have pancolitis lasting more than 8 years.

Mild to Moderate Disease

- Begin *sulfasalazine*, 500 mg four times a day with meals, and increase the dosage as tolerated over several days to 4 g/d. Continue this dosage for 2 to 4 weeks until symptoms abate, and then decrease it to the smallest dosage that maintains control of symptoms (usually 2 g/d, although sometimes 4 g/d are required).
- Substitute a nonsulfa 5-ASA preparation (e.g., *olsalazine*, 500 mg twice a day; *mesalamine*, 1 g four times a day) in patients who are sulfa allergic, cannot tolerate sulfasalazine, or experience a suboptimal response from sulfasalazine.
- If sulfasalazine or another 5-ASA preparation fails to achieve control within a few weeks, begin oral *prednisone*, starting with a dose of 40 mg/d. Initially give in divided doses for patients who are having symptoms round the clock but change to an every-morning program as soon as possible to limit the degree of adrenal suppression. Continue this dosage for 7 to 10 days.
- If control is achieved, begin tapering prednisone by 5 to 10 mg every 2 weeks to the lowest dosage necessary to suppress disease activity. An alternate-day program (using the same total weekly dose that maintains control) may be tried to minimize chronic steroid therapy side effects (see Chapter 105).
- Once steroids are tapered off and disease activity ceases, decrease sulfasalazine to a maintenance dose of 2 g/d and continue for at least 1 year to maintain remission. If olsalazine is being used, prescribe 1 g/d for maintenance.

Moderate to Severe Disease

- Start with *prednisone*, 60 mg/d in divided doses, and *sulfasalazine* at 4 g/d. Once the symptoms come under control, give the entire prednisone dose in the morning and begin tapering empirically by 5 mg/wk. Continue the sulfasalazine at 1 g four times a day indefinitely.
- If food intake is inadequate over time because of nausea or abdominal pain, consider supplementing the diet with a nutritionally balanced *low-residue liquid dietary preparation* (e.g., Magnacal, Ensure, Sustacal, Isocal).
- Monitor carefully for marked blood loss, volume depletion, severe abdominal pain, distention, and peritoneal signs; any of these is an indication for prompt hospital admission, parenteral therapy, and urgent surgical consultation.
- Refer for consideration of steroid-sparing immunosuppressive therapy (6-MP or azathioprine) patients requiring persistently high doses of steroids.
- Refer for consideration of elective surgery, patients refractory to maximal medical therapy, those requiring daily steroids for prolonged periods (more than 6 months), and those found on cancer screening to have a stricture or dysplasia.

Ulcerative Proctocolitis

- If disease is limited to the rectosigmoid, begin treatment with oral sulfasalazine (as noted above) or a topical agent. Enemas of *hydrocortisone or 5-ASA* are both effective topically. Hydrocortisone can be administered rectally using a 100-mg *retention enema* taken once nightly, a 25-mg *suppository* once or twice daily, or a 90-mg *foam* preparation once or twice daily. Selection of preparation can be based on patient preference and empirical results. Use a 5-ASA enema if there is concern about steroid absorption and systemic side effects. Dose is 2 to 4 g/d for acute symptoms and 1 g/d for maintenance. Continue therapy until symptoms clear; continue sulfasalazine or isoleucine for prophylaxis.

Crohn's Disease

General Measures

- Document the extent of disease by barium studies or colonoscopy. Postpone barium enema and colonoscopy until disease activity subsides.
- Limit the fiber content of the diet in patients with cramps and diarrhea.
- Decrease the fat intake to less than 80 mg/d when there is steatorrhea.
- Conduct a trial of restricting milk products from the diet of patients with diarrhea; if the diarrhea promptly improves, continue with a lactose-restricted diet.
- Supplement the diet with a multivitamin preparation that contains five times the normal daily vitamin requirements plus iron, calcium, magnesium, and zinc.
- Consider short-course opiate therapy (e.g., *loperamide* 2 to 4 g or codeine 15 mg with meals and before bed) for symptomatic relief of diarrhea; use caution, obstruction may be aggravated, and prolonged use can lead to narcotic dependence.
- Advise partial bowel rest and use of elemental low-residue dietary preparations when cramps and diarrhea are severe.
- Admit for refractory disease, severe bleeding, toxicity, abdominal pain, abscess formation, or evidence of obstruction. Such patients need surgical consultation.

Colonic Disease

- Begin *sulfasalazine* (500 mg four times a day) and quickly increase the dosage to 1 g four times a day over several days; continue for 4 to 8 weeks. Use *olsalazine* (500 mg twice a day) or *mesalamine* (up to 4.8 g/d) for the sulfa-intolerant patient or the patient unresponsive to sulfasalazine.
- If there is a response to sulfasalazine, continue for 4 to 6 months and then stop if symptoms have ceased. Maintenance sulfasalazine and olsalazine do not prevent recurrences, but there is a prophylactic benefit associated with mesalamine use. For maintenance, prescribe mesalamine at the lowest dose that sustains a remission (usually 2.4 to 3.6 g/day).
- If there is no response to 5-ASA agents, *switch to metronidazole* in doses of 10 to 20 mg/kg/d (e.g., 250 to 500 mg three times a day) and continue for a 4-week trial. If there is a satisfactory response, continue for 4 to 6 months, then stop if symptoms have ceased.
- If there is inadequate response to metronidazole, switch to *prednisone* 60 mg/d; four times a day dosages may be required at the outset for round-the-clock control.
- As disease activity subsides, give the entire dosage in the morning and begin tapering it to the lowest dosage that controls the symptoms (often as little as 5 mg/d). Continue this dosage until all evidence of disease activity ceases (and then at least for 1 year); an alternate-day schedule may suffice.
- For refractory disease or patients requiring chronic steroid therapy, refer for consideration of immunosuppressive therapy with *6-MP, azathioprine* (both 50 mg/d), or one of the newer anti-inflammatory/immunomodulator therapies (e.g., *methotrexate, infliximab*).

Perianal Disease

- Prescribe metronidazole (750 to 2,000 mg/d) for refractory perianal disease; a prolonged course of treatment may be necessary.

Ileal Disease

- The effectiveness of sulfasalazine for ileal disease is not well established, although some patients with mild disease may benefit. *Olsalazine* (500 mg twice a day) or *mesalamine* capsules (up to 4.8 g/day) may provide better results and is worth a 4- to 6-week trial.
- If there is no response or if ileal symptoms are severe, then prescribe *prednisone* (60 mg/d) and use in the same fashion as for colonic involvement (see above).
- Consider use of *6-MP or azathioprine* (50 mg/d) for patients with fistulas, refractory symptoms, or persistent requirements for very high steroid dosages. A 6-month trial is often necessary. Treatment is continued for 12 months and then cessation is attempted, although long-term therapy is sometimes necessary and successful in maintaining remission. Because immunosuppressive therapy can cause marrow suppression and carcinogenesis, gastroenterologic consultation is essential if it is to be used.

CHAPTER 74 APPROACH TO THE PATIENT WITH FUNCTIONAL GASTROINTESTINAL DISEASE

Functional gastrointestinal (GI) disease accounts for a large proportion of the GI complaints seen in office practice, not only in the primary care setting but also in the referral practices of gastroenterologists. The international working group consensus definition of functional GI disease is "a variable combination of chronic or recurrent GI symptoms not explained by structural or biochemical abnormalities. They include symptoms attributed to the pharynx, esophagus, stomach, biliary tree, small and large intestine or anorectum." Included under the rubric of functional GI disease are two common often troubling syndromes: *irritable bowel syndrome (IBS) and nonulcer dyspepsia*. The former is associated with large bowel discomfort or pain, disturbed defecation, and distention, often predominated by constipation, diarrhea, or gaseousness. The latter is characterized by upper abdominal discomfort, bloating, distension, and nausea, which is often but not necessarily exacerbated or triggered by eating. Another increasingly appreciated functional malady is *irritable esophagus* (sometimes referred to as esophageal spasm; see Chapter 61). In many cases of functional disease, there is a strong interplay between biopsychosocial factors and gut physiology.

The primary care physician needs to become expert in the recognition and management of these conditions, not only because they can mimic more serious disease (sometimes leading to unnecessary testing and treatment), but also because they are the source of much worry, functional impairment, and substantial health care expenditures.

IRRITABLE BOWEL SYNDROME

IBS is a functional disturbance of intestinal motility and visceral perception, strongly influenced by emotional factors. It accounts for about half of GI complaints seen by physicians. Epidemiologic studies suggest that nearly 20% of adults suffer from some form of the condition, although only a fraction actually seek medical attention. "Spastic bowel," "mucous colitis," and "spastic colitis" are less accurate terms sometimes used to connote the syndrome. When mistaken for organic disease, it can result in unnecessary testing or frustrating attempts at therapy. Careful diagnosis and a comprehensive approach to management (including a strong patient–doctor relationship) are essential to optimizing patient outcomes.

Pathophysiology and Clinical Presentation

The Emerging Pathophysiologic View of IBS is one of functional disturbances in motor activity and visceral perception, triggered or exacerbated by psychological distress and luminal irritants. *Abnormal motor function* is a hallmark of this syndrome, capable of producing both *diarrhea* and *constipation*. Both may occur in alternating fashion or one may predominate. Nonpropulsive colonic contractions and slow-wave myoelectric patterns at two to three cycles per minute constitute about 40% of electrical and contractile activity at rest in patients with IBS, compared with 10% in healthy patients. When excessive, these contractions may impede propulsion of stool, prolong transit time, and cause constipation. Diarrhea occurs when the increase in contractility is localized to the small bowel and proximal colon. A pressure gradient develops, causing accelerated movement of intestinal contents. Meals normally cause an increase in colonic contractions, but controlled study has shown that patients with irritable colon syndrome have a significantly exaggerated increase in motor response to food. Patients with diarrhea-predominant disease have more jejunal, fast, and high-amplitude contractions postprandially than do healthy individuals, resulting in reduced colonic transit time.

Abnormalities in motor function may help explain the constipation and diarrhea but do not adequately account for the *abdominal pain* and *anorectal discomfort* experienced. Recent balloon manometry studies of patients with IBS show *excessive sensitivity* to balloon distention in the ileum, rectosigmoid, and anorectum. In patients with a predominance of diarrhea, there are reduced thresholds for initiation of reflex motor activity and discomfort; urgency is precipitated at abnormally small volumes of balloon distention. In patients with constipation, the threshold for reflex motor activity is abnormally high, and emptying is delayed. Fecal material collects and hardens, and the bowel becomes distended. Pain ensues.

The combination of abnormal motor and sensory functioning has the potential to cause the patient much discomfort. For example, increased sensitivity can trigger excessive reflex motor activity, leading to a cycle of anorectal discomfort or pain before a bowel movement, a sense of incomplete evacuation after one, and increased frequency of movements. Data also suggest that patients with IBS experience alterations in flow of visceral sensory afferent data and abnormalities in its central processing, perhaps as a result of learned behavior or underlying psychopathology.

Situational stress has long been considered an important contributing factor. Hypermotility in response to stress has been documented in both healthy persons and patients with IBS, but the latter show a significantly higher frequency of life stress.

In addition, a high prevalence of *psychopathology* has been uncovered in patients with IBS presenting for care. Somatization, personality disturbances, anxiety, and depression are among the conditions frequently identified. Although it is well recognized that psychological stress may alter bowel function, careful study of IBS reveals psychopathology to be more a *predictor of illness behavior* than a direct cause of the bowel disease. Psychiatric symptoms and poor coping skills usually predate bowel complaints. Disturbances in bowel function can be especially troubling to patients with preexisting psychopathology and more likely to precipitate medical encounters than might similar symptoms in otherwise well-adjusted persons. This finding has been invoked to explain why only a fraction of patients with IBS ever present for medical care. Patients with IBS who do not consult physicians have been found to be psychologically similar to control subjects.

What seems to characterize the patient persistently bothered by symptoms is the greater prevalence of serious situational stresses, psychopathology, and perhaps learned visceral responses to bowel discomfort and threatening situations. Such factors may modify the underlying pathophysiology and illness behavior, determining severity of symptoms, frequency of episodes, and thresholds for seeking and continuing with medical care.

Recently, a greater appreciation has emerged for *intraluminal factors* that might alter bowel motor function and cause it to behave in an "irritable" manner, such as selective *malabsorption* of certain sugars, like *lactose* (the common dairy product sugar), fructose (the common citrus fruit sugar), and *sorbitol* (often found in "sugar-free" candy). Sorbitol is a common sweetener in candies and chewing gum and is capable of causing bloating and diarrhea if taken in large amounts, as are milk products in patients with lactose intolerance. One study suggests that *food allergies* may play a role in some patients. *Bile acid* malabsorption has been detected in up to 10% of patients with diarrhea-predominant IBS. The resulting large quantities of fatty acids descending on the colon can trigger painful rapid contractions, leading to marked discomfort and diarrhea.

Clinical Presentation is illustrated by a series of 50 patients treated in an outpatient unit. Most patients (62%) experienced onset of symptoms before age 40; 50% were under 30 at time of onset; and one fourth were under 20. *Chronicity* was the rule, with little change in symptoms over time, except for waxing and waning. Duration was in years. *Abdominal pain* was present in 90%, *mucous* stools in 36%, *pelletlike stools* in 38%, *diarrhea* alone in 10%, and *excessive flatus* in 36%. Fifty percent considered their symptoms related to stress, 34% denied this, and 66% manifested symptoms of anxiety or depression. Abdominal pain was most often in the left lower quadrant or lower abdomen (62%), but in 28% there were multiple sites of pain. Upper abdominal involvement occurred in 38%. The pain was typically achy rather than crampy, often relieved by a bowel movement or passage of flatus. It was unusual for the pain to awaken the patient. Radiation was variable and even extended into the left chest and arm when gas was trapped in the splenic flexure.

Small, hard, infrequent stools and an empty rectal ampulla characterize constipation. Prolonged retention of stool allows full absorption of intestinal water content. The diarrhea is typically small in volume, associated with visible amounts of mucus, and may follow a hard movement by a few hours. There may be urgency. Dyspepsia and excessive gaseousness are also reported (see above). Weight loss is rare; symptoms usually parallel situational stresses. Rectal bleeding is absent unless there is coincident hemorrhoidal disease.

Clinical Course

IBS is a chronic relapsing condition with no evidence of significant morbidity or mortality. A prospective British study providing follow-up at 2-month intervals over 3 years found that severity waxed and waned but the constellation of symptoms remained remarkably constant. At 1 year, 50% were unchanged, 36% improved, 12% were symptom free, and 20% were worse. The symptom-free period was usually less than a few months. One third of employed patients lost time from work. There was no correlation between time lost and number of visits to the doctor; 40% made five or fewer visits and 46% made none at all. At 2 years, a similar pattern was

found. Only one patient remained symptom free from the first year.

Studies on clinical course identified groups of patients with different prognoses. The group with symptoms triggered by a major life stress enjoyed long symptom-free periods after the acute problem abated, whereas those with continuous intestinalcomplaints in response to daily living rarely became asymptomatic.

Diagnosis and Initial Evaluation

Clinical criteria for diagnosis of IBS were specified by *Manning* and colleagues in the late 1970s. Although not derived quantitatively (e.g., by multiple regression analysis), these symptom-based criteria have been largely validated and are widely used for suggesting the diagnosis of IBS:

- Continuous or recurrent symptoms during several months of abdominal pain or discomfort relieved with defecation or associated with a change in frequency or consistency of stool, and/or
- An irregular or varying pattern of disturbed defecation at least 25% of the time, consisting of two or more of the following: altered frequency; altered consistency; straining, urgency, or feeling of incomplete evacuation; passage with mucus; and bloating or feeling of distention.

Although the sensitivity and specificity of the Manning criteria have, for the most part, been confirmed, there are some questions regarding the discriminant value of individual items. Moreover, some clinical situations require ruling out organic pathology that might resemble and be mistaken for IBS (see below). A combination of detailed history taking and careful physical examination, combined with selective parsimonious testing and a few diagnostic trials of therapeutic measures, will usually provide the best combination of completeness and cost efficacy.

The *Rome criteria* are another commonly used set of diagnostic criteria, very similar to the Manning criteria and often used for patient selection in clinical studies.

Overall Approach to Workup. Because many patients with IBS harbor fears of serious underlying disease, they commonly pressure physicians into ordering a plethora of diagnostic studies. Such cost-ineffective testing can be minimized by conducting a detailed history and careful physical examination that specifically elicits and addresses patient concerns, concluding the initial visit with a thorough review of key findings and their meaning (see below), and using the clinical presentation to determine the need for any further diagnostic testing. Often, the diagnosis of IBS can be made exclusively on clinical grounds. When a careful initial assessment is conducted, there is little risk of missing organic illness. Prospective studies with up to 30 years of follow-up have shown only a 1% rate of missed diagnoses of organic disease in patients carefully assessed at the outset.

When constipation predominates, it may be necessary to rule out a malignancy, particularly in patients over the age of 40 who have weight loss or a family history of colon cancer. In such patients, one needs to consider *flexible sigmoidoscopy with or without barium enema or colonoscopy* (see Chapter 65). In most others, a *stool test for occult blood* and a *complete blood count* (for microcytic anemia) should suffice. The absence of evidence for GI blood loss helps exclude organic disease. A clinical trial of *increased dietary fiber, stool softeners* (dioctyl sodium sulfosuccinate), or an *osmotic laxative* (psyllium) complements the diagnostic assessment. Patients taking diuretics should have a serum *potassium* checked, because hypokalemia may reduce bowel contractility and produce an ileus.

When diarrhea predominates, dietary review is essential for clues of intolerance to lactose or sorbitol. A check of *blood sugar* is needed to rule out diabetes mellitus (which may present as diarrhea due to diabetic gastroenteropathy; see Chapter 102), as is a check of the *stool for ova and parasites*. A diagnostic trial of eliminating sorbitol-containing candies and restricting lactose-containing milk products (yogurt containing live cultures are relatively lactose free) helps rule out contributions from intraluminal factors. A *lactose-hydrogen breath test* is an alternative means of testing for lactose intolerance. A trial of the bile acid-binding resin *cholestyramine* serves as a simple test for bile acid malabsorption. If diarrhea persists undiagnosed, a *sigmoidoscopy with or without mucosal biopsy* might be reasonable to exclude inflammatory bowel disease and collagenous and lymphocytic forms of colitis (see Chapter 64).

Abdominal pain and bloating necessitate ruling out obstruction. During an episode of pain, a timely *plain film of the abdomen* should suffice. Such bloating and discomfort may also occur with lactose, fructose, or sorbitol intolerance, which can be tested for as detailed above.

Psychological Assessment. Because the prevalence of underlying psychopathology is very high in patients with IBS, definitive therapy often requires identifying and addressing the patient's psychological difficulties. In the context of conducting a thorough workup, the clinician needs to sensitively elicit details of the patient's life situation, aspirations, accomplishments, frustrations, and losses. Concerns, fears, expectations, and responses to previous life stresses can also be very informative, as can the mental status of the patient on examination. *Anxiety disorders* are commonly identified (see Chapter 226), but *depression* (see Chapter 227) and *somatization* (see Chapter 230) often go unrecognized.

Principles of Management

Establishing a strong patient–doctor relationship, treating important underlying psychopathology, modifying diet, and supplementing these efforts with judicious use of medication constitute the basic approaches to management of the patient with IBS. No single treatment modality has proven successful in randomized placebo-controlled studies, but patient confidence in the diagnosis and a strong patient–doctor relationship are central to effective management. Such a relationship helps to minimize unnecessary repetition of diagnostic evaluations, dependence on drugs for provision of symptomatic relief, and excessive use of ambulatory medical services.

Establishing a Strong Patient–Doctor Relationship. The first rule in the care of patients with IBS is to *take their symptoms seriously* and not dismiss them as inconsequential. Such an approach communicates a sense of caring and is essential to the formation of an effective patient–doctor relationship, the *sine qua non* of IBS management. As noted earlier, it begins with a careful history and physical examination that addresses potentially serious etiologies, especially those of concern to the patient (e.g., cancer, inflammatory bowel disease). One cannot overemphasize the therapeutic importance of such an initial evaluation.

Once IBS has been identified (usually by the end of the initial or second office visit), the physician needs to *review the diagnosis* with the patient. Anxious emotionally troubled patients, such as those who present with IBS, often believe there is something seriously awry and will not accept a simplistic "there's nothing wrong with your bowels." They appreciate knowing the basis for their diagnosis and how more worrisome conditions were ruled out. In this way, the patient does not leave frustrated, feeling the "doctor cannot find what is wrong."

The establishment of a supportive *doctor–patient relationship* in conjunction with providing reassurance, explanation, and advice can have an important impact on outcome. When such care was given to patients in the prospective British study cited earlier, most reported feeling better, less concerned about their bowels, and more able to cope with their symptoms and the stresses of daily life. Although relapses were frequent, these seemed to be less important when they occurred in the context of close medical support. The failure of many physicians to provide adequate support is suggested by the 20% rate of self-referral to alternative medicine practitioners noted in patients with IBS. Developing a positive doctor–patient relationship has been found to be a key determinant in reducing use of ambulatory health services by IBS patients.

Management of Underlying Psychopathology. A distinguishing characteristic of patients who present to physicians with IBS is their high probability of underlying psychopathology. Often this is manifested by an exaggerated emotional response to bowel symptoms. Sometimes, the best intervention is withdrawing all previously prescribed medications and simply listening empathically to the patient's problems, helping them cope with their life situation. When specific underlying psychopathology is identified, treatment should be directed toward it. Success rates are high in such circumstances. When bowel symptoms are not due to a well-defined psychiatric illness, use of psychotropic agents is less effective and not recommended. Casual use of popular combination preparations such as a benzodiazepine/antispasmodic formulation should be avoided. A double-blind controlled study of 52 patients manifesting nonspecific anxiety showed that *diazepam* had no effect on bowel complaints compared with placebo.

Depression. Patients with IBS who manifest evidence of depression and receive antidepressant therapy have a high rate of improvement. Both *amitriptyline* and *desipramine* in low doses (50 to 100 mg qhs) have been found to be particularly effective in depressed IBS patients with diarrhea, due in part to their anticholinergic activity reducing bowel hyperactivity (see below). In patients with constipation, a tricyclic with strong anticholinergic effects may actually worsen symptoms. An antidepressant with minimal anticholinergic activity might be a better choice (e.g., a *selective serotonin receptor inhibitor* [SSRI] such as *sertraline* or a *tricyclic antidepressant* with minimal anticholinergic activity [*nortriptyline*]).

Chronic Anxiety. Many patients with IBS suffer from chronic anxiety, but one must be careful not to prescribe anxiolytics chronically because of their strong potential

for inducing addiction and causing withdrawal syndromes (see Chapter 226). An *antidepressant with anxiolytic properties* may be a reasonable substitute (e.g., *doxepin, nortriptyline, trazodone, or an SSRI*; see Chapter 227).

Somatization Disorder. Treatment of patients with somatization disorders first requires withdrawing the vast array of medications prescribed by the multitude of physicians they have visited over the years and then setting up regularly scheduled visits for them to talk about their symptoms and personal problems. Such supportive therapy by the primary physician often suffices to alleviate much of their complaining and need for medication (see Chapter 230).

Behavioral methods are worth considering in highly motivated patients. The emphasis is on changing behavior rather than on gaining insight. They provide a sense of control and enhance health-promoting behaviors. *Relaxation techniques* help those with exaggerated sympathetic responses to stress. Patients are taught how to blunt such responses and relax skeletal muscles. *Biofeedback* is used predominantly for treatment of fecal incontinence, aiming for improved control over internal sphincter activity. The method is expensive, but promising. *Hypnosis* has been used successfully to reduce pain perception.

Psychotherapy represents an important treatment option for patients who seek to deal with their illness through better understanding. To be successful, the therapy has to be viewed as personally relevant. The goal is learning to understand and cope with psychosocial stresses. Controlled studies have found psychotherapy plus medication to be superior to medication alone in reducing bowel symptoms. Methods range from traditional insight-focused therapy to cognitive-behavioral approaches, where the emphasis is on identifying stressors and thoughts that precipitate symptoms.

A *multifaceted approach* seems to be the best strategy. In a study of combined therapy that included medication, psychotherapy, and relaxation techniques, results were best when the treatment program used a combination of approaches. Predictors of a good response included presence of overt anxiety or depression, short duration of bowel symptoms, and absence of constant or diffuse pain.

Dietary Measures. Although a major part of the therapeutic effort in IBS involves redirecting the patient's attention away from his or her bowels, it is often necessary to provide patients with symptomatic relief before they are willing to turn their attention to the factors precipitating their symptoms. Dietary manipulations are sometimes helpful in this regard.

Foods that might exacerbate IBS should be avoided, including caffeinated beverages, alcohol, sorbitol-containing candies and gums, citrus fruits in those with fructose intolerance, and milk products in those who prove lactose intolerant. Reducing intake of such poorly digestible carbohydrates as beans and cabbage may help patients suffering from bloating, gas, and abdominal pain.

Many IBS patients insist they have *food allergies* as the cause of their symptoms. Although recent study suggests an increased incidence of food allergies in IBS, true food allergies are rare and typically cause acute hypersensitivity reactions, not chronic GI complaints. No changes in colonic motor activity have been found to occur in such patients on intake of the offending food. However, food intolerance (as noted above) is often noted in patients with IBS, and it may be worthwhile trying to avoid foods that seem poorly tolerated. Some food intolerance is mislabeled as IBS. For example, patients with gluten intolerance (adult celiac disease, nontropical sprue) may present with abdominal discomfort and diarrhea. Persistent diarrhea, bloating, cramping, and excessive flatus may be manifestations of underlying lactose intolerance. A 1- to 2-week trial of restricting a suspected offending food or substance is reasonablewhen clinical suspicion is high. On the other hand, patients who present having already restricted an unnecessarily large number of foods can have them added back. Rechallenging them with the purported offending agent rebuilds their confidence and avoids nutritional deficiency.

Increasing dietary fiber can help restore propulsive colonic motor activity. However, clinical studies examining bran and high-fiber diets have produced variable results, often no better than control diets due, in part, to a large placebo effect. In a double-blind trial of 50 patients eating a standardized bran biscuit or placebo, both groups reported subjective improvement in more than 50% of the subjects. A more recent controlled but unblinded British study of 26 patients showed significant improvement in symptoms and colonic motor activity in the bran-fed group compared with control subjects. Certainly there is no harm in prescribing a high-fiber diet, and it may have other health benefits such as reducing the risk of colon cancer (see Chapter 76). However, some patients report worsening of bloating and gaseousness with initiation of a high-fiber diet due to bacterial metabolism of nondigestible fiber, although this subsides with time. It is best to start with the equivalent of about 1 tablespoon of bran daily and build up to 3 tablespoons per day as tolerated.

An alternative is to use *bulking agents*, such as the hydrophilic colloid *psyllium* (Metamucil). A total daily dose of 15 to 25 g/d is necessary to achieve benefit and most helpful in IBS patients bothered predominantly by constipation. *Low-residue diets* have been tried. There is no evidence that they are of any use.

Drug Therapy. Pharmacologic intervention should proceed only in the context of a balanced program that includes patient education and support. Precipitously or prematurely resorting to pharmacologic measures in a hasty attempt to suppress symptoms completely can lead to frustration and excessive, even dangerous, escalations of drug intake. In fact, at the outset of therapy, it is often useful to *stop all nonessential medicines* that may affect bowel function, especially irritant laxatives. Nevertheless, there is a role for carefully selected short-term applications of medication when some symptomatic relief is deemed necessary.

Diarrhea. Patients suffering from disabling diarrhea may benefit from use of an opiate derivative. Transit time is prolonged, water and ion absorption is enhanced, and anal sphincter tone is strengthened. These effects result in less diarrhea, rectal urgency, and fecal soiling. *Loperamide* (in doses of 2 to 4 mg four times a day) is the preferred opiate derivative, being less habit forming and less likely to exert central nervous system effects than other derivatives, such as *tincture of opium* or *diphenoxylate*. Patients with diarrhea due to bile acid malabsorption experience improvement with *cholestyramine*. As noted earlier, those with an underlying depression may benefit from use of a tricyclic antidepressant with anticholinergic activity (e.g., *amitriptyline* 50 to 100 mg/d).

Constipation. No drugs have been proven safe and effective for use in IBS patients suffering from constipation. The prokinetic agent *cisapride* is under investigation and may soon be available. It facilitates acetylcholine release from the myenteric plexus. Although transiently helpful in patients with constipation, the drug appears best for dyspeptic symptoms. *Metoclopramide* does not act on the lower bowel and is not recommended for use in IBS. Drugs with anticholinergic activity should be avoided, because they are likely to worsen constipation. As noted above, if antidepressants are needed, it is best to select a preparation without anticholinergic activity (e.g., trazodone, fluoxetine).

Abdominal Pain and Distention. Patients suffering from postprandial pain and distention often request symptomatic relief. *Anticholinergic agents* have been used in such circumstances. The rationale is to reduce the cholinergic stimulation of colonic activity that occurs in response to a meal. The anticholinergic *dicyclomine* (10 to 20 mg before a meal) is the preparation most often recommended in this context. Although such agents have been shown to inhibit the postprandial increase in nonpropulsive colonic contractions, their clinical effectiveness is unproven. However, the consensus is that they are worth a try in cases in which nonpharmacologic measures have failed. They are best prescribed for short-term use. Chronic use should be avoided, because of the risk of worsening constipation and pain. *Combination preparations* containing a tranquilizer (e.g., a benzodiazepine or a barbiturate) and an anticholinergic are promoted as "*bowel relaxants*" or "*antispasmodics.*" They are heavily advertised yet of no proven benefit and best avoided because of their habituation potential and poor efficacy. Whether the newer anxiolytics, which are nonsedating and free of habituation potential (e.g., *buspirone* 15 to 30 mg/d), will prove beneficial remains to be proven. Studies are ongoing on the use of opioids, enkephalins, and other agents that have potential for blocking or modulating gut pain receptors.

Herbal Therapy. Herbal therapies have become very popular among patients who suffer from chronic functional conditions that resist a simple approach to cure. Most herbal therapies have not been subjected to scientific study. Chinese herbal medicine is a centuries-old remedy for GI symptoms. In the only randomized, double-blind, placebo-controlled trial to date using standardized preparations of Chinese herbal medicine in patients fulfilling standard diagnostic criteria for IBS, patients treated with the herbal preparation for 16 weeks showed significant improvements in scores for bowel symptoms and global state and in patient scores for daily functioning. Such intriguing preliminary findings need to be confirmed and more importantly need to prove durable over time, because symptoms returned rapidly in the above study after cessation of herbal therapy.

Patient Education

Because IBS is a condition characterized by an exaggerated response to symptoms, patient education is central to effective management. As noted earlier, the basic elements of the patient education effort include addressing patient fears, providing a specific diagnosis, and explaining the pathophysiologic basis of symptoms. In patients with symptoms triggered by psychosocial stress, an explanation (perhaps aided by diagrams) of how such stress can lead to functional alterations in bowel motility helps patients to better understand their condition and cope with it.

When important situational stress or psychopathology is uncovered, it needs to be discussed openly so that the patient can begin to focus on the underlying issues

rather than on bowel symptoms. Sometimes, having the patient keep a diary of symptoms, stresses, and feelings can help reveal connections that have otherwise eluded the patient. The major lesson to be mastered by patients with IBS is the relationship between their psychological state and symptoms, a message that often takes patience, sensitivity, and skill to communicate effectively. It is important not to push discussion and treatment of psychological issues beyond what the patient is prepared to accept. Patients initially unwilling to consider such issues should be respected, but once a supportive relationship is established, they often begin to cope better and spend less time obsessing about their bowels and more on the underlying issues triggering their "disease."

Patients not psychologically minded can still be helped greatly by changing the focus of their care from cure of symptoms to improvement in functional status. At each office visit, instead of asking for an in-depth recitation of bowel complaints, the physician spends more time inquiring into how the patient is dealing with the demands of daily life and helping the patient to cope with them. The visit agenda shifts from eliminating symptoms to solving problems. Such a shift is often remarkably refreshing and revealing; it helps improve functional capacity and reduces the intensity of bodily complaints.

Indications for Referral and Admission

This is a condition in which a continuous relationship is essential, and any perceived need for referral should be acted on only after thorough discussion with the patient. In general, referral is helpful when there are refractory disabling symptoms, such as uncontrollable diarrhea, or when serious psychopathology is encountered. Less disturbed patients may also benefit from psychiatric referral, but only if the patient is accepting of a psychological dimension to the illness and is motivated to delve into it. A hospital admission may, in rare circumstances, be appropriate and very beneficial in helping the patient to learn new means of coping with stress and providing a respite from an intolerable living situation.

Management Recommendations

- Take the patient's bowel complaints seriously; do not minimize their importance or deny their "reality."
- Elicit a full psychosocial database and a complete history of the patient's bodily symptoms.
- Conduct a thorough workup that includes a detailed investigation of all possible etiologies, both organic and psychological.
- Provide a thorough explanation of the diagnosis and directly address the patient's concerns and fears.
- Establish a supportive relationship and begin supportive psychotherapy for patients with underlying situational or psychosocial stresses.
- Identify, discuss, and treat specifically any underlying depression (see Chapter 227), anxiety disorder (see Chapter 226), somatization (see Chapter 230), or other psychiatric condition.
- When treating a depressed patient with antidepressant medication, consider its degree of anticholinergic activity and match it appropriately to bowel symptoms (e.g., amitriptyline 50 to 100 mg qhs is helpful for the patient with diarrhea; an SSRI [e.g., sertraline 25 mg/d] is a better choice in the patient with IBS bothered by constipation; see Chapter 227).
- Stop all nonessential medicines that may affect bowel function, especially irritant laxatives.
- For the patient bothered predominantly by constipation, increase dietary fiber and recommend regular exercise. Add a bulking agent such as psyllium (Metamucil), 1 rounded teaspoon in 8 oz of water three times a day if constipation is still troublesome. A stool softener (e.g., dioctyl sodium sulfosuccinate) is sometimes helpful.
- If the patient finds abdominal pain and distention intolerable, resort to a trial of anticholinergic therapy (e.g., dicyclomine 20 mg four times a day), but only if other measures have failed. It may also be useful for diarrhea. Use only for a short period of time. Tricyclic antidepressants with anticholinergic activity may also be worth a trial (e.g., amitriptyline 50 to 100 mg qhs), but avoid these if constipation is bothersome.
- For the patient with diarrhea, evaluate first for underlying bowel pathology (e.g., parasitic disease, colitis; see Chapter 64) and then limit intake of potentially contributing substances such as caffeine, sorbitol-containing candies and chewing gums, alcohol, and dairy products (except for yogurt preparations). When short-term symptomatic relief is essential, prescribe a 2- to 5-day supply of loperamide, 1 tablet twice a day as needed. Exercise caution with opiate use because of its addiction potential in this chronic condition.
- For patients with refractory diarrhea, consider a diagnostic trial of cholestyramine (4 g three or four times a day), which will counter any concurrent bile acid malabsorption.
- Major dietary restrictions are usually unnecessary. However, if there is a strongly suggestive history of intolerance to a food or substance, consider a 1- or 2-week trial of omitting its intake. Sorbitol and lactose are the most common offenders.
- Despite the presence of chronic anxiety, avoid use of sedatives, tranquilizers, and combination preparations containing benzodiazepines or barbiturates. The risks of habituation and withdrawal outweigh any benefit. Antidepressants with anxiolytic activity (e.g., amitriptyline, trazodone, doxepin) are reasonable alternatives, as might be the nonaddicting azapirone anxiolytics (e.g., buspirone).
- Help redirect the patient's attention away from bowel symptoms and endless searches for cure and toward better coping with daily stresses; focus on accomplishments rather than symptoms, on taking control through exercise, good eating habits, and behavioral changes rather than on repeated recitation of symptoms.
- For motivated patients with well-identified psychosocial stressors, consider referral for a combination of behavioral techniques and psychotherapy.
- At this time there is insufficient evidence to recommend a trial of Chinese herbal medicine.
- See patient at regular intervals and be available for help at times of increased stress.

NONULCER DYSPEPSIA

Nonulcer dyspepsia is a poorly defined condition characterized by recurrent upper abdominal pain and discomfort that frequently, but not exclusively, occurs with eating. The discomfort may encompass bloating, nausea, distention, early satiety, and anorexia. The term *dyspepsia* literally means "bad digestion," although it is not meant to be synonymous with or inclusive of other symptoms of "indigestion" (such as heartburn, eructation, or regurgitation). Rather, the emphasis is on the abdominal pain, which may resemble the discomfort of peptic ulcer disease, thus the term "nonulcer." Older terms for this condition also alluded to its ulcer-negative status, including "x-ray–negative dyspepsia" and "functional dyspepsia."

Nonulcer dyspepsia is twice as prevalent as ulcer-related dyspeptic disease and one of several GI conditions that can cause upper abdominal pain in the absence of an ulcer (see Chapter 58). Billions of dollars are spent annually on its evaluation and treatment, yet remarkably little is known about its pathogenesis. However, new data are emerging, and the primary care physician needs to understand the relative importance of diet, smoking, acid secretion, gastric motility, stress, and *Helicobacter* infection to fashion a rational and cost-effective treatment plan.

Pathophysiology, Clinical Presentation, and Course

Mechanisms. The pathophysiology of nonulcer dyspepsia remains largely unknown. A number of factors have been proposed, and as in many other functional disorders, the etiology is probably multifactorial.

Dysmotility. Among the most consistent abnormalities is disordered upper GI motility. Gastric emptying is delayed, and gas transit is slowed in about half of dyspeptic patients. Distention and bloating are common and thought to be manifestations of this slowing.

Altered Nociception (visceral perception) is suggested by the increase in pain reported by about half of dyspeptic patients to intragastric balloon inflation at volumes that do not cause pain in normal persons.

Psychological Factors. Patients who present with dyspepsia have higher frequencies of anxiety, depression, and neuroticism, and exacerbations of symptoms often coincide with increases in situational stress. However, investigators cannot tell if this pattern is because of the role of psychological factors in dyspepsia or because of the role of such factors in health-seeking behavior. It is noteworthy that persons with dyspepsia report greater stress in their lives.

Excessive Acid Production. Although excess acid production may play some role in nonulcer dyspepsia (especially patients who go on to develop a peptic ulcer), it does not appear to be the predominant pathogenic factor. Patients and control subjects show little difference in gastric acid secretion. H2-blocker therapy and antacids are little better than placebo in providing relief, but combination therapy and use of proton-pump inhibitors does provide relief for some patients, probably those with an underlying ulcer "diathesis" or concurrent esophageal reflux.

Helicobacter Infection. Of great interest has been the contribution of *Helicobacter pylori* infection because it can cause gastritis. *H. pylori* infection is present in about 60% of cases of nonulcer dyspepsia, but this high frequency is not much greater than that for the population at large. Large-scale, randomized, placebo-controlled

studies of eradicating *Helicobacter* infection have shown only modest benefit (e.g., 25% long-term cure rates compared with rates of 7% to 21% in omeprazole-treated control subjects). These results indicate that although *Helicobacter* infection may be important in a small subset of patients, it is not the major causative that was hypothesized.

Maldigestion/Malabsorption of Carbohydrates. Dyspeptic symptoms are common in persons with lactase deficiency and those who take in large amounts of nonabsorbable sugars through heavy use of chewing gum, diet foods, and related products with sorbitol, fructose, or mannitol.

Other Factors. A number of other potential precipitants have been examined. *Smoking, alcohol, coffee, and tea* were not found to have any relation to nonulcer dyspepsia. Although *fatty food intolerance* is a common complaint in dyspeptic patients, controlled studies using disguised meals fail to confirm fatty foods as precipitants. *Bile reflux* has been proposed and when found can cause dyspepsia-like symptoms, but no increase in bile concentrations have been found in dyspeptic patients who have not undergone prior surgery. *NSAIDs* and *aspirin* are well-recognized gastric irritants, but in case-controlled studies no relation was found between their use and nonulcer dyspepsia.

Clinical Presentation. Recurrent upper abdominal pain and discomfort are the hallmarks. In about half of instances, symptoms are associated with meals. Bloating and gaseous distention may accompany the pain. Acid reflux, biliary colic, painful or altered defecation, and chronic pain are not considered part of its presentation but rather features of other forms of nonulcer upper abdominal pain; however, they often coexist with dyspepsia (e.g., 25% of dyspeptic patients also report reflux symptoms).

Clinical course is benign, with little evidence that the condition ultimately leads to peptic ulceration or other forms of upper GI pathology. Previously, nonulcer dyspepsia was seen as part of a continuum that progressed to duodenitis and frank peptic ulceration, but this suspicion has not been confirmed (although a small subset of patients go on to develop a peptic ulcer). Typically, the condition is chronic. Although it may wax and wane, it usually does not worsen substantially.

Workup

Because the symptoms of nonulcer dyspepsia are nonspecific and may mimic more serious pathology, the diagnostic task is to rule out the must-not-miss etiologies. At the top of the list are gastric carcinoma, complicated peptic ulcer disease, and erosive esophagitis and low-grade chronic pancreatitis, biliary tract disease, and IBS. Upper GI endoscopy can readily identify and distinguish among many of these conditions—particularly gastric cancer, peptic ulcer, and esophagitis—but the high frequency and harmlessness of nonulcer dyspepsia and the high cost of endoscopy necessitate some risk stratification.

Upper Endoscopy. Selectivity is necessary for cost-effective workup. If everyone was studied endoscopically at the time of initial presentation, the yield would be extremely low and the testing would be wasteful, because most will have nonulcer dyspepsia and a normal study. Most authorities recommend a workup strategy based on risk stratification for the serious pathology noted above. Consensus criteria cite age older than 45 years (or any other demographic risk factor for gastric cancer) and unexplained weight loss, persistent nausea and vomiting, dysphagia, odynophagia, jaundice, iron deficiency anemia,or a positive guaiac stool test as indicative of increased risk of serious underlying pathology. Although a relatively low threshold is set for endoscopy by using a cutoff age of 45 years (some use older than 50 years, others older than 55 years), the cost of endoscopy can be quickly surpassed by indefinite unnecessary use of commonly used empiric therapies (e.g., acid suppression, prokinetic agents), not to mention the cost of delay in diagnosis of a more serious potentially treatable condition and the persistent worry about cancer by the patient.

These recommendations are based on cost-effectiveness analyses; they need to be validated by prospective study. Nonetheless, those who are deemed low risk can skip endoscopy and proceed to consideration of Helicobacter testing (see below). Subsequent endoscopic investigation of low-risk patients deserves consideration in those who fail to respond to a trial of empiric therapy or later develop any of the manifestations suggestive of more serious disease.

Testing for *H. pylori* Infection. Low-risk patients benefit from testing for *Helicobacter* infection, because eradication cures symptoms in the 20% of *Helicobacter*-positive dyspeptics who prove to have a peptic ulcer or a peptic ulcer "diathesis" and the 20% of *Helicobacter-positive* dyspeptics with nonulcer dyspepsia who respond to eradication of the infection. Serologic study for *Helicobacter* antibodies (see Chapter 68) usually suffices for this purpose.

Other Studies. The clinical presentation can also determine the need for other investigations. Patients with heartburn are likely to have gastroesophageal reflux and should be worked up accordingly (see Chapter 61). Patients reporting paroxysmal attacks of constant epigastric or right upper quadrant pain lasting a few hours and radiating into the back require consideration of biliary tract disease and *abdominal ultrasound* and *liver function testing* (see Chapter 69). Unrelenting upper abdominal pain radiating into the back, especially if alcohol related, suggests chronic pancreatitis. Serum *amylase* and abdominal ultrasound are indicated (see Chapter 72). Altered bowel habits in conjunction with upper abdominal pain argue for IBS involving the transverse colon; colitis and bowel cancer may need to be ruled out by *colonoscopy or barium enema* (see above).

Principles of Management

Given the poor understanding of the precise pathophysiology of nonulcer dyspepsia, its likely multifactorial nature, and the lack of tight correlation between clinical presentation and response to treatment, it should not be surprising that there is little consensus on how best to treat the condition. Options include eradication of *Helicobacter* infection, chronic acid suppression, prokinetic therapy, dietary manipulations, and psychotherapy.

Eradication of *Helicobacter* Infection. Those who are *Helicobacter*-positive are reasonable candidates for eradication of the *H. pylori* infection (see Chapter 68), even though most test-positive nonulcer dyspeptics are unlikely to respond. Because there are other benefits to *Helicobacter* eradication beside cure of dyspeptic symptoms (see Chapter 68), treatment is not without merit even if there is no response clinically.

Acid Suppression. Contrary to common belief, there is little evidence that acid-inhibiting or acid-neutralizing treatment significantly improves symptoms in patients with documented nonulcer dyspepsia. Much of the confusion about the efficacy of such antiulcer therapy seems to result from a substantial placebo effect, the heterogeneous nature of patients with dyspepsia, and poor characterization of patients in many studies. Randomized controlled trials have failed to demonstrate consistent benefit from use of antiulcer therapy in patients with carefully documented nonulcer dyspepsia. This correlates with data showing little excess acid production in most of these patients. Those who respond to empiric therapy may be the subset with an underlying peptic ulcer diathesis. Some interpret response to empiric proton-pump inhibition as a sign of underlying gastroesophageal reflux or peptic ulcer disease. More and better data are required to clarify the use of these very expensive drugs in dyspepsia. In the meantime, physicians are likely to continue prescribing acid-suppression antiulcer therapy empirically because there is little else to offer patients. If such therapy is to be offered, it should be given for a limited time and not continued if symptoms fail to resolve.

Enhancing Gastric Motility. If indeed nonulcer dyspepsia is a disease of altered upper GI motility, then drugs that facilitate such motility would be expected to be beneficial. *Metoclopramide*, the original dopaminergic blocking agent available for stimulating gastric motility, provides some benefit as short-term therapy. Unfortunately, long-term administration of the drug is associated with risk of tardive dyskinesia, making it inappropriate for prolonged use. *Cisapride* is the first of another class of prokinetic agents that release acetylcholine at the myenteric plexus to stimulate upper GI motility. It appears better tolerated than metoclopramide, but data on its efficacy and long-term safety are still pending. A proarrhythmic effect has been noted and caution is indicated when used with other agents (see Chapter 61).

Diet, Alcohol, Smoking, and Stress. No data indicate that a low-fat diet, restriction of alcohol, cessation of smoking, or reduction of stress have any consistently positive effect on nonulcer dyspepsia. The lack of effect may be as much a function of the heterogeneous nature of the dyspeptic population as it is an indication of true absence of benefit. Most authorities recommend taking a careful history to identify any precipitants and responding to them. In otherwise refractory cases where there is a clearcut association between dyspepsia and psychosocial factors, the latter should be addressed thoroughly (see Chapter 226, Chapter 227), and Chapter 230).

Patient Education and Indications for Referral

Patients who present with recurrent upper abdominal pain are fearful of cancer and other serious forms of GI pathology. For many, the first priority is knowing that they do not have a life-threatening illness. As with any disorder that can mimic more worrisome illness, the patient's concerns should be taken seriously and addressed directly (see the Reassurance section on IBS above; the same principles and approach apply here).

Referral to a gastroenterologist is indicated when endoscopy is considered. The most appropriate candidates are those at increased risk of gastric malignancy and other serious upper GI pathology (see above). At times, a consultation with the gastroenterologist will help reassure the low-risk but overly concerned patient, although the need for such referrals can be kept to a minimum by thorough patient education and support.

CHAPTER 75 MANAGEMENT OF DIVERTICULAR DISEASE

Diverticula, abnormal herniations of colonic mucosa through the muscularis, are extremely common and increase with age. Autopsy studies estimate their presence in 20% of people over 40 and in 70% of those over 70. About 15% of people with the condition develop attacks of *diverticulitis*, in which the diverticula become plugged and inflamed. It is possible that the recent emphasis on increasing the fiber content of the diet will reduce the incidences of diverticula and their complications in Western countries. The primary physician encounters many elderly patients with gastrointestinal (GI) complaints referable to diverticular disease. The physician must effectively and economically recognize and treat mild manifestations of disease, reduce the chances of complications, and decide when admission and surgical intervention are necessary.

PATHOPHYSIOLOGY, CLINICAL PRESENTATION, AND COMPLICATIONS

Pathophysiology. Increased intracolonic pressure causes herniation of colonic mucosa. Consequently, diverticula occurmost frequently in the sigmoid colon, where the colon is narrowest and pressure is greatest; however, diverticula can occur anywhere within the colon, including the ascending portion, which makes for atypical clinical presentations. Diverticula show a predilection for points of relative weakness in the muscularis, especially where branches of the marginal artery penetrate the colonic wall. The possibility of muscular degeneration has been suggested but remains unproven. Current research indicates that the *low fiber content* of modern diets has an important causal role, producing less bulky stool and increased intracolonic pressure. *Irritable bowel syndrome*, with its abnormal colonic motor activity and segmentation, might contribute to diverticular formation by way of increased intraluminal pressures.

The diverticular sac that ensues is a thin purely mucosal structure. Obstruction of the sack's neck by undigested food residues or a fecalith leads to distention and *microabscess* formation as mucous secretions accumulate and bacteria proliferate. If the blood supply to the sac becomes mechanically compromised, the sac may perforate. *Microperforations* commonly occur, producing peridiverticular and pericolonic inflammation and abscess formation. Walling off is the rule because these perforations typically occur adjacent to mesocolon. The bowel lumen is typically uninvolved. Even if a peridiverticular abscess ruptures into the peritoneal cavity, gross peritonitis from fecal soilage usually does not occur because the diverticular neck is sealed by obstructing material.

A less common but potentially catastrophic complication of diverticular disease is *free colonic perforation*, which occurs from rupture of an uninflamed diverticulum. Fecal soilage follows, because there is no plug in the diverticular neck to prevent leakage of bowel contents. Frank peritonitis is the consequence.

Clinical Presentation and Course. *Diverticulosis* is usually asymptomatic and often discovered incidentally on barium enema. However, colonic motor activity is sometimes disturbed, and intermittent left lower quadrant pain may result. Constipation is common, as is constipation alternating with diarrhea, and occasionally there is tenderness.

Diverticulitis is characterized by left lower quadrant pain, tenderness, fever, and leukocytosis in a patient with known diverticulosis. Frequently a tender mass is noted. Right-sided presentations are possible, especially in Asian populations, and may mimic appendicitis or Crohn's disease. The diagnosis is made clinically during an acute attack and confirmed later by barium enema, once the risk of perforation subsides. At times, the radiologic findings resemble those of cancer or Crohn's disease, and colonoscopy is needed for more definitive evaluation. In rare instances, there are extraintestinal manifestations (arthritis, pyoderma gangrenosum) that may simulate those of Crohn's disease and lead to misdiagnosis. Bladder symptoms (dysuria, urgency, frequency) may occur if the process occurs adjacent to the bladder or bladder nerves.

The major *complications* of diverticular disease are perforation, obstruction, and bleeding. *Perforations* may lead to abscess formation. The abscesses may spontaneously drain into the bowel or erode into an adjacent organ, such as the ureter, bladder, or vagina, forming *fistulas.* Perforations that fail to become walled off may cause peritonitis. Those that enter the vagina result in vaginal gas or feces; those that erode into the urinary tract lead to dysuria or pneumaturia. Chronic inflammation can thicken the bowel wall and cause *obstruction.* Erosion into a blood vessel may result in brisk rectal *hemorrhage*. Diverticular disease is one of the most common causes of lower GI hemorrhage and a leading consideration in patients who present with brisk rectal bleeding (see Chapter 63). In a 15-year study from the Lahey Clinic, the incidence of hemorrhage, obstruction, or perforation from diverticular disease was 15%.

DIAGNOSIS

Diverticulosis. As noted earlier, diverticulosis is usually an incidental finding in a patient undergoing a *barium enema or colonoscopy* for another reason. However, the diagnosis should also be considered in a patient presenting with relatively painless but brisk rectal bleeding. If the bleeding is not too severe, *proctosigmoidoscopy* can be performed to confirm the diagnosis and site of blood loss.

Diverticulitis. The diagnosis of acute diverticulitis should be suspected in an older patient who presents with new onset of left lower quadrant abdominal pain, low-grade fever, focal tenderness with or without guarding, and an elevated white blood cell count. In rare instances, the pain may be suprapubic or localized to the right lower quadrant if there is a redundant sigmoid or a right-sided diverticulum. Nausea, vomiting, and diarrhea or constipation may accompany the bowel complaints and simulate gastroenteritis. Absence of bowel sounds suggests peritoneal inflammation. In situations of diagnostic uncertainty, confirmatory testing can be obtained.

Computed tomography (CT) of the abdomen has become the test of choice for immediate confirmation of acute diverticulitis, supplanting barium enema. Although more expensive than barium enema, CT has proven more cost effective. Diagnostic findings include inflammation of pericolic fat, peridiverticular abscess, thickening of bowel wall more than 4 mm, and presence of diverticula. The test can be used to differentiate cancer from diverticulitis and provides the opportunity for guiding needle aspiration and drainage of large abscesses (greater than 5 cm). Although CT is the current diagnostic test of choice, it is not without its shortcomings. The false-negative rate can be as high as 20%, due in part to inability to detect small abscesses and to differentiate tumor from diverticulitis when there is marked bowel wall thickening.

Proctosigmoidoscopy performed with a flexible sigmoidoscope can be done comfortably, safely, and with a minimum of bowel preparation when it is essential to rule out other causes of serious colonic pathology, such as inflammatory bowel disease and cancer. Inability to pass the flexible sigmoidoscope beyond the rectosigmoid junction due to acute bowel inflammation is strongly suggestive of acute diverticulitis.

Barium enema can demonstrate diverticulitis; the finding of contrast outside the bowel lumen is an important diagnostic feature. However, many clinicians are reluctant to order a barium enema during the acute phase of illness, because of concern that the air insufflation used to perform the test might sufficiently increase intraluminal pressure to dislodge the obstructing diverticular plug and cause bowel perforation and fecal soilage. Although this concern is disputed, it is common practice to delay performing a barium contrast study until after inflammation quiets down. The diagnostic accuracy of bariumstudy has been questioned by some investigators, especially its ability to differentiate between diverticular disease and malignancy, which is better detected by endoscopic study.

Differentiating Diverticulitis from Colon Cancer. One of the most important diagnostic tasks in the assessment of suspected diverticulitis is differentiation from colon cancer. Both produce similar clinical presentations and similar radiologic findings on barium enema. CT at the time of initial diagnosis sometimes can help make the distinction, but sensitivity falls in the setting of marked bowel wall thickening. Lower GI *endoscopy* is the more definitive test, allowing for direct visualization and biopsy if tumor is present. The test is usually done after acute symptoms have quieted down.

PRINCIPLES OF MANAGEMENT

Diverticulosis. The goals of therapy are prevention of symptoms, relief of pain, and avoidance of complications. Because diverticular disease is believed to be, in part, a manifestation of a low-fiber diet, *bran* has been tried in therapy. Prospective British studies of bran use have shown reversal of abnormal bowel physiology and

reduction in symptoms in over 90% of cases. The average amount of bran needed to achieve an effect is 15 g/d. Some individuals are bothered by flatulence and bloating during the first 2 to 3 weeks of bran use, but this usually resolves with continued bran intake.

Patients unable to tolerate bran may be treated with bulk agents such as *psyllium* (Metamucil). Irritant laxatives should be avoided. The efficacy of *anticholinergics* is controversial; painful spasm may be lessened, but the risk of constipation is increased, raising the likelihood of inspissation of fecal material. Indigestible materials (e.g., seeds) that may block the mouth of a diverticulum should be omitted from the diet.

Acute Diverticulitis. This can be treated at home when symptoms are mild and there is no evidence of widespread peritoneal inflammation. A key requirement is ability to maintain good oral intake of fluids. One aim of therapy is to markedly reduce bowel activity and thus lessen the chance of perforation. *Rest* and *clear liquids* usually suffice. Strong analgesics and antipyretics should not be prescribed because they may mask signs of worsening inflammation. A course of broad-spectrum oral antibiotics is commonly prescribed (e.g., *trimethoprim-sulfamethoxazole* or *ciprofloxacin*, plus *metronidazole* for anaerobic coverage), especially when there is fever, although its efficacy is unproven. Antibiotic treatment is continued for 3 to 5 days beyond resolution of fever.

An important decision in the therapy of diverticulitis is whether to treat the patient medically or opt for *elective surgical resection* of the involved bowel after initial resolution of symptoms. Proponents of surgical therapy argue that the frequency of complications warrants prophylactic operation once a patient experiences an attack of diverticulitis. The courses of 132 patients at Yale–New Haven Hospital with documented uncomplicated diverticulitis were analyzed. Of the 99 treated medically and 33 treated surgically, the rates of recurrence were almost identical. Moreover, three fourths of the patients never had more than one attack. The increased length of hospitalization and postoperative morbidity were not balanced by any marked reduction in rate of recurrence or complications. However, the presence of abscess, perforation, or obstruction is an indication for *immediate surgery*. Although controlled data are lacking, most authorities recommend treatment with a high-fiber diet after acute symptoms have ceased.

INDICATIONS FOR ADMISSION AND REFERRAL

The development of a temperature greater than 101°F on antibiotic therapy, inability to take fluids orally, or worsening or persistence of pain or peritoneal signs indicate need for admission. Sometimes, a markedly elevated white blood cell count may be the only clue to a deteriorating situation; many patients with diverticulitis are elderly and may not demonstrate much fever, abdominal pain, or peritoneal signs. The management of a patient with bleeding, abscess, or perforation requires surgical consultation; operative intervention may be urgent.

THERAPEUTIC RECOMMENDATIONS AND PATIENT EDUCATION

Diverticulosis. For the patient with known diverticula and occasional pain or constipation, the following recommendations should be observed:

- Increase the fiber content of the diet. The best sources are bran, root vegetables (particularly raw carrots), and fruits with skin. Bulk laxatives such as psyllium hydrophilic mucilloid (Metamucil) can be used in patients who cannot tolerate bran, but these are relatively expensive.
- Inform patients that any bloating or flatulence due to bran intake usually resolves with continued use.
- Advise patients to avoid foods with seeds or indigestible material that may block the neck of a diverticulum, such as nuts, corn, popcorn, cucumbers, tomatoes, figs, strawberries, and caraway seeds.
- Have patients avoid laxatives, enemas, and opiates because they are potent constipating agents.
- Anticholinergics are worth considering in patients with recurrent cramping pain, but they may increase constipation and the risk of inspissation of fecal material.
- Instruct patients to report fever, tenderness, or bleeding without delay.

Diverticulitis. For patients with mild diverticulitis (temperature less than 101°F, white cell count below 13,000 to 15,000), the following recommendations should be observed:

- Prescribe bedrest and a clear liquid diet.
- Use mild nonopiate analgesics for pain.
- Monitor temperature, pain, abdominal examination for signs of peritonitis, and white blood cell count for elevation.
- If the patient is febrile, consider a broad-spectrum antibiotic program (e.g., trimethoprim-sulfamethoxazole DS 1 tablet twice a day or ciprofloxacin 500 mg twice a day, plus metro-nidazole 500 mg four times a day) and continue until patient is afebrile for 3 to 5 days.
- Arrange for prompt hospitalization if temperature goes above 101°F despite antibiotics, pain worsens markedly, peritoneal signs develop, or white cell count continues to rise.

CHAPTER 76 MANAGEMENT OF GASTROINTESTINAL CANCERS

ALLAN H. GOROLL

INTRODUCTION

Gastrointestinal malignancies are among the most common tumors found in adults. The treatment of local disease is the province of the surgeon, but management of advanced disease is a responsibility often shared by the primary physician in close conjunction with oncologic colleagues. It is important for the primary physician to know the indications, limitations, efficacy, and side effects of available treatment modalities to help counsel the cancer patient and make best use of therapies offered by the surgeon, radiation therapist, and oncologist.

Recent developments in combining chemotherapy and radiation therapy with surgery for treatment of gastrointestinal cancer have added substantially to palliation and potential for cure, although mortality is still high (50% to 80%). Moreover, improvements in management of the gastrointestinal complications of cancer, such as obstruction, ascites, and cachexia, have improved the quality of life for these patients (see Chapter 91).

ESOPHAGEAL CANCER

Carcinoma of the esophagus is difficult to diagnose and treat because symptoms usually do not occur until late in the course of illness. As a result, by the time symptoms develop, palliation is often the only therapeutic option. Of the 12,000 new cases of esophageal cancer diagnosed annually, less than 10% survive 5 years. Consequently, emphasis is on early detection and prevention. There are two histologic types: epidermoid (squamous cell) and adenocarcinoma; they currently occur with about equal frequency, but adenocarcinoma is increasing in frequency more rapidly than any other cancer in the United States.

Risk Factors. Precipitants of epidermoid carcinoma include heavy smoking, excessive alcohol use, achalasia, and distant lye ingestion. The risk factors for adenocarcinoma are less well established, but chronic severe gastroesophageal reflux is a principal etiologic factor; both duration and severity contribute to risk.

Clinical Presentation. Adenocarcinoma often appears in the setting of *Barrett's esophagus*, a premalignant metaplastic change that is the consequence of prolonged severe acid reflux disease. Barrett's esophagus has a significant potential for dysplastic transformation leading to malignancy (see Chapter 61). Aside from heartburn, such patients are usually asymptomatic at the time of malignant transformation.

The first symptoms of esophageal cancer may go unnoticed because they can be nonspecific (e.g., a mild burning discomfort associated with swallowing, sometimes referred to as *odynophagia*). More typically, the symptoms at time of presentation include *dysphagia* and progressive *inanition*, manifestations of late disease. Dysphagia indicates a markedly narrowed esophageal lumen and a substantial tumor burden.

Although these tumors begin as superficial mucosal lesions, they tend to spread silently under the mucosa and extend readily into the mediastinum, because the esophagus has no serosal surface barrier. Tumor may extend regionally into the trachea and regional lymph nodes and vertically up and down the esophageal mucosa and submucosa. Distant metastases occur in the liver and intraabdominal node-bearing areas. At the time of diagnosis, less than one third of patients have cancer confined to the esophageal wall, the stage in which cure is possible with surgical resection.

Diagnosis. Early diagnosis is among the best means of improving outcome and requires a high index of suspicion. Patients with a long-standing history of severe heartburn should be considered for *endoscopy* and *biopsy*, because they have an increased risk of Barrett's esophagus and adenocarcinoma. Those found to have metaplastic change indicative of Barrett's esophagus are candidates for a program of regular surveillance endoscopy and biopsy (see Chapter 61). Those who show dysplastic change need referral for possible surgical resection. New onset of odynophagia in a heavy smoker or drinker should also trigger consideration of endoscopy. Although the presence of small nodules, minor erosions, thickened folds, or mucosal depressions is suggestive of early cancer, mucosal biopsy is required for definitive diagnosis.

Staging. Besides biopsy to determine depth of tumor penetration (the primary determinant of staging), there are a number noninvasive means useful to the staging evaluation. Physical examination should include a check for supraclavicular adenopathy and hepatomegaly. *Computed tomography (CT)* of the chest and upper abdomen should be performed to check for mediastinal invasion. CT provides about the same degree of sensitivity for detection of invasion as does *magnetic resonance imaging (MRI)*, which can also be used for this purpose, although it is more expensive than CT. *Endoscopic ultrasound* is proving useful in determining depth of invasion and appears superior to CT for this purpose.

T1 and T2 disease refers to tumor confined to the esophageal wall, T3 refers to invasion through the wall, and T4 indicates metastatic disease. Nearly 80% who present with dysphagia have at least T3 disease.

Principles of Management. The few controlled studies available find surgery the modality of choice for primary therapy, which includes attempt at cure. However, only some patients have potentially curable disease at the time of detection. Moreover, treatment with curative intent is fraught with high rates of local recurrence and distant metastasis. Combination programs are being explored to reduce the risk of recurrence. In most instances, therapy remains palliative.

Nutrition. *Nutrition* is one of the first priorities. The morbidity of esophageal carcinoma is due largely to the severe dysphagia, odynophagia, and inanition that characterizes advanced disease. Many patients are unable to swallow their own saliva. Even partial obstruction leads to weight loss and cachexia. A more than 10% weight loss at the time of presentation is a poor prognostic sign. Good nutrition helps sustain immunologic competence and ability to tolerate the stresses of treatment. Blenderized diets and liquid diet supplements are helpful, and hyperalimentation is used as a temporary means in patients with the potential for meaningful survival.

Surgery. *Surgery* currently is the modality of choice for *primary therapy*. It provides the potential for cure for the 10% of cases found to have disease confined to the mucosa and for those with severe dysplasia or carcinoma in situ found during surveillance biopsy of Barrett's esophagus (see Chapter 61). The type of *esophagectomy* performed is determined by the location of the tumor. Achieving tumor-free margins of at least 2 cm is required. Except for very early disease picked up by surveillance (which might allow for a more localized resection), most cases usually require resection of at least a substantial portion of the esophagus, necessitating a major thoracoabdominal procedure. Perioperative morbidity and mortality are high in such surgeries, with death rates of nearly 10% and major nonfatal complications in up to 30%. Median survival for patients undergoing surgery for cure is about 2 years, although considerably higher for those with very early disease confined to a small area of mucosa. Three-year survival in the largest of randomized surgical series is in the range of 25%. Preoperative irradiation does not appear to add much benefit, but when combined with preoperative chemotherapy, the results are more promising (see below).

Most authorities also consider surgery the *palliative treatment* of choice, performed to reestablish the ability to swallow. Palliative surgical resection is most successful in patients with disease confined to the distal esophagus. However, even partial esophagectomy is a major procedure, with high risk of major postoperative complications and surgical mortality. The best results reported for palliative surgery include an 85% rate of symptomatic improvement, 17-month mean survival, and 20% 5-year survival.

Radiation Therapy. *Radiation therapy* is a consideration in persons with locally advanced disease not amenable to surgical resection. Such therapy has theoretic appeal because many of these cancers are squamous cell tumors, which tend to be very radiosensitive; however, their central intrathoracic location adjacent to the such key structures as the heart, lungs, and spinal cord makes delivery of curative doses difficult without causing radiation injury. A program of chemotherapy (see below) added to radiation enables use of lower radiation doses and provides superior survival (25% at 5 years) compared with radiation alone (6%) in patients with localized disease, be it adenocarcinoma or squamous cell cancer. Local-regional persistence of disease is the principal cause of treatment failure, suggesting to some

that surgery after chemoradiation might be worthwhile (see below).

Chemotherapy. The high risk of distant and local failures with surgery and radiation has prompted trials of chemotherapeutic regimens for use in *combination* with curative-intent surgery or radiation. The addition of *cisplatin* and *fluorouracil* improves outcomes in patients treated with radiation therapy but not in those undergoing surgical resection. Better chemotherapeutic regimens are being sought. Initial results with *paclitaxel* show it to be highly active against esophageal cancers.

Multimodality Therapy. The combination of all three modalities appears promising, particularly when chemoradiation is applied before surgery. In the best randomized trial to date of such multimodal therapy, mean survival was 16 months versus 11 months for surgery alone, and 3-year survival was 32% versus 6%. More data are needed on long-term survival to judge the benefit.

Laser Therapy. *Laser therapy* is available for palliation in patients too ill to undergo surgery or radiation. Results are encouraging, adverse effects are few, and therapy can be performed on an outpatient basis after an initial 2- to 3-day hospitalization. Relief is achieved, but there is no change in survival rate.

Stenting and Dilatation. For dysphagic patients too ill for surgery, palliation can be provided by endoscopic placement of a polyvinyl *stent*. Esophageal *dilatation* is useful for temporary relief. Gastrostomy may be of help for nutrition but provides no symptomatic relief from disabling dysphagia.

Prevention. *Prevention* remains the most effective means of dealing with this devastating cancer. Efforts to achieve cessation of *smoking and alcohol abuse* (see Chapter 54 and Chapter 228) are essential to reduce the risk of epidermoid cancers. Surveillance *endoscopy* plus biopsy of high-risk patients (e.g., those with Barrett's esophagus) offers the potential to identify dysplastic transformation and early adenocarcinoma, hopefully leading to marked improvements in survival. The optimal approach to surveillance remains to be determined (see Chapter 61). Similarly, the identification of chronic symptomatic reflux as a risk factor for adenocarcinoma raises the possibility that acid-suppression therapy (e.g., by proton-pump inhibition) might reduce the chances of malignant transformation of esophageal mucosa (see Chapter 61). Prospective randomized study is needed.

GASTRIC CANCER

There are approximately 20,000 new cases of gastric cancer in the United States each year and 14,000 deaths attributable to it annually; however, the incidence has been decreasing markedly in the United States, although this cancer remains one of the most common worldwide. Mortality remains relatively unchanged. Overall 5-year survival is about 10%. Onset is rare before the age of 45 years, but incidence increases markedly thereafter. Improvement in outcome has been linked to advances in early diagnosis. Patients with early gastric carcinoma (disease confined to the mucosa and submucosa) have a 5-year survival in excess of 90%. Unfortunately, extension occurs rather early.

About 95% of gastric malignancies are *adenocarcinomas*, with those that are well differentiated and circumscribed having a much better prognosis than those that are poorly differentiated and infiltrative. Lymphomas account for most of the remaining 10%.

Risk Factors. Throughout the world, dietary factors appear to play a major role, linked at least in part by the contribution of *Helicobacter pylori* infection to pathogenesis. Large-scale epidemiologic studies find a strong independent association between Helicobacter infection and risk of gastric carcinoma. *H. pylori* infection is most prevalent among populations with inadequate means of food preservation and high risk of food spoilage, populations with the highest prevalences of gastric cancer. The unexplained decline in gastric cancer in the United States over the last half century may be related to improvements in food handling. Infection of the gastric mucosa by the organism leads to chronic inflammation and development of atrophic gastritis, a recognized premalignant change. Infection during childhood is believed to be especially harmful. It is estimated that up to 70% of cases are causally related to Helicobacter infection, but only a small number of persons with the infection develop gastric carcinoma, suggesting additional causative factors.

In countries where risk is high, research suggests that dietary *nitrate* sources are important risk factors. Foods associated with increased risk of gastric cancer include dried salted fish, which are rich in *nitrates*. The nitrates may be converted to carcinogenic nitrites and nitroso compounds by bacteria found in unrefrigerated partially decomposed food. This may account for the high rates of gastric cancer among lower socioeconomic groups. (Well-refrigerated and carefully handled raw fish popular in Japan and more recently in the United States as served in sushi bars does not appear to carry a nitrite risk). In the United States, nitrate sources include hot dogs and other processed meats such as cold cuts.

Other identified risk factors include *previous gastric surgery* (usually Billroth II anastomosis) and *achlorhydria*. Increased prevalences also occur among Native Americans, Asians, Hispanics, and Scandinavians.

Clinical Presentation. Clinical presentation can be subtle, making early diagnosis difficult. Unexplained iron deficiency *anemia* or asymptomatic *guaiac stool test positivity* may be the only manifestation. Nonspecific abdominal pain, gastric ulceration with or without bleeding, weight loss, and obstruction are the major patterns of clinical presentation, but most are manifestations of advanced disease. About 75% of patients with early disease have *epigastric pain* as the initial complaint; it may be subtle and resemble *dyspepsia*. Most are free of the nausea, vomiting, anorexia, and weight loss that characterize more advanced disease. *Gastric ulcer* is an important presentation, characterized by a suspicious appearance on barium study or endoscopy or a more benign-appearing radiologic defect that fails to heal completely or quickly recurs after 6 weeks of ulcer therapy (see Chapter 68). The disease often progresses silently until signs of metastatic disease, such as enlargement of the *left supraclavicular lymph nodes or ascites*, become evident and cause the patient to seek medical attention.

Diagnosis. A high index of suspicion is warranted; early diagnosis provides the best chance for survival. Patients over the age of 45 years presenting with any of the manifestations noted above should undergo testing as early as possible. *Endoscopy* with *brushings* and *biopsy* is the preferred method for definitive diagnosis. In the absence of an ulcer, all atypical areas of mucosa should be biopsied. Endoscopy has largely replaced upper gastrointestinal series for diagnosis, in part because it permits the obtaining of biopsy specimens.

Course. Spread occurs by direct extension and by seeding of the lymphatics, blood vessels, and peritoneal surface. Metastases develop locally and at distant sites, most frequently the *liver* (40%), *lung* (15%), and *bone* (15%). Among patients who come to surgery, approximately 80% are found to have *lymph node* metastases, whereas 40% have *peritoneal involvement* and 35% show spread to the liver or lung.

Principles of Management. Surgery is the treatment of choice, but the ability to achieve cure is limited by the finding of metastatic disease at surgery in 80%. Adjuvant chemotherapy is being used to reduce the high risk of metastasis, but the overall survival rate has not changed in the past two decades. Prevention and early detection are the best hopes at present in improving outcomes.

Surgery. *Surgery* is the primary mode of treatment, both for cure and palliation. Median survival for patients managed by complete surgical resection is in excess of 3 years. The 5-year survival rate varies according to location of the tumor: it is 25% in patients with distal lesions and 10% for those with proximal ones. When lymph node involvement is found, survival falls by 50%. The surgical loss of the stomach's food reservoir function necessitates small frequent feedings. Without careful patient education and use of high-calorie supplements, total gastrectomy can lead to malnutrition. Subtotal or total gastrectomy is optimal for management of bleeding or obstruction related to tumors at the gastroesophageal junction. *Linitis plastica* or total wall involvement of the stomach is incurable and not manageable by surgery.

Chemotherapy. *Chemotherapy* (using such agents as 5-fluorouracil [5-FU]) as the sole mode of treatment in patients with metastatic disease produces responses in almost 40% of patients. The average duration of response is 9 months, but there is no improvement in survival. Complete responses are rare. Reports of efficacy for *adjuvant chemotherapy* after surgical resection are encouraging but require confirmation. Unlike adenocarcinoma, gastric *lymphomas* are responsive to chemotherapy after gastrectomy (see Chapter 84), with 5-year survival approaching 40%. Combination chemotherapy is being considered for patients with primary gastric lymphoma that is unresectable.

Radiation. Adenocarcinomas of the stomach are not radiosensitive at tolerable doses. Neither radiation used alone nor as part of an adjuvant program with chemotherapy has improved survival. Likewise, postoperative radiation does not seem to be of much benefit in patients with gastric lymphoma.

Patient Monitoring. *Patient monitoring* should be guided by symptoms and not by routine testing for potential metastatic sites, because only palliative therapeutic options exist for patients with advanced disease.

Prevention and Early Detection. Although the relationship between *Helicobacter* infection and gastric carcinoma is becoming increasingly well established, it remains to be proven that eradication or prevention of *Helicobacter* infection will reduce risk (see Chapter 68). Nonetheless, improvement in food handling and preservation and assuring that young children are not exposed to spoiled food seem like reasonable public health measures at this time. Early detection through endoscopic or radiologic screening has been carried out in populations where risk is very high (e.g., Japan). Such measures would not be cost effective in the United States, where disease prevalence is relatively low and declining.

PANCREATIC CANCER

Carcinoma of the pancreas is the fourth leading cause of cancer death in the United States. Mortality is high (close to 99% at 5 years); fewer than 20% survive 1 year. High death rates are due partially to difficulties in early detection, which stem from the tumor's retroperitoneal location. For decades, pancreatic cancer had been increasing in frequency, but incidence has plateaued since 1973. There are about 25,000 new cases annually. The disease is rare before age 45, but incidence rises rapidly thereafter. There is a slight male predominance.

Hypotheses regarding pathogenesis include concentration and excretion of carcinogens by acinar cells inducing neoplastic transformation among ductal cells. Established risk factors include heavy *alcohol consumption* and heavy *smoking*. Diabetes mellitus, chronic pancreatitis, and exposures to dry-cleaning chemicals and gasoline are also suspected contributing factors. The validity of a statistical association with coffee consumption has been disproved.

Clinical Presentation. In most instances, the tumor remains silent until late in the course of disease, with presentation determined largely by the tumor's location. In about two thirds of cases, the cancer begins in the head of the pancreas; in the remainder, it occurs in the body or tail. Disease that originates in the pancreatic head near the pancreaticobiliary junction may extend locally to obstruct bile flow and cause *painless jaundice*—one of the few potentially early symptomatic presentations of pancreatic cancer. Jaundice, with or without pain, is an eventual manifestation in about 50% of patients, although in many it is due to metastasis or late extension.More often than not, symptoms are late in onset and nonspecific. Disease of the body or tail may present with vague upper abdominal or back *pain* or *discomfort*, unexplained *weight loss*, unexplained *depression*, or even migratory *thrombophlebitis*. Carcinomas of the tail may not cause symptoms until they metastasize. Pancreatic cancer is also an important cause of ectopic hormone production (insulin, glucagon, corticotropin) and unexplained onset of *diabetes* or *pancreatitis*. Persistent *nausea and vomiting* suggest invasion and obstruction of the upper gastrointestinal tract.

The clinical course of pancreatic carcinoma is dominated by regional extension into the retroperitoneum and liver. The tumor tends to spread perineurally and lymphatically. Median survival for patients with extrapancreatic tumor is 12 weeks from time of presentation and 19 to 42 weeks for those with tumor confined to the pancreas.

Diagnosis. Diagnosis no longer requires laparotomy, but tissue may still be needed because symptoms and signs may be nonspecific and there are no definitive blood tests. The workup begins with abdominal *ultrasonography or CT*. Both have the capacity to detect lesions as small as 2 cm and to image the biliary tree and pancreatic ducts. In many cases, both are ordered. Ultrasound is usually the initial study in patients with jaundice, because the test is readily available and provides a quick and inexpensive means of diagnosing common bile duct obstruction. It also can detect tumor before it distorts the pancreatic contour, an advantage it has over CT. CT provides better definition of the tumor and adjacent structures, helping to determine anatomy and detect metastasis to the liver and draining lymph nodes. MRI techniques offer no advantages over CT, although advances in MRI may eventually prove useful. Pancreatic radionuclide scanning is not used due to poor diagnostic accuracy.

When a distinct pancreatic mass is identified, *fine-needle aspiration biopsy* can be performed percutaneously, guided by direct ultrasound or CT visualization. Limiting the yield from needle biopsy is the large zone of fibrosis and inflammation that typically surrounds the tumor. The procedure is the confirmatory test of choice in patients with disease believed to be metastatic or unresectable. Drawbacks include a substantial false-negative rate and the risk of seeding along the needle tract.

Patients with a mass at the pancreaticobiliary junction are excellent candidates for *endoscopic retrograde cholangiopancreatography (ERCP)*. Early ampullary lesions causing jaundice can be visualized and biopsied directly, leading to prompt diagnosis, definitive treatment, and improved 5-year survival (as high as 50%). A pancreatogram is taken during ERCP, with ductal narrowing, obstruction, and extravasation of dye comprising additional signs of malignancy (although they also can occur in chronic pancreatitis). An irregular stricture longer than 10 mm is characteristic of cancer. Cytologic sampling, especially that obtained by brushing, has a reported sensitivity approaching 85%, although results vary.

Serum tumor markers have always been appealing, although of limited use in diagnosis. *CA 19-9*, a tumor marker developed with monoclonal antibody technology, has been tested for its utility in detecting and monitoring pancreatic cancer. Although sensitive in the setting of advanced disease, the test is often normal in early stages. In addition, specificity has been disappointing; high levels have been reported in other gastrointestinal cancers (bile duct, colon). It is not recommended for screening but can be useful in differentiating chronic pancreatitis from pancreatic cancer and in follow-up surveillance (provided levels were high before surgery and fall immediately after). Other serum tumor markers examined include carcinoembryonic antigen (CEA) and the ratio of testosterone to dihydrotestosterone. None has proven sufficiently sensitive or specific to warrant use in routine diagnosis.

Principles of Management. The chance for cure is limited because it depends on surgically removing the entire tumor, which is usually well advanced by the time it is detected. Careful staging is critical. One needs to distinguish between tumors that are localized and resectable, localized and not resectable, and metastatic. In addition, patients with duodenal obstruction need to be identified because they require operation.

Staging. CT with contrast is the staging procedure of choice for visualizing the tumor and detecting liver and large lymph node metastases. Such metastases rule out resectability. Microscopic nodal disease is not visible by CT, but neither is it considered a contraindication to surgery (although palliation rather than cure may be the objective). Many surgeons view data from *angiography* as useful—major vascular involvement indicates inoperability. The utility of a staging *laparoscopy* for patients being considered for surgery has become evident. Upward of 40% of such patients are found at laparoscopy to have previously undetected peritoneal or omental metastases, which rule out resectability. These three tests are complementary and greatly increase the determination of surgical candidacy. They can save many patients from undergoing unnecessary laparotomy. If any one test is positive, only 5% will have a resectable tumor at laparotomy, but if all three are negative, the rate increases to 78%. *Endoscopic ultrasound with transendoscopic fine-needle aspiration* is a new technology that allows determination of spread beyond the pancreatic capsule and determination of local nodal involvement.

Surgery. Only patients with relatively small lesions confined to the head of the pancreas are candidates for *curative surgery*. This accounts for no more than 5% to 22% of patients who present with the disease. The risks of surgery are great, the operations formidable, and postoperative complications serious. Operative mortality frequently approaches or even exceeds the 5-year survival rate. The decision to subject a patient with pancreatic cancer to a major operation with a high degree of operative mortality and only modest chances for substantially improved survival must be made individually.

The operation of choice is the *Whipple procedure* (pancreatoduodenectomy), which requires a surgical tour de force and should be attempted only by surgeons able to perform it with less than 5% mortality. Five-year survival rates are best in patients with a small (2 cm or less) tumor, approaching 30% at centers with surgical expertise in performing the operation. Survival increases to 57% if lymph nodes prove to be negative (unfortunately, an uncommon occurrence). Overall 5-year survival had been 5%, but reports of 15% to 25% are now appearing in conjunction with advances in staging, case selection, and operative technique. Regional pancreatectomy or total pancreatectomy provides no survival benefit.

Surgery is also recommended for *palliation*. Patients with biliary obstruction are candidates for biliary bypass or endoscopic stent placement, which can relieve jaundice and lower the risk of cholangitis. Surgical or percutaneous ablation of the celiac ganglion can provide relief from intractable pain.

Radiation Therapy. *Radiation therapy* is applied to patients with localized but unresectable disease. However, only when used in conjunction with 5-FU therapy does it prolong survival. Intraoperative radiation is also being promoted, but survival benefit remains to be defined. Preoperative courses of radiation and chemotherapy are being studied. Radiation therapy has also been used for control of intractable retroperitoneal pain; 4 to 6 months of relief have been reported.

Chemotherapy. *Chemotherapy* has traditionally offered little to persons with unresectable disease. The standard chemotherapeutic agent, *5-FU*, has a poor response rate (about 20%) and no proven ability to prolong survival. *Gemcitabine*, a recently developed nucleoside analogue, appears to be more effective than 5-FU, able to reduce pain, improve functional status, and slightly improve survival. This agent is now U.S. Food and Drug Administration approved for use as first-line therapy in

persons with locally advanced or metastatic disease and in those previously treated with 5-FU.

Supportive Measures. *Supportive measures* are essential, not only to patients who are dying of their disease (see Chapter 87) but also to those who have undergone pancreatectomy. In the latter group, insulin therapy and pancreatic enzyme preparations are needed. Insulin requirements are in the range of 20 to 30 units per day.

COLORECTAL CANCER

Colorectal cancer is one of the most common malignancies and, although one of the more potentially curable cancers, results in 50,000 deaths annually. Over 150,000 new cases develop each year.

Risk Factors. Among the suspected etiologic factors is an increased exposure to chemical carcinogens present within the bowel lumen. High-risk patients are those with a *first-degree relative* with colorectal cancer (especially if cancer developed at an early age), long-standing *pancolitis, familial polyposis*, or *Gardner's syndrome* (polyps, osteomas, epidermoid cysts, soft tissue tumors). Loss of the tumor suppressor gene p53 has been found in colorectal cancer patients. High-fiber diets may lessen risk, but recent large-scale epidemiologic data in women cast some doubt on earlier positive findings. Epidemiologic evidence does suggest that regular use of aspirin may reduce the risk of fatal colon cancer. Calcium supplementation moderately reduces the risk of recurrent adenomatous polyp formation. Early diagnosis through screening is a high priority in the approach to this condition, offering the best chance of reducing mortality (see Chapter 56).

Adenomatous polyps, villoglandular polyps, and *villous adenomas* represent premalignant lesions that may also harbor early cancers. Most colon cancers derive from these lesions, making their timely detection and removal essential. Hyperplastic "polyps" are not premalignant lesions (see below and Chapter 56).

Clinical Presentation. The clinical presentation of colorectal cancer is related to the site of the tumor. Tumors of the ascending colon may be asymptomatic until late stages, producing little more than mild *iron deficiency anemia* or intermittently *guaiac-positive stools*. Tumors of the descending colon and rectosigmoid can cause symptoms earlier in the course of illness, presenting as rectal *bleeding or change in bowel habits* (diarrhea and constipation). At the time of surgery, 50% to 75% of patients demonstrate tumor that has penetrated the bowel wall; 60% of these show regional metastases.

Rectal cancers commonly present with occult or frank rectal bleeding, with or without an alteration in bowel habits. *Tenesmus* is usually a late symptom representing extension of the tumor beyond the bowel wall. Rectal or perianal pain is a consequence of the invasion of the pararectal structures in the sacral plexus. Tumor often arises on the posterior wall, making it particularly important to examine the rectal ampulla on routine rectal examination.

Prognosis and Clinical Course. Prognosis depends on extent of penetration and local spread. A modification of the standard *Dukes' classification* serves as a useful system for staging (Table 76-1). Stage A patients have tumor limited to the submucosa and a 5-year survival in excess of 90%. Those with stage B disease have a 5-year survival ranging from 70% to 85%. Once the serosal surface and lymph nodes are involved, stage C, survival falls to 30% to 65%. Prognosis is also adversely affected by presence of polyploidy and mucin production in the tumor and by preoperative elevation of serum CEA level (more than 5 ng/mL).

STAGE	DESCRIPTION	5-YEAR SURVIVAL (%)
A	Lesion confined to submucosa; nodes negative	>90%
B1*	Muscularis involved but not serosa; nodes negative	80–85
B2*	Lesion extends through serosa; nodes negative	70–75
C1*	Lesion extends into muscularis only; nodes positive	70–75
C1*	Lesion extends through serosa; 1–4 nodes positive	60–65
C2*	Lesion extends through serosa; >4 nodes positive	30–45

Boston: American Cancer Society. 1990:244, with permission.

Table 76-1. Staging for Colorectal Cancer

The most common sites of metastasis are the *liver* (60% overall and 30% of solitary metastases) due to portal blood flow draining the intestines, the *peritoneal surface* (30%), and the *lung* (20%). Brain, skin, and local recurrences occur in less than 5%. Rectal cancers tend to invade locally and to recur in the pelvis alone or in association with distant metastases to the liver or lung, bypassing the intraabdominal cavity.

Diagnosis. Diagnosis in a patient suspected of colorectal cancer (e.g., because of guaiac-positive stools, rectal bleeding, unexplained iron-deficiency anemia, or change in bowel habits) is best accomplished by *colonoscopy* that extends to the cecum. The combination of flexible *sigmoidoscopy plus barium enema* is a second choice where colonoscopy is not available, but barium study does not allow for biopsy and the false-negative rate can be as high as 40% for single-contrast studies. Sensitivity is improved with use of air-contrast techniques, but elderly patients find such barium studies uncomfortable.

For patients in whom a cancer is detected in the rectosigmoid, a preoperative examination of the entire colon all the way to the cecum is required, either by colonoscopy or air-contrast barium enema, because *synchronous tumors* are present in up to 5% of patients. Similarly, colonoscopy is needed when a benign adenomatous polyp is found on examination of the rectosigmoid.

Staging. Staging for colon cancer is based predominantly on findings at surgery and pathologic examination (Table 76-1). Liver scanning and CT are not usually performed preoperatively because the results do not affect the decision to remove the tumor. However, *CT or MRI* of the pelvis can help determine extent of a rectal cancer and candidacy for surgery. A preoperative CEA level provides a baseline for postoperative monitoring of colorectal cancer and helps assess prognosis. Detailed examination of draining lymph nodes is especially important in patients with stage B (stage II) disease. Histopathologically, negative nodes may still contain tumor, necessitating molecular testing to uncover micrometastasis that is associated with a much worse prognosis and a need for stage C treatment.

Treatment. Patients with disease detected in the early stages have an excellent prognosis, emphasizing the important of early diagnosis and treatment, including removal of polyps that represent premalignant disease (see Chapter 56).

Surgery. *Surgery* is the primary modality of therapy, both for cure and for palliation (e.g., to prevent or relieve bowel obstruction). For colon cancer, *colectomy* is the procedure of choice. Because the tumor spreads lymphatically, adequate amounts of bowel on both sides of the lesion must be removed to avoid cutting into intramural lymphatics that may contain cancerous cells. Patients presenting with obstruction may benefit from a temporary diverting colostomy followed at a later date by reanastomosis. *Salvage surgery*, often with curative intent for a single resectable recurrence of tumor (e.g., in the abdomen, lung, or liver), is being increasingly offered by surgeons, encouraged by the low perioperative mortality risk and the roughly 25% 5-year disease-free survival rate.

Surgical management of *rectal cancer* consists of *abdominoperineal resection*, aided by adjuvant radiation therapy. When possible, an effort is made to preserve the anal sphincter. Tumors of the upper two thirds of the rectum can usually be resected in conjunction with construction of an anastomosis; those of the lower third require an abdominoperineal resection with a permanent sigmoid colostomy. Sometimes unwise attempts are made to limit the resection to preserve the sphincter; inadequate surgical margins are taken, leading to local recurrence and death. Alternatives to abdominoperineal resection include local excision, fulguration, and intrarectal radiation therapy. Only patients with small exophytic tumors in the lower third of the rectum should be considered for such alternative therapy.

The appreciation that adenomatous polyps, villoglandular polyps, and villous adenomas may harbor cancers or be premalignant has led to the recommendation of *polypectomy* when detected, aided greatly by fiberoptic colonoscopy and sigmoidoscopy. Cancer confined to the polyp is considered carcinoma *in situ*; detectable invasion of the stalk or muscularis necessitates *colectomy*.

Radiation Therapy. *Radiation therapy* has no established role in colon cancer, in contrast to its important place in the treatment of rectal cancer. The tendency of rectal cancers that have penetrated the bowel wall to recur locally is high (30% to 50%). Adjunctive use of radiation therapy in such patients significantly reduces the risk of local recurrence and improves survival. Patients with extensive local disease are irradiated preoperatively. This reduces tumor size and allows for subsequent resection. Postoperative radiotherapy is reserved for those whose findings at surgery suggest high risk of recurrence (i.e., those with stage B2 or C). In addition, the application of adjuvant radiation therapy postoperatively has permitted an anterior resection with primary anastomosis in many patients who would otherwise require a colostomy.

Chemotherapy. *Chemotherapy*, consisting of postoperative application of *levamisole and 5-FU*, can significantly reduce the risk of recurrence in patients with resected stage C colon cancers. In the largest prospective randomized clinical trial of this adjuvant program, the recurrence rate decreased by 40% and the death rate by 33%. Levamisole alone had minimal effect on out-comes. Typically, treatment is begun as soon as possible after surgery.

For patients with advanced nonresectable disease, 5-FU remains the only option. None of the other drugs or drug combinations has proven superior to 5-FU alone. The response rate is about 20%, but there is little chance of a meaningful prolongation of survival. The addition of *leukovorin* to 5-FU increases the response rate modestly to 30% to 35% but does not enhance survival and has side effects of its own.

Other Modalities. Other modalities have been asserted. At one point, claims were made for high-dose *vitamin C*. Randomized, double-blind, control study has shown that such therapy is no better than placebo. No benefit has been found with *immunotherapy*.

Monitoring. Attentive follow-up is essential because of the risk of a second bowel cancer (occurring in up to 5% of patients) and appearance of new polyps. Moreover, a new primary in the bowel or a single metastasis to the lung or liver is amenable to curative resection with a 25% chance of disease-free survival at 5 years. Regularly scheduled *colonoscopy* should begin 6 months after surgery and take place every 24 to 36 months if no polyps are found and every 6 months if they are. Any encountered polyps are removed. If colonoscopy is unavailable or cannot reach the cecum, air-contrast *barium enema* is an adequate substitute in conjunction with sigmoidoscopy.

Early detection of potentially resectable recurrent or metastatic disease in the abdomen or lung requires additional monitoring. Periodic *chest x-ray* every 6 months for the first 12 to 48 months has been suggested as a low-cost approach to screening for lung metastasis. The *CEA* is a marker that correlates with tumor burden in colorectal cancer. It has proven useful in detection of disease recurrence and is used in monitoring after initial resection. The recommended interval for CEA determinations is every 6 months for the first 2 years, provided that the CEA was elevated before surgery and fell to low levels within 2 to 4 weeks after it. If the CEA rises by 30% or more per month from its postoperative level, then a search for curable recurrent disease should be undertaken. However, sensitivity and specificity have been found wanting, especially for early detection of liver metastases, causing some investigators to suggest periodic abdominal *ultrasound* or *CT* for this purpose. Evidence that CEA surveillance is cost effective and saves a significant number of lives remains to be obtained. Careful patient selection is warranted. *MRI* does not appear to offer any advantages over CT and costs considerably more to perform. The most cost-effective approach to monitoring remains to be established.

As noted earlier, one should also monitor symptoms (weight loss, fatigue, change in bowel habits), the physical examination (especially chest and abdomen), and *alkaline phosphatase* (rises with infiltration of the liver) to help detect recurrent but curable disease.

Supportive Therapy. Patients who have undergone abdominoperineal resection with permanent or temporary colostomy need careful counseling pre- and postoperatively to help them adapt to their situation. Becoming comfortable with the details of ostomy care and having an opportunity to discuss their fears and concerns (sexual function, odor, appearance, bag changes, recurrence of cancer) are essential components of the rehabilitation effort. Ostomy groups and stoma nurses are important resources for the patient, but there is no substitute for a supportive understanding patient–doctor relationship.

Patients presenting with nonresectable disease benefit from a comprehensive review of prognosis, available treatment modalities, and patient and family preferences. A meeting set up by the primary care physician to include the patient and family can be most helpful in facilitating communication, addressing the obvious but difficult questions regarding prognosis and treatment, and formulating a personalized plan that aims to maximize the patient's quality of life, comfort, and dignity. It helps assure the patient and family of close follow-up and a program of support that makes sense to all. Such a meeting may also be an opportune time to address the elements necessary to complete an advance directive (see Chapter 1.2).

Prevention. A host of approaches have been proposed, some (e.g., screening) of proven benefit in reducing colorectal cancer morbidity and mortality and some less well established (e.g., NSAIDs, calcium, dietary measures).   Updated: 04/14/03

Screening (see Chapter 56). The best established approach to prevention is a program of periodic screening to detect and remove early stage cancers and precursor lesions, such as adenomatous polyps. Screening methods proven to save lives include fecal occult-blood testing, sigmoidoscopy, and colonoscopy; barium enema sometimes serves as an alternative. All polyps detected need to be removed and subjected to pathologic examination.   Updated: 04/14/03

Genetic Testing. The contribution of genetic testing to prevention is just beginning to be explored as genetic risk factors are identified in familial forms of colorectal cancer. In *hereditary nonpolyposis colorectal cancer* (the most common of the familial colorectal cancer syndromes), upward of 25% of family members are found under study conditions to have deleterious mutations in the *hMSH2* or *hMLH1* gene, mutations that confer a significantly increased risk of cancer and warrant heightened surveillance and preventive measures. Such high frequencies of important prognostic information suggest routine genetic testing as a future management recommendation for hereditary forms of colon cancer, especially for hereditary nonpolyposis. New colorectal cancer patients who should be suspected for hereditary nonpolyposis include those with a family history of a first-degree relative with colorectal or endometrial cancer, age less than 50 years at time of diagnosis of colorectal cancer, or a history of multiple cancers. Some authorities suggest molecular screening of such patients and the subsequent testing of the families of those who manifest important gene mutations.

Diet, Vitamins, Exercise, and Nonsteroidal Antiinflammatory Drugs. A number of dietary preventive measures have been touted with varying degrees of supporting evidence. Ever since Burkett's observation of very little colorectal cancer in African societies taking a high-fiber diet, *dietary fiber* has been viewed as useful in prevention of colorectal cancer. Numerous case-control studies support this view, but the well-designed prospective Nurses Health Study failed to find any benefit from increased fiber intake, at least in women. In the same Nurses Health Study, long-term (more than 15 years) use of multivitamins, particularly *folic acid*, was associated with significantly reduced cancer risk. A high *calcium* intake is associated with a moderate reduction in risk of polyp recurrence. *Physical activity* in men appears beneficial (truncal obesity is detrimental). Use of aspirin and NSAIDs has been explored in high-risk persons. Although significant reduction in rate of polyp formation has been demonstrated, there is still no evidence of an incremental survival benefit over that provided by periodic screening.   Updated: 04/14/03

Hormones and Medications. *Hormone replacement therapy* in postmenopausal women has been shown in some studies to decrease risk of colorectal cancer and large adenomas by nearly 35%, but the association is not well established by prospective study and the benefit disappears quickly with cessation of hormone therapy. The use of *aspirin* and other NSAIDs initially appeared to be beneficial, but subsequent large-scale study failed to confirm the association between NSAID use and reduced risk.

Management of Colorectal Polyps

See also Chapter 56. The finding of a sporadic polyp on screening sigmoidoscopy is a common event. Most are not true polyps but just small *hyperplastic* mucosal outcroppings that have no malignant potential. Polyps representing true neoplasia with the potential for malignant transformation include *villous adenomas, tubular adenomas, and mixed tubulovillous adenomas*. Villous adenomas have the highest malignant potential and tend to be larger and more sessile than tubular or mixed tubulovillous adenomas (see Chapter 56, Table 56-1). With adenomatous polyps, the risk of malignancy increases with polyp diameter. Lesions less than 1 cm have a 0.5% chance of harboring malignancy; for polyps greater than 3.0 cm, the risk increases to over 15%. Small tubular adenomas account for nearly 70% of the polyps found. Polypectomy reduces the risk of new colon cancers by 70% to 90%.

All polypoid lesions found should be excised and sent for histologic categorization. Those that prove to be hyperplastic require no additional action, but truly neoplastic lesions are an indication for colonoscopy, because of the increased risk of synchronous premalignant polyps or even cancer-containing lesions proximal to the reach of the sigmoidoscope. However, the magnitude of this risk and thus the need for colonoscopy is uncertain in the large group of patients found to have only a single small (less than 0.5 cm) tubular adenoma on sigmoidoscopy. Of the two best prospective cohort studies performed in primary care settings in persons with

diminutive tubular adenomas, one found the risk of proximal disease to be nil, whereas the other noted a 5% risk of concurrent cancer and a 30% risk of another polyp. Subsequent cross-sectional analysis of data from a large health maintenance population population found that tubulovillous or villous histology in the distal lesion was the most powerful predictor of proximal pathology; also predictive were age greater than 65 years, more than one distal adenoma, and positive family history of colorectal cancer. Pending additional data to help settle the controversy, one can use these risk factors to help select for colonoscopy patients most likely to have an important proximal lesion.

The optimal frequency for repeat colonoscopy is unsettled. The best determinant of frequency is individual risk. Current consensus guidelines recommend performing the first follow-up study in 3 years, followed by one every 5 years if the first study is normal (see Chapter 56). Patients with familial adenomatous polyposis are at very high risk of developing colorectal cancer (approximately 50% by age 40). Prophylactic colectomy is often recommended for such persons. Colonoscopic surveillance is an effective alternative to prophylactic colectomy in persons with hereditary nonpolyposis colorectal cancer mutations discovered through genetic screening.

PART 6 HEMATOLOGIC AND ONCOLOGIC PROBLEMS

CHAPTER 77 SCREENING FOR ANEMIA

Anemia is a sign of illness rather than a diagnosis in itself. The incidental finding of a low hematocrit or hemoglobin level suggests a host of underlying conditions that range from the trivial to the life-threatening. Patients with fatigue or other subjective symptoms often ask about their "blood count." The absence of anemia in such instances is reassuring. But is the patient who is otherwise well likely to benefit from either the identification or the treatment of asymptomatic anemia? The answer to this question depends on the prevalence and nature of the conditions most likely to cause asymptomatic anemia, and on the relationship between the hemoglobin level and those symptoms attributed to its reduction.

EPIDEMIOLOGY AND RISK FACTORS

By far the most common cause of asymptomatic anemia is *iron deficiency* resulting from the inadequate dietary replacement of iron lost from the body. Daily iron requirements for men and postmenopausal women are between 0.5 and 1 mg. Because additional iron is needed by menstruating and pregnant women, their daily requirements are 2 mg and 2.5 mg, respectively. Because only 5% to 10% of the 10 to 20 mg of the iron contained in the average adult diet is absorbed, it is not surprising that iron deficiency is common in women of childbearing age. Population studies have found 10% to 20% of menstruating women to have abnormally low concentrations of hemoglobin (usually <12 g/100 mL). Between 20% and 60% of pregnant women have hemoglobin levels below 11 g/100 mL. Anemia is less likely to occur in women taking birth control pills and more likely to occur in women with intrauterine devices. Iron deficiency is rare in male adults; if present, it is a clear indication for diligent investigation of the gastrointestinal tract. Absorption of iron may be decreased after gastrectomy or in the presence of achlorhydria.

Sideroblastic and megaloblastic anemias are much less common. The prevalence of *pernicious anemia*, the most common form of vitamin B_{12} deficiency, is 0.1% in persons of Northern European extraction. Pernicious anemia is much less common among other ethnic and racial groups. *Folate deficiency* is common during pregnancy and in patients with alcoholic liver disease, in whom it is often accompanied by sideroblastic anemia. Anticonvulsant drugs, including phenytoin, primidone, and phenobarbital, may interfere with folate absorption, so that megaloblastic anemia results. *Thalassemia* minor is a common cause of mild anemia in patients of Mediterranean or Far Eastern extraction. *Sickle cell disease* and trait, by far the most common forms of hemoglobinopathy, are discussed separately (see Chapter 78).

NATURAL HISTORY OF ANEMIA AND EFFECTIVENESS OF THERAPY

Obviously, the natural history of anemia depends on the underlying cause. What symptoms can mild or moderate anemia be expected to produce? The hyperkinetic symptoms that follow compensatory increases in cardiac stroke volume and heart rate are rarely present before hemoglobin levels have fallen to 7.5 g/100 mL. Other highly subjective symptoms, including irritability, fatigue, and headache, have been attributed to milder degrees of anemia. A British survey, however, found no relationship between the frequency of such symptoms and the level of hemoglobin (ranging from 8 to 12 g/100 mL) among women found to have iron-deficiency anemia during a screening program. Indirect evidence showed that levels under 8 g/100 mL were associated with symptoms severe enough to prompt presentation to a physician. Among the asymptomatic women identified by screening, no benefits of treatment were detected. It has been noted by some investigators that symptoms associated with vitamin B_{12} deficiency may predate the onset of anemia (see Chapter 79 and Chapter 82).

Most studies of screening for anemia have been conducted in the preoperative or inpatient setting. The few that have been performed on outpatients have shown little benefit. In a Swiss study of the utility of the complete blood cell count in 595 outpatients attending a university-based clinic, 34 (5.8%) had a low hemoglobin level, and a new diagnosis (iron deficiency without serious underlying pathology) was made in only three of them (0.5%). Another report from Britain demonstrated a 10% prevalence of anemia among screened women. The absence of treatable underlying conditions other than iron deficiency was noteworthy, and, again, no benefits of treatment could be demonstrated.

Iron-deficiency anemia is not uncommon among pregnant women and has been associated with a twofold to threefold increased risk for low birth weight, preterm delivery, and perinatal mortality. Screening for anemia is generally recommended as part of the first prenatal evaluation. The results of randomized trials of iron supplementation for pregnant women without anemia or with mild anemia have been mixed. When iron supplementation is prescribed for women who already have children, they should be reminded of the risk of overdose among toddlers; 30% of fatal pediatric overdoses can be attributed to iron supplements.

SCREENING AND DIAGNOSTIC TESTS

The laboratory measurements of *hematocrit* and *hemoglobin concentration* are straightforward. Automated methods are reliable and reproducible when specimens are properly handled. The mean hematocrit for adult men at sea level is 46%, with a range of 41% to 51%; for women, the mean is 42% and the range is 37% to 47%. Slight differences may be noted when automated techniques are used to measure the hematocrit. The normal mean hemoglobin concentration is approximately 16 g/100 mL for men, with a range of 14 to 18 g/100 mL; for women, the mean is 14 g/100 mL and the range is 12 to 16 g/100 mL. In men over 65, the mean falls to 13.5 g/100 mL, and in women over 65, it falls to 13.1 g/100 mL. It must be remembered, as with all continuous laboratory variables, that the choice of a reference value for defining normality is arbitrary. This is particularly true in light of the unclear relationship between significant symptoms and mild "anemia."

CONCLUSIONS AND RECOMMENDATIONS

- Anemia is a common condition. It may be secondary to serious underlying disease or a simple dietary deficiency. Determination of the hemoglobin concentration or hematocrit is recommended as an important part of the evaluation of a variety of presenting complaints, including fatigue, weight loss, abdominal pain, and gastrointestinal bleeding (see Chapter 8, Chapter 9, Chapter 58, and Chapter 63).
- Although determination of the complete blood cell count may provide clues in asymptomatic patients to the presence of early treatable disease, such as gastrointestinal malignancy, more sensitive and more specific screening methods are available and preferred (e.g., stool guaiac testing and sigmoidoscopy for early detection of colorectal cancer; see Chapter 56).
- No clear relationship has been found between mild to moderate degrees of anemia and significant symptoms. No clearly measurable benefits after the treatment of mild anemia have been identified in screening studies.
- Thus, routine screening for anemia in nonpregnant, asymptomatic patients is not recommended.
- Iron-deficiency anemia is common among pregnant women and is associated with poorer outcomes of pregnancy. Screening for anemia at the time of the first prenatal visit is recommended.

CHAPTER 78 SCREENING FOR SICKLE CELL DISEASE AND SICKLE CELL TRAIT

Sickle cell disease is the most common of the clinically significant hemoglobinopathies. In the United States, the disease and trait occur almost exclusively among African-Americans. Sickle cell disease afflicts 1 in 375 African-Americans and 1 in 60,000 whites. During the late 1960s and early 1970s, sickle cell disease received a great deal of attention in the medical and lay press. The importance of screening for the disease and trait was stressed. Some states legislated mandatory screening programs.

Sickle cell disease (the hemoglobin SS homozygous state) is usually identified during childhood. Patients in whom anemia is not identified by screening are often given the diagnosis after they present with impaired growth, increased susceptibility to infection, or painful crisis. Screening of adults is aimed at the identification of asymptomatic carriers of sickle cell trait (the hemoglobin AS heterozygous state). The principal objective is to reduce the prevalence of the homozygous condition by means of genetic counseling. Whether or not screening benefits the people screened has been debated. Screening performed without subsequent education and counseling can be harmful. An understanding of the natural history of sickle cell trait and disease, sensitivity to the concerns of affected patients, and selective use of available screening tests are all necessary if such harmful effects are to be avoided.

EPIDEMIOLOGY AND RISK FACTORS

Sickle cell disease has a prevalence of less than 0.35% among African-American children in the United States. Double heterozygotes, including those with hemoglobin SC or S-b-thalassemia, are even less common. The prevalence of sickling disease is lower among adults because the life span of SS homozygotes and double heterozygotes is decreased.

Screening surveys have documented a prevalence of sickle trait of 7.4% among African-American veterans and 8.7% in the African-American community of San Francisco. Some studies have shown regional differences in prevalence. Prevalence does not decrease with age. Sickle cell trait is present with a low frequency in Southern Italy and with a higher frequency in parts of Greece. It remains a rare finding in Americans of Mediterranean extraction.

NATURAL HISTORY OF SICKLE CELL DISEASE AND EFFECTIVENESS OF THERAPY

The natural history of *sickle cell disease* is variable. Most children exhibit failure to thrive and have frequent infections. Anemia is usually moderate but can become severe, often as a result of infection or folate deficiency. The course is punctuated by painful crises precipitated by infection, dehydration, or hypoxia. Organ infarction, congestive heart failure, cholelithiasis, and skin ulcers are some of the complications of chronic disease. Because supportive care has improved, the life expectancy of patients with sickle cell disease has increased; however, it still remains significantly shortened, by 25 to 30 years in comparison with that of African-Americans who do not have sickle cell disease.

In contrast, life expectancy is not affected by *sickle cell trait.* AS red blood cells sickle at a much lower oxygen tension than do SS cells. The only clinical abnormality that occurs with any frequency among patients with sickle cell trait is painless hematuria, presumably the result of small infarcts of the renal medulla, where red cells are particularly susceptible to sickling.

Concern about a risk for sudden death during extreme physical exertion in patients with sickle trait has been raised by case reports and population studies of military recruits. Indeed, the presence of sickle trait was associated with an increased risk for otherwise unexplained sudden death among military recruits who were engaged in extreme exertion during basic training. This led to a suggestion that African-American recruits and athletes be screened for sickle trait. However, although the relative risk for sudden death may be elevated, the absolute risk still appears to be very small (about 1 in 3,000 in the Army recruit study) and practically nil for physically well-conditioned persons during exercise (no episodes of sudden death attributable to sickle trait among Olympic or professional athletes, even when they performed at high elevations).

Thus, for untrained persons with sickle trait, a small increase in risk may indeed exist, especially at extremes of exertion and altitude, but under most other circumstances, sickle trait appears to be a benign condition. Some data even suggest that the reason for an occasional sudden death in patients with what appears to be ordinary sickle trait is the undetected presence of an electrophoretically silent hemoglobin variant migrating like hemoglobin A but causing significant sickling in patients heterozygous for hemoglobin S.

If sickle trait is a generally benign condition, then the principal reason for screening adults is to provide genetic counseling. It is important to consider the effectiveness of such counseling. Evidence suggests that the identification and counseling of heterozygotes do not alter marriage and parenthood decisions. The person who does not wish to make such decisions on the basis of carrier status is not likely to benefit from screening. Some families have been traumatized by questions of paternity raised by indiscriminate screening. Because of the confusion among patients and physicians about differences between sickle cell disease and trait, unnecessary anxiety may be the most common result. Surveys have demonstrated that many internists and general practitioners do not sufficiently understand the implications of screening test results to be able to counsel patients properly.

SCREENING AND DIAGNOSTIC TESTS

Screening tests for sickle cell trait are inexpensive and reproducible. Results of tests for sickling, including the use of 2% metabisulfite solution and the more expensive commercial methods, are positive in the presence of hemoglobin S, but the tests do not distinguish between homozygotes, heterozygotes, and double heterozygotes (hemoglobin S combined with thalassemia or hemoglobin C). Hemoglobin electrophoresis can also be performed inexpensively; however, it is not a substitute for a test of sickling because some nonsickling hemoglobin variants travel in the same electrophoretic band as hemoglobin S (e.g., hemoglobin Lepore). Examining a peripheral blood smear and checking a reticulocyte count provide supportive data for diagnosis of sickle cell disease (see Chapter 79).

A number of techniques have been developed to diagnose sickle cell disease during early gestation of fetuses at risk. Chorionic biopsy has been used successfully to identify sickle cell disease during the first 6 to 8 weeks of pregnancy. The availability of prenatal diagnosis should be explained before screening. Careful counseling must also precede the responsible application of any prenatal diagnostic method. Risks of the procedure to mother and fetus, risks of false-positive and false-negative test results, and the acceptability of therapeutic abortion should be discussed.

CONCLUSIONS AND RECOMMENDATIONS

- Sickle cell disease is a serious health hazard that usually presents during early childhood. Screening of newborn infants permits appropriate prophylaxis and immunization and is recommended.
- Sickle cell trait is generally a benign condition. Although there is some question of an increased relative risk for sudden death in untrained persons required to exert extreme physical effort at very high altitude, the absolute risk is extremely low and nil in trained persons.
- Thus, the principal reason for screening adults for the presence of sickle trait is to facilitate genetic counseling. Screening of high-risk pregnant women at their first prenatal visit should be preceded by counseling about the subsequent need for paternal testing and the availability of prenatal diagnosis. Indiscriminate screening followed by inadequate counseling may be harmful and is not likely to provide benefits to those persons who will not revise marriage and parenthood decisions on the basis of test results.
- Screening for sickle trait should be offered to African-American adults in reproductive age groups. The implications of test results should be fully explained before testing is performed.

CHAPTER 79 EVALUATION OF ANEMIA

In most instances, the office presentation of anemia is incidental, with no obvious cause and no hemodynamic compromise. Because anemia is not a diagnosis, its appearance necessitates identification of the underlying cause, especially in men, women who are neither menstruating nor pregnant, and the elderly; in all these groups, the probability of disease is high. In more than 50% of cases, a clinically important cause is discovered. The task for the primary physician is to design a cost-effective assessment that concentrates on testing for causes of prognostic significance.

DEFINITION, PATHOPHYSIOLOGY, AND CLINICAL PRESENTATION

Definition. Anemia is defined as a reduction in the hematocrit or hemoglobin concentration. The widely accepted World Health Organization definition is expressed in terms of hemoglobin concentration: for male adults, below 13 g/dL; for nonpregnant women, below 12 g/dL; for pregnant women, below 11 g/dL. Although the cutoff points are somewhat arbitrary, derived statistically from population data, these numbers can have meaning for individual patients, as they tend to correlate with health status and prognosis, particularly in the elderly. Although the mean hemoglobin concentration tends to decline with age, the significance of anemia does not, and consequently the diagnostic criteria are not adjusted downward for age. Because anemia is defined in terms of red cell mass and hemoglobin concentration, a spurious diagnosis of anemia may be made when the plasma volume is expanded. Similarly, if the plasma volume is contracted, a true anemia may be masked.

Pathophysiology. Anemia may result from *bleeding, inadequate red cell production,* or *excessive red cell destruction*; often, two or more mechanisms are operating simultaneously. Production is decreased when defects in stem cell proliferation or differentiation, DNA synthesis, or hemoglobin synthesis, or a combination of these deficiencies, is present. Excessive destruction can result from membrane disorders, abnormal hemoglobins, enzyme deficiencies, and a host of extrinsic problems, such as mechanical disruption or antibody-mediated injury.

The development of symptoms and signs depends on the abruptness and severity of onset, age of the patient, and ability of the cardiopulmonary system to compensate for the decrease in blood volume and oxygen-carrying capacity. When onset is gradual, symptoms may be minimal because there is adequate time for compensatory adjustments to occur. Important responses include an increase in 2,3-diphosphoglycerate, which facilitates oxygen delivery to tissues, and expansion of the plasma volume.

Clinical Presentation. Symptoms are a function of the severity and speed of onset of the anemia. Patients experiencing a rapid onset of anemia, with little time for compensatory mechanisms to act, are likely to have the most symptoms. Those who have a hematocrit above 30% and a gradual onset and are otherwise in good health rarely note symptoms. However, if the hematocrit falls further, *exertional dyspnea* and *fatigue* may begin to appear after strenuous activity. Greater reductions in the hematocrit result in cardiopulmonary symptoms that come with less activity. Age and cardiopulmonary reserve are also important determinants of symptoms. A potpourri of nonspecific complaints frequently accompanies anemia, including headache, tinnitus, poor concentration, palpitations, vague abdominal discomfort, anorexia, nausea, and diarrhea or constipation. *Tachycardia* and diminished peripheral resistance occur as the hemoglobin falls below 7.5 g/100 mL; a *systolic flow murmur* resulting from high output is common. *Pallor* is an obvious finding, best seen in the conjunctiva, but it is of little help as an indicator of severity. More specific clinical findings depend on the underlying cause, which can best be classified on the basis of red cell morphology (determined by appearance on a Wright-stained peripheral smear, mean corpuscular volume calculated by an autoanalyzer, and degree of anisocytosis).

Microcytic Anemias

Iron Deficiency. *Inadequate dietary intake, inadequate absorption,* and excessive *blood loss* may result in iron-deficiency anemia. Most patients with mild disease are asymptomatic, manifesting only a low-grade microcytic anemia. In otherwise healthy menstruating women, iron deficiency is often blamed for a host of symptoms, including *fatigue, headache, paresthesias,* and *irritability.* Although fatigue may certainly be a manifestation of severe anemia, the correlation between these symptoms and hemoglobin concentration has been poor in women with mild anemia. In placebo-controlled double-blinded studies, they fail to show consistent symptomatic benefit with iron therapy. *Menorrhagia* is attributed by some investigators to instances of iron deficiency, but this is disputed by others. *Pica* and *dysphagia* (caused by an esophageal web) are classic, although rare, features today.

The physical findings that occur in iron deficiency are a bit more specific. *Atrophic glossitis* is commonly found, as is *cheilitis;* koilonychia, with spooning, ridging, and thinning, is rare. Other physical findings and symptoms are manifestations of the underlying cause. The earliest laboratory changes are depletion of marrow iron stores and a corresponding *fall in serum ferritin.* These are followed by a *decrease in serum iron* and an *increase in transferrin,* which produce in many cases a reduction in the *transferrin saturation* to *less than 16%.* The first change in the peripheral blood is a drop in the *hematocrit* and *hemoglobin concentration.* An *anisocytosis* develops, manifested by an elevation in the *red cell distribution width* (RDW). Later, with increasing severity of anemia (hemoglobin concentration <9 g/dL), red cells become *microcytic* and eventually *hypochromic.*

Anemia of Chronic Disease. A common accompaniment of chronic inflammatory diseases and malignancy, the anemia of chronic disease is believed to involve trapping of iron by activated macrophages, which renders the iron unavailable for erythropoiesis. In addition, some suppression of erythropoiesis by humoral substances (interleukins, tumor necrosis factor, prostaglandins), elaborated in the course of the underlying chronic disease process, often occurs. Interestingly, erythropoietin is inappropriately low in almost all cases. The anemia is usually moderate, with hemoglobin levels in the range of 7 to 11 g/dL. Both serum iron and iron-binding capacity are reduced. The smear is most often *normocytic* but can be *hypochromic* and even *microcytic,* mimicking iron deficiency. The *serum iron falls* before anemia sets in; *transferrin saturation* may be below 16%, again simulating iron deficiency. However, marrow iron stores and *ferritin* levels are *normal* or increased.

Another important anemia of chronic disease is that associated with *HIV infection,* which affects the bone marrow. Myelofibrosis occurs. Anemia is seen in about 15% of asymptomatic HIV-positive persons, 45% with AIDS-related complex, and 75% of those with untreated AIDS. For unknown reasons, *erythropoietin* is inappropriately *low.* The smear in most cases is *normochromic–normocytic. Rouleaux* formation resulting from circulating immune complexes sometimes develops, but hemolysis is uncommon. The anemia can be exacerbated by *medications* used in the treatment of HIV infection (zidovudine, pentamidine, trimethoprim, sulfonamides). Zidovudine is especially toxic to marrow, causing anemia in about 30% of instances. *Neutropenia* and *thrombocytopenia* occur to a lesser extent. Patients most susceptible to the adverse hematologic effects of zidovudine are those with a low CD4-cell count, preexisting anemia, concurrent vitamin B$_{12}$ deficiency, or neutropenia.

Thalassemia Minor (Thalassemia Trait). This condition is typically detected in asymptomatic patients undergoing an evaluation for a microcytic hypochromic anemia that does not respond to iron. A gene defect leads to impaired red cell maturation by causing an excess of either a- or b-chains of hemoglobin to accumulate. The most prevalent form is b-thalassemia trait, common among persons of Mediterranean ancestry. It is associated with an increase in *hemoglobin A$_2$.* There are no characteristic physical findings. The red cell count is elevated, and the smear may reveal *target cells, basophilic stippling, polychromatophilia, poikilocytosis,* and *anisocytosis* in addition to microcytosis. a-Thalassemia trait is seen among African-Americans. The hemoglobin A$_2$ level is normal, but a mild anemia, hypochromia, and microcytosis are present.

Sideroblastic Anemias are a heterogeneous set of disorders that include a *primary* type, which may be a preleukemic state; a *congenital* pyridoxine-responsive variant; and *secondary* variants associated with rheumatoid arthritis, polyarteritis, malabsorption, chronic alcoholism, cancer, porphyria, lead poisoning, and true pyridoxine deficiency. These, too, are conditions of abnormal red cell maturation. They can lead to significant anemia requiring repeated transfusion of red cells. Their hallmark is the accumulation of nonheme iron within the mitochondria of red cells. When stained for iron, immature red cells demonstrate a ring of stain around the nucleus (*ringed sideroblasts*). In the primary type, patients are typically over the of age 60 and may have *primary myelodysplasia,* a proliferative disease of the bone marrow in which a clone of stem cells suppresses production of other cell lines. A *secondary myelodysplastic syndrome* occurs as a consequence of cancer chemotherapy. The spleen is usually not enlarged, as it is in myeloproliferative disorders. The smear is classically microcytic but may be macrocytic or dimorphic, especially in acquired forms. Cells can be hypochromic, which leads to confusion with iron deficiency. Anisocytosis and poikilocytosis are pronounced. *Serum iron is*

elevated, as is *transferrin saturation*. Marrow iron stains show many abnormal ringed sideroblasts. The anemia may be refractory, sometimes followed by marrow failure and acute myeloid leukemia.

Macrocytic Anemias

Vitamin B$_{12}$ Deficiency. A classic cause is reduced gastric production of intrinsic factor, as occurs in *pernicious anemia* and after subtotal *gastrectomy*. The association of pernicious anemia with *Hashimoto's thyroiditis* and *vitiligo* suggest an autoimmune mechanism, confirmed by the identification of autoantibodies to intrinsic factor and parietal cells. Dietary lack is rare because vitamin B$_{12}$ is available in everyday foods, and body stores can hold up to a 3-year reserve. However, patients with achlorhydria or hypochlorhydria resulting from atrophic gastritis or gastric surgery may fail to split cobalamin from food, resulting in so-called *food-cobalamin malabsorption*, which is thought to be responsible for much of the B$_{12}$ deficiency seen in the elderly and those with prior gastric surgery. Population studies find a prevalence of vitamin B$_{12}$ deficiency of 1.9% in persons over the age of 60 years. *Blind-loop syndrome* and *terminal ileal disease* are other causes.

Onset is gradual. In pernicious anemia, symptoms usually become evident in the sixth decade. Gastrointestinal problems such as *anorexia* and *diarrhea* may predominate. *Sore tongue* resulting from *atrophic glossitis* is a classic presentation, as is *numbness* and *tingling* in the extremities associated with peripheral neuropathy. The neurologic deficits result from defects in the maintenance of myelin integrity. Besides peripheral neuropathy, injury to the posterior columns and corticospinal tracts of the spinal cord (i.e., *subacute combined degeneration*) may be present, manifested by disturbances of *position* and *vibratory sense and incoordination, spasticity,* and *upturned toes*. Cerebral dysfunction may also ensue, leading to *memory loss, depression,* and *irritability*. If vitamin B$_{12}$ deficiency is uncorrected, demyelination can progress to axonal degeneration and irreversible neuronal death. Nerve damage can occur in the absence of anemia.

By the time the anemia is discovered, it may be severe. *Hypersegmented polymorphonuclear leukocytes* are an early finding on peripheral blood smears that is specific for the megaloblastic anemias. *Oval macrocytes* are also characteristic, although poikilocytosis is considerable. Classically, the mean corpuscular volume rises above 100 µm^3 and the serum vitamin B$_{12}$ level falls below 100 pg/mL, but in up to a third of cases macrocytosis may be absent or the vitamin B$_{12}$ level may be greater than 100 pg/mL. The serum concentration of *holotranscobalamin II* (the vitamin B$_{12}$ carrier protein) begins to decline before the vitamin B$_{12}$ level does. Macrocytosis may be absent if concurrent iron deficiency is present, but the hypersegmented polymorphonuclear leukocytes persist. In pernicious anemia, *achlorhydria* is found on stimulation testing. Serum homocysteine levels frequently become elevated, which may predispose to vascular disease (see [Chapter 31](#)); levels of the *methylmalonic acid* increase.

Folate Deficiency. Inadequate dietary intake is the usual cause, as body stores are limited to a 3-month reserve. Chronic alcohol abuse is the classic cause. Increased demand sometimes occurs, as in pregnancy, hemolysis, malignancy, or severe psoriasis. Decreased uptake resulting from malabsorption or drugs (e.g., phenytoin, other anticonvulsants) also can trigger the anemia. The same is true for folate antagonists such as methotrexate, trimethoprim, and triamterene. Hematologic features resemble those of vitamin B$_{12}$ deficiency; no neurologic deficits are present. Folate deficiency is an important cause of *hyperhomocysteinemia*, which is associated with increased risk for arterial and venous thrombosis (see [Chapter 31](#)).

Liver Disease. Hepatocellular disease is responsible for a host of anemias, especially when accompanied by alcoholism and poor diet. It accounts for many cases of macrocytic anemia. Folate deficiency, marrow suppression, hypersplenism, bleeding, and bile salt alteration of the red cell membrane all contribute. The smear shows considerable poikilocytosis with *spiculated red cells* and some *macrocytes*; if folate deficiency occurs, a megaloblastic picture is superimposed.

Sideroblastic Anemia. [See above](#).

Normochromic–Normocytic Anemias

Hemolytic Anemias are a diverse group. Inherited forms are caused by intrinsic red cell defects; acquired types depend primarily on extrinsic mechanisms, such as immunologic or mechanical injury. Clinical presentations vary according to rate of destruction, compensatory adaptations, and underlying cause. Jaundice sets in when the capacity of the liver to conjugate excess bilirubin from hemoglobin breakdown is exceeded; the serum level of unconjugated bilirubin climbs. *Splenomegaly* evolves as trapping of damaged red cells progresses. Sudden fever, chills, headache, back and abdominal pain, and *hemoglobinuria* characterize severe acute hemolysis.

The reticulocyte count is elevated unless an accompanying marrow defect is present. The peripheral smear usually appears normochromic–normocytic but may be macrocytic because of the release of immature forms during rapid red cell destruction and regeneration. Polychromatophilia is common, and *nucleated red cells, stippling, schistocytes,* and *Howell-Jolly bodies* may be noted. *Spherocytes* occur in *hereditary spherocytosis*, a condition of reduced cell membrane area resulting from a defect in synthesis of the membrane protein spectrin. *Spherocytosis* is also seen in *immune hemolytic anemia* as a consequence of membrane loss.

Sickle Cell Disease is the most prevalent hemolytic condition in the African-American population. *Sickle cell trait* is asymptomatic and anemia is absent, although mild hematuria caused by sickling in the hypertonic renal medulla sometimes occurs. The peripheral smear is normal except for an occasional *target cell*. Hemoglobin electrophoresis reveals less than 50% of total hemoglobin to be of the S variety. Patients homozygous for the sickle cell gene have *sickle cell anemia*, a much more serious condition in which painful crises are precipitated by stress (especially infection). Intravascular sickling ensues, the red cells become rigid, and vascular occlusion may result, leading to arterial desaturation, hemolysis, and organ damage. *Leg ulcers, hepatomegaly, hematuria, renal concentrating defects*, and mild *jaundice* commonly occur. Patients report acute, severe *pain* in the lower extremities, back, or abdomen. *Fever* and *leukocytosis* may also be present. Attacks typically last from a few hours to a few days, then resolve spontaneously. Aplastic crises develop when a concurrent illness suppresses erythropoiesis. The smear is normochromic; *sickled cells* may be noted in addition to target forms. Hemoglobin electrophoresis reveals a predominance of *hemoglobin S*. Addition of a reducing agent, such as metabisulfite, to a drop of blood causes the cells to sickle within a few minutes and confirms the diagnosis.

Glucose-6-phosphate Dehydrogenase Deficiency is a sex-linked red cell defect compromising the enzyme that maintains hemoglobin in an unoxidized state. In its episodic form, seen in African-Americans, the condition causes hemolysis after exposure to oxidant compounds (sulfonamides, antimalarials) or infection. A chronic variety occurs in persons of Mediterranean ancestry.

Drug-induced Hemolytic Anemias usually manifest an immune mechanism, such as adsorption to the red cell of drug—antibody complexes (quinidine); adsorption to the red cell of drug to form a hapten, followed by binding of antidrug antibody (high-dose penicillin); or induction of a red cell "autoantibody" (long-term methyldopa). The hallmark of most drug-related hemolytic episodes is a positive *direct Coombs' test* result. Withdrawal of the offending agent ends the process.

Autoimmune Hemolytic Anemias result when patients produce antibodies against their own red cells. They are classified according to the type of antibody produced (immunoglobulin G or immunoglobulin M). Those of the *IgG class* are directed against the Rh antigen. Most are *"warm" autoantibodies;* although many are idiopathic, about 50% occur in the context of lymphoma, lupus, ulcerative colitis, or chronic lymphocytic leukemia. The diagnosis is made by detecting IgG and C3d proteins on the red cell surface. Macrophages that can detect these proteins bind the involved red cells. Hemolysis is mostly extravascular. The red cells are cleared by the spleen. The *IgM* form of autoimmune hemolytic anemia is a *cold hemagglutinin* condition. These antibodies are seen in mycoplasmal, Epstein-Barr virus, or cytomegalovirus infection and in lymphoproliferative conditions. *Cold agglutinin* titers are markedly elevated in the setting of hemolysis (>1:1,000).

Aplastic Anemias are usually idiopathic but may be linked to a marrow toxin (cytotoxic drugs, radiation), an idiosyncratic drug reaction (chloramphenicol, gold, sulfur compounds, carbamazepine), or a viral infection (hepatitis B virus, hepatitis C virus, cytomegalovirus, HIV, parvovirus). Onset is gradual, with fatigue and bleeding noted first; infection is a later problem. No organomegaly occurs. The smear appears normochromic–normocytic, but the number of platelets is diminished. There are no signs of increased red cell production. The reticulocyte count is zero, and a pancytopenia is present.

Renal Failure. The anemia of chronic renal failure is caused by a reduction in both production and survival of red cells. Lack of erythropoietin and metabolic injury to erythrocytes are postulated mechanisms. The severity of the anemia parallels the degree of azotemia. The smear is normochromic–normocytic; burr cells are sometimes prominent.

Hypothyroidism is associated with a number of anemic states. The most common is a mild normochromic–normocytic anemia. Iron deficiency may occur secondary to heavy menstrual bleeding. Also, a macrocytic picture that clears after administration of exogenous thyroid hormone is sometimes encountered. A true megaloblastic anemia caused by vitamin B$_{12}$ deficiency occurs in about 10% of hypothyroid patients with a macrocytic smear; the relation between hypothyroidism and pernicious

anemia is unresolved, but an autoimmune mechanism is postulated.

Anemia of Chronic Disease. See above.

DIFFERENTIAL DIAGNOSIS

A practical method for organizing the many causes of anemia is to group them according to (a) the appearance of the Wright-stained smear of the peripheral blood and (b) the electronically determined red cell indices. This method allows causes to be classified into normochromic-normocytic, hypochromic-microcytic, and macrocytic categories (Table 79.1) and facilitates workup.

Microcytic (MCV <80)
1. Iron deficiency
2. Anemia of chronic disease
3. Thalassemia trait
4. Sideroblastic anemia

Normocytic (MCV 80–100)
1. Hemolysis
   a. Drug-induced
   b. Autoimmune (idiopathic, collagen disease, lymphoma)
   c. Cold agglutinin–induced (viral infection, lymphoma)
   d. Hemoglobinopathy (sickle cell disease, G-6-PD deficiency)
   e. Hereditary spherocytosis
   f. Microangiopathy (heart valve, jogging, vasculitis, DIC)
2. Chronic disease, including HIV infection
3. Renal failure
4. Hypothyroidism
5. Myelofibrosis
6. Early stage of iron deficiency
7. Sideroblastic anemia
8. Mixed anemia (e.g., iron and vitamin B₁₂ deficiencies)

Macrocytic (MCV >100)
1. Vitamin B₁₂ deficiency
2. Folate deficiency
3. Aplastic anemia
4. Acute hemolysis or hemorrhage with brisk reticulocytosis
5. Chronic liver disease
6. Myelodysplastic syndromes
7. Hypothyroidism, severe

MCV, mean corpuscular volume; G-6-PD, glucose-6-phosphate dehydrogenase; DIC, disseminated intravascular coagulation.

Table 79.1. Differential Diagnosis of Anemia (Representative Etiologies)

Iron deficiency accounts for most of the anemias seen in the office setting. In community-based primary care practices, iron deficiency is the underlying cause in 95% of anemic women and 50% of anemic men. In male patients and the elderly, the source is typically occult bleeding from an underlying gastrointestinal lesion, which is identified in about half of cases. The prevalence of iron deficiency anemia among premenopausal women is conservatively estimated to be 15%, rising to well over 30% during pregnancy. Even in menstruating women with iron deficiency, an underlying gastrointestinal lesion is not uncommon. Iron deficiency resulting from malabsorption may be the initial presentation of adult celiac disease. Among immigrants from impoverished countries, hookworm infestation is a leading malabsorptive cause of iron deficiency.

Other common causes of anemia include vitamin B_{12} deficiency (nearly 10% of cases) and chronic disease (at least 5% of cases). Among the elderly, vitamin deficiencies are common, with folate deficiency accounting for about 15% of cases and vitamin B_{12} deficiency for about 10%.

WORKUP

Diagnosis and Morphologic Categorization of Anemia

The diagnosis of anemia is based on measurement of the *hematocrit* or *hemoglobin concentration* of venous blood. Any abnormal test result needs to be repeated for confirmation before further evaluation is undertaken. Proper interpretation requires consideration of the patient's *intravascular volume status.* An overly expanded plasma volume will dilute the red cell mass and lead to a false-positive diagnosis. Conversely, dehydration can mask an underlying anemia.

Morphologic categorization helps focus the subsequent evaluation, which proceeds according to whether the anemia is microcytic, macrocytic, or normocytic. Examination of the Wright-stained *peripheral blood smear* and determination of the *red cell indices* (mean corpuscular volume, or MCV, and mean corpuscular hemoglobin concentration, or MCHC) with an autoanalyzer are the time-tested means of classifying anemias morphologically. Recent advances in flow cytometry have made possible an automated means of determining the degree of variability in size of a patient's red cells. This measure of anisocytosis is referred to as the *red cell distribution width* (RDW). Technically, the RDW is the coefficient of variation of cell volume; it serves as a means of detecting red cell heterogeneity, which could previously be done only by examination of the peripheral smear. Although examination of the Wright-stained smear still provides morphologic information unattainable from other sources, the combined use of the MCV and RDW for the initial classification of anemias markedly enhances interpretation (Table 79.2).

MCV <80 MICROCYTOSIS	MCV 80–100 NORMOCYTOSIS	MCV >100 MACROCYTOSIS
Low RDW		
Anemia of chronic disease	Hypoproliferation (e.g., renal failure)	Aplastic anemia
Most thalassemias	Hereditary spherocytosis	Myelodysplastic syndromes
	Anemia of chronic disease	
High RDW		
Iron deficiency	Sickle cell disease	Megaloblastic anemias
Sideroblastic anemia	Early iron deficiency	Acute hemolysis or hemorrhage
Hemoglobin H	Marrow infiltration Chronic hemolysis	Liver disease

MCV, mean corpuscular volume; RDW, red cell distribution width.

Table 79.2. Classification of Anemias by Use of Data from Automated Cytometry

The peripheral smear and red cell indices should be analyzed together; they provide complementary information. Overdependence on machine-generated indices can lead to errors in diagnosis. For example, anemia resulting from deficiencies of both iron and vitamin B $_{12}$ often produces a dimorphic population of microcytic and macrocytic red cells readily observed on peripheral smear, yet the electronically determined MCV will calculate the average size and erroneously suggest a normocytic type of anemia. Moreover, some vitamin B_{12}–deficient patients with normal ferritin levels have normocytic indices.

The Wright-stained smear can also mislead when used alone, and it often lacks sensitivity. Cells that are easily flattened out (as in liver disease) may appear larger on smear than they actually are; the MCV will give a more correct determination of size. The sensitivity of the smear in the detection of iron deficiency has been found to be as low as 49%.

Determination of red cell size on the peripheral smear is facilitated by using the nucleus of the mature small lymphocyte as a good reference standard for normal red cell diameter. One can also prepare a control smear of known blood to help judge abnormalities. Use of the MCV and appearance on peripheral smear serves to classify the anemia morphologically and facilitate evaluation.

Not all automatically determined cell indices have proved valuable. Careful studies suggest that the MCHC and the mean corpuscular hemoglobin (MCH) add little to the evaluation of anemia, although the MCHC is still used as a means of quantifying the degree of hypochromia.

Workup by Morphologic Category: Microcytic Anemia

Initial Assessment. The basis for the classification of microcytosis is the presence of small red blood cells on smear and an *MCV of less than 82* fL. A prime

consideration should be iron deficiency and the important underlying conditions that might precipitate it, but thalassemia and anemia of chronic disease are also important to consider, and sometimes sideroblastic anemias.

History should focus on any abnormal blood loss, change in bowel habits, melena, heavy use of aspirin or NSAIDs, family history of anemia (especially in those of Mediterranean descent), concurrent malignancy, HIV infection, symptoms of other chronic infections or chronic inflammatory disorders, number of pregnancies, pica, dysphagia, history of lead exposure, dietary iron intake, quantity of menstrual blood loss, gastric resection, changes in nails, and soreness of the tongue.

Physical Examination includes checking for glossitis, cheilitis, koilonychia, lymphadenopathy, hepatosplenomegaly, rectal mass, stool positive for occult blood, pelvic mass, and other signs of chronic infectious, inflammatory, and neoplastic disorders.

Laboratory Studies usually allow one to differentiate iron-deficiency anemia, thalassemia, sideroblastic anemia, and anemia of chronic disease, although some overlap does occur and may cause confusion and wasteful expenditures if tests are not thoughtfully selected.

Testing for Iron Deficiency. The test of choice for screening and diagnosis of iron deficiency is determination of the level of serum *ferritin*, the storage protein for iron, which correlates best with marrow iron stores. Levels are somewhat higher in men than in women and increase gradually with advancing age. The test is highly sensitive and specific for the diagnosis of iron deficiency. For example, a serum concentration below 15 µg/L has a predictive value for iron deficiency of more than 90% when the pretest probability is only 50%. A level above 100 µg/L virtually rules out the diagnosis. Ferritin is also an acute-phase reactant that rises in response to inflammatory disease or hepatocellular dysfunction, which potentially limits the sensitivity of this test in such settings. However, when the serum ferritin level is below 50 µg/L in the setting of inflammatory or liver disease, the test retains much of its predictive value for iron deficiency. Levels between 50 and 100 µg/L constitute a diagnostic "gray zone," in which case careful attention to other clinical and laboratory data is required to obtain an accurate diagnosis.

Measurements of the *serum iron* level and *total iron-binding capacity* (TIBC) and of the *transferrin saturation* [calculated as a percentage: (Fe/TIBC) × 100] have been traditional components of the workup for iron deficiency, but under most circumstances, they add little information beyond that obtained from the ferritin determination and they lack its sensitivity or specificity. These tests need not be ordered routinely in patients with microcytic anemia. Nonetheless, a transferrin saturation below 16% has been used as a criterion for iron deficiency. However, the specificity of the figure is limited because some patients with the anemia of chronic disease manifest similar reductions in transferrin saturation. Nonetheless, the more typical pattern for the anemia of chronic disease is a low iron level and low TIBC, in contrast to the low iron level and increased TIBC characteristic of iron deficiency. The *RDW* is almost always increased.

Bone marrow aspiration and examination of a sample stained for *iron stores* comprise the "gold standard" for the diagnosis of iron deficiency, but up to 20% of aspirates are unsatisfactory, yielding insufficient marrow stroma. Ferritin testing has all but eliminated the need for marrow aspiration in the diagnosis of iron deficiency, but the test is sometimes necessary in confusing cases. A *therapeutic trial* of oral iron therapy can also be used in uncomplicated cases as a simple alternative to determination of the ferritin level or examination of the marrow. The reticulocyte count is monitored during a 7- to 10-day period. A significant rise in the reticulocyte count is strong evidence for the diagnosis of iron deficiency.

When the cause of the iron deficiency is not evident, a *workup for gastrointestinal blood loss* is indicated. Idiopathic iron-deficiency anemia is associated with a gastrointestinal tract lesion in about one half to two thirds of cases. The most common upper gastrointestinal lesion is peptic ulcer; colon cancer is the leading colonic lesion in this setting. Site-specific symptoms are predictive of the location of the lesion. Concomitant lesions are present in fewer than 1% of cases, so that it is unnecessary to study both the upper and lower gastrointestinal tract if a likely source is found on the first examination. *Endoscopy* is the test methodology of choice (see [Chapter 63](#)). Barium studies are considerably less sensitive, and their yield is nil in the setting of a negative endoscopic evaluation. The vast majority of patients with no detectable lesion on upper and lower gastrointestinal endoscopy have a favorable prognosis; most respond to iron therapy. Those who do not are likely to have an underlying medical illness. Menstruating women require workup just as do other patients; screening for occult gastrointestinal blood loss is particularly important. A positive fecal occult blood test result, hemoglobin below 10 g/dL, and abdominal symptoms are predictive of the endoscopic finding of a gastrointestinal lesion in an anemic menstruating woman.

When iron *malabsorption* is suspected clinically, consideration should be given to testing for adult celiac disease (*antiendomysial IgA antibodies, small-bowel biopsy*); if the patient is from an undeveloped country, checking the *stool* for evidence of hookworm *ova* and *parasites* is in order.

Testing for Thalassemia. Once iron deficiency has been ruled out as the cause of microcytic anemia, the focus shifts to differentiating between anemia of chronic disease, thalassemia, and sideroblastic anemia. History is very important in this regard. A person of Mediterranean extraction without underlying chronic illness is likely to have thalassemia trait, which necessitates a look at the *peripheral smear* for abnormalities of red cell morphology (e.g., *target cells, poikilocytosis*) and a check of the *red cell indices* for *reduced MCHC* and *increased red cell count*. Determination of the *hemoglobin A$_2$* level can confirm the diagnosis, but it may not be elevated if concurrent iron deficiency is present. A *hemoglobin electrophoresis* may be needed when thalassemia trait is suspected in an African-American patient because hemoglobin A$_2$ is not increased in a-disease.

Differentiating Anemia of Chronic Disease from Sideroblastic Anemia. Once iron deficiency and thalassemia trait are deemed to be of low probability, then the task shifts to differentiating anemia of chronic disease from sideroblastic anemia. Here, the *serum iron* level and *TIBC* may be of help. In the anemia of chronic disease, the serum iron level and *transferrin saturation* are likely to be below normal or reduced; in sideroblastic anemia, both are often increased, as is the serum *ferritin*. Such an increase in the absence of another reason for iron overload suggests a sideroblastic state and the need for a bone marrow aspirate to search for ringed sideroblasts.

Workup by Morphologic Category: Macrocytic Anemia

Initial Assessment. The criteria for inclusion in this group are an MCV above 95 fL, a normal MCHC, and macrocytes on smear. Often, the latter are hard to detect in mild cases. Marked macrocytosis (MCV >115 fL) identified electronically is associated with a high probability of folate or vitamin B$_{12}$ deficiency, liver disease, or alcoholism accompanied by liver disease.

Megaloblastic versus Nonmegaloblastic. The first objective is to distinguish megaloblastic from nonmegaloblastic causes. The *peripheral smear* is the single most helpful test. The presence of *hypersegmented polymorphonuclear leukocytes* (having nuclei with five or more lobes) is among the earliest and most specific signs of a megaloblastic anemia, seen in more than 65% of cases. *Oval macrocytes* are also an early and characteristic finding but may be absent in the setting of concurrent iron deficiency. An increase in hypersegmented polymorphonuclear leukocytes can be screened for by counting the number of neutrophils with five or more lobes in a routine 100-cell differential. Finding three neutrophils with five lobes or even one with six is strong presumptive evidence for megaloblastic anemia.

Bone marrow aspiration may be needed in confusing situations (such as differentiating a sideroblastic anemia from a truly megaloblastic type, or searching for megaloblastic changes in a patient with a low-normal vitamin B$_{12}$ level), but a peripheral smear suffices in most instances. It must be remembered that megaloblastic marrow changes can revert to normal within 12 to 24 hours of therapy, and thus treatment should be delayed if marrow examination is anticipated. However, neutrophil hypersegmentation may persist for up to 2 weeks after initiation of vitamin replacement.

Folate versus Vitamin B$_{12}$ Deficiency. Once a megaloblastic anemia has been identified, the focus shifts to folate versus vitamin B$_{12}$ deficiency. History and physical examination can give important clues. A history of gastric surgery, inflammatory bowel disease, Hashimoto's thyroiditis, vitiligo, or raw fish intake (fish tapeworm) may provide the substrate for vitamin B$_{12}$ deficiency. Neuropsychiatric symptoms and signs in addition to those of subacute combined system disease further suggest vitamin B$_{12}$ deficiency, as do the findings of glossitis and diarrhea. Alcoholism, poor nutrition, pregnancy, blood dyscrasias, sprue, severe psoriasis, and anticonvulsant intake suggest folate lack. Antimetabolite therapy with folate antagonists such as methotrexate can cause a megaloblastic picture with normal serum folate levels.

Serum folate and *vitamin B$_{12}$* determinations are helpful, but a number of pitfalls are encountered in interpreting the results. The bioassay for vitamin B$_{12}$ is affected by recent antibiotic intake. Assays in which radioactive cobalt or immunologic techniques are used are not affected. However, up to a third of patients with documented pernicious anemia will have vitamin B$_{12}$ levels above 100 ng/L (the often-cited cutoff for diagnosis). Persistence in pursuing the diagnosis is necessary when clinical suspicion is high. Vitamin B$_{12}$ levels may be artificially low in patients with folate deficiency alone; folate and vitamin B$_{12}$ levels must always be measured together. Recent intake of green vegetables can cause a false rise in the serum folate level. Concomitant measurement of serum and red cell folate is needed to establish the

diagnosis of a true folate deficiency.

Serum measurements of *methylmalonic acid* and *total homocysteine* enhance sensitivity of diagnostic testing and are helpful in cases in which the serum vitamin B_{12} or folate result is confusing. Both folate and vitamin B_{12} are needed for the conversion of homocysteine to methionine. In both folate and vitamin B_{12} deficiency, homocysteine is increased, but only in B_{12} deficiency is methylmalonate increased.

An empiric means of determining vitamin B_{12} or folate deficiency is to conduct a *therapeutic trial* of replacement therapy. Such a trial is appropriate when serum assays are unavailable or the results are equivocal. The hematocrit and reticulocyte counts are measured twice before administration, then followed every few days for up to 10 days after a small but effective dose of vitamin B_{12} (e.g., 100 µg IM) or folate (1 mg IM) has been given. The trial result is positive if a significant rise in reticulocyte count occurs within 10 days. It is important to use only small folate doses in such trials. Large folate doses can transiently and nonspecifically improve the hematologic picture in a patient with vitamin B_{12} deficiency and lead to its progression by obscuring the diagnosis.

Determining the Cause of Vitamin B_{12} Deficiency. To distinguish vitamin B_{12} deficiency caused by malabsorption from that caused by lack of intrinsic factor, an *oral Schilling test* with and without intrinsic factor is used. An unlabeled IM dose of 1,000 µg of vitamin B_{12} is given to saturate binding sites. Then an oral dose of radioactive vitamin B_{12} without intrinsic factor is given, and both urine and plasma samples are taken to determine the amount of vitamin B_{12} absorbed. The test is repeated with the addition of intrinsic factor. In malabsorptive states, no improvement will occur with intrinsic factor, whereas it will in pernicious anemia. One difficulty with the test is that vitamin B_{12} deficiency can cause malabsorption, which confuses test interpretation. Thus, the test should be postponed until the deficiency is corrected. In addition, sensitivity is not very high; false-negative results occur in up to 40% of cases. The commonly used double isotope method of performing the Schilling test (labeled free cobalamin and labeled cobalamin bound to intrinsic factor are administered at the same time) often produces false-negative results. The Schilling test is not helpful for detecting food-cobalamin malabsorption. Such patients have a normal test result because the test uses free cobalamin and does not assay the ability to split cobalamin from food.

Two other tests can improve the diagnostic accuracy and yield in cases of suspected pernicious anemia. Testing for *anti–intrinsic factor antibody* provides a highly specific approach to diagnosis. The test helps confirm the presence of pernicious anemia; specificity is high so long as no vitamin B_{12} is injected within 48 hours of testing; sensitivity is only modest (60% to 70%). Determination of the *serum gastrin* level may also be helpful because it is elevated in more than 80% of cases. *Antiparietal cell antibodies* are present in more than 90% of cases, but the false-positive rate can be as high as 10% to 30%.

If pernicious anemia is found, *endoscopic examination* of the stomach is indicated because of the increased risk for gastric cancer and carcinoid tumors; thyroid function needs to be assayed by determination of the thyroid-stimulating hormone level.

Nonmegaloblastic Macrocytic Anemias. These can be divided into subgroups according to whether marrow activity is increased, normal, or decreased. To make this determination, a *reticulocyte count* is obtained. (A normal value is 0.8% to 2.5% in male patients and 0.8% to 4.1% in female patients; correction for anemia is made by multiplying the reticulocyte count by the hematocrit and dividing the result by 0.45.) Reticulocytes are increased by hemorrhage or hemolysis; in the absence of overt bleeding, a workup for hemolysis is indicated (see below). Low-normal or decreased counts occur in myxedema and chronic liver disease and are indications for performing thyroid and liver function studies (see Chapter 71 and Chapter 104). Marked reductions may occur in myelophthisic states and sideroblastic anemia. The patient should be questioned and examined carefully for symptoms of any of these conditions, and the smear should be studied again for teardrop and fragmented forms and for sideroblasts, respectively. A *bone marrow biopsy* is indicated when a sideroblastic anemia or a myelophthisic process is a concern; aspiration of the marrow may yield only a dry tap and is insufficient.

Workup by Morphologic Category: Normochromic–Normocytic Anemia

This category encompasses a diverse group of conditions that can be classified according to the marrow response, manifested by the *reticulocyte count.*

Elevated Reticulocyte Count: Workup for Hemolysis. If no evidence of recent brisk bleeding is present, then hemolysis and its precipitants require consideration. The history is reviewed thoroughly for medications (e.g., penicillins, cephalosporins, macrolides, tetracyclines, sulfa drugs, quinidine, methyldopa); symptoms of sickle cell disease (e.g., fever and attacks of chest, musculoskeletal, and abdominal pain); a family history of anemia; symptoms of a viral infection (mononucleosis, cytomegalovirus infection, viral hepatitis); lymphoproliferative disease; and systemic lupus. During the physical examination, the patient is checked for splenomegaly and signs of an underlying viral, lymphoproliferative, or connective tissue disease (see Chapter 12, Chapter 84, and Chapter 146).

The laboratory assessment includes a check of hemolytic indices: *bilirubin, haptoglobin,* and *lactic dehydrogenase.* Haptoglobin is the most sensitive but least specific because it is an acute-phase reactant. Lactic dehydrogenase and unconjugated bilirubin are less sensitive but more specific for significant hemolysis. In a patient taking a potentially offending drug, a *direct Coombs' test* should be undertaken to assess the possibility of drug-related hemolysis. A drug-related or infection-related episode in an African-American patient should also raise the question of glucose-6-phosphatase deficiency, especially when the drug is a sulfonamide or an antimalarial. An African-American patient presenting with painful episodes of hemolysis should have a smear examined and a *hemoglobin electrophoresis* obtained, and a *metabisulfite test* for sickling of red cells should be performed. If an underlying lymphoproliferative disorder or connective tissue disease is detected, then consideration of an immune hemolytic anemia is appropriate and a sampling of the blood for *IgG autoantibodies* is indicated. Concurrent viral infection or lymphoproliferative disease raises the question of an IgM-based hemolytic process and the need to check *cold hemagglutinin* levels. Bone marrow examination in cases of suspected hemolysis is unnecessary.

Reticulocyte Count Not Appropriately Elevated: Workup for Metabolic Disease. A metabolic basis of marrow suppression is suggested by this presentation. Causes that require consideration include renal failure, myxedema, Addison's disease, and alcoholic liver disease. Even early forms of vitamin B_{12} deficiency and iron deficiency may present with relatively normal red cell indices, as can the anemia of chronic disease, so that they also must be checked for (see above).

Reticulocyte Count Nil: Workup for Aplastic Anemia. A very low or absent reticulocyte count is suggestive of an aplastic anemia, especially if accompanied by evidence of pancytopenia on the peripheral smear and cell counts. A history of drug use (e.g., chloramphenicol, phenylbutazone, antimetabolites, gold, zidovudine, pentamidine), toxin exposure (benzene, insecticides), or recent viral illness may provide a clue to the cause. In the majority of instances, the history is unrevealing. Bone marrow biopsy is indicated if the condition persists after all drugs are halted.

SYMPTOMATIC THERAPY

Few patients who present with an anemia of gradual onset require immediate correction of the anemia. The one exception is the patient with significant cardiopulmonary disease, who may be compromised by a decrease in oxygen-carrying capacity (i.e., hematocrit <30%). In almost all other instances, evaluation should proceed in an orderly manner, and therapy should be withheld until a specific diagnosis can be made and a specific therapy can be implemented (see Chapter 82). The exception to this rule is the use of therapy as a diagnostic trial (e.g., vitamin B_{12} replacement). All too common is the practice of simultaneously prescribing multiple hematinics, which obscure important findings and the detection of serious underlying disease. The elderly and others with limited cardiopulmonary reserve should be admitted for inpatient evaluation and consideration of transfusion therapy when they are experiencing dyspnea, angina, or marked fatigue because of their anemia.

PATIENT EDUCATION

Many patients think anemia is caused by a vitamin deficiency or iron deficiency and consequently attempt self-treatment before seeing a physician. Others request vitamin therapy. A common error among both patients and physicians is to attribute symptoms of depression, such as fatigue and listlessness, to an underlying anemia. Unless the hematocrit is well below 30%, or the patient has very little cardiopulmonary reserve, this attribution is unjustified (see Chapter 8). Finally, the patient needs to be told to what extent the anemia accounts for symptoms, what the possible causes are, and what the appropriate workup will be.

RECOMMENDATIONS

All Cases

- Classify the anemia and conduct the workup on the basis of peripheral smear and MCV: microcytic if MCV is below 82 fL and red cells are small, macrocytic if MCV is above 95 fL and red cells are large, and normocytic if MCV is between 82 and 95 fL and red cells are normal in size.

Microcytic Anemia

- Test first for iron deficiency. Obtain a serum ferritin, the test of choice for iron deficiency. One need not order a serum iron or TIBC for a diagnosis of iron deficiency unless there is reason to suspect that the ferritin may be elevated as a consequence of acute inflammation. If iron deficiency is found but its cause is not evident, begin a search of the gastrointestinal tract for a source of occult blood loss (see Chapter 63).
- If iron deficiency is ruled out, assess for thalassemia. Check for Mediterranean extraction and family history of anemia or thalassemia. Examine the peripheral smear and red cell indices for characteristic manifestations (e.g., target cells, teardrops, increased red cell count, reduced MCHC), and consider testing for hemoglobin A$_2$ level.
- If iron deficiency and thalassemia have been ruled out, obtain a transferrin saturation and ferritin level to help differentiate anemia of chronic disease from sideroblastic anemia. If both are elevated, then consider a bone marrow aspirate to check for ringed sideroblasts.

Macrocytic Anemia

- Examine the peripheral smear for hypersegmented polymorphonuclear leukocytes and oval macrocytes. If they are present, obtain serum vitamin B$_{12}$ and folate levels.
- If the serum vitamin levels are not diagnostic, obtain serum homocysteine and methylmalonate levels enhance diagnostic sensitivity or alternatively, perform a diagnostic trial with a small dose of vitamin B$_{12}$ or folate, monitoring reticulocyte count.
- If vitamin B$_{12}$ deficiency is detected, consider a Schilling test to differentiate lack of intrinsic factor from malabsorption.
- If the macrocytic anemia is nonmegaloblastic, obtain a reticulocyte count and examine the peripheral smear to determine if marrow activity is increased, normal, or decreased.
- If the reticulocyte count is high in the absence of hemorrhage, check for hemolysis; if it is normal or slightly reduced, consider hepatic and thyroid dysfunction; if markedly reduced, review peripheral smear for teardrops and ringed sideroblasts and consider bone marrow biopsy.

Normocytic Anemia

- Check the reticulocyte count and determine if it is elevated, inappropriately normal, or low.
- If the count is elevated, evaluate for evidence of recent hemorrhage; if none, confirm hemolysis with haptoglobin, bilirubin, and lactate dehydrogenase determinations.
- If hemolysis is confirmed, check for a drug-induced cause (direct Coombs' test), an autoimmune type (IgG or cold agglutinins), or a hemoglobinopathy (sickle cell disease, glucose-6-phosphatase deficiency).
- If the reticulocyte count is not elevated, search for underlying hepatocellular, endocrine, and renal failure (see Chapter 71, Chapter 104, and Chapter 142, respectively) and for early iron-deficiency anemia and anemia of chronic disease (see above).
- If the reticulocyte count is nil, the peripheral blood count and smear show pancytopenia, teardrop forms and fragmented cells, and halting all potentially offending medications does not result in prompt restoration of marrow function, then order a bone marrow biopsy.

CHAPTER 80 EVALUATION OF ERYTHROCYTOSIS (POLYCYTHEMIA)

When an elevated red cell count, hemoglobin concentration, or hematocrit occurs unexpectedly, it raises the question of *polycythemia*, a term used to denote an absolute increase in circulating red cell mass (some use the term *erythrocytosis* for all increases in red cell mass except those with an autonomous etiology). The upper limit of normal for a hematocrit is 52% for men and 47% for women. In the context of marked dehydration or severe chronic lung disease, the elevation may come as no surprise. In the absence of obvious concurrent disease, a search for an important underlying illness (e.g., polycythemia vera, occult malignancy, right-to-left shunt, hemoglobinopathy) is warranted. The finding may even be spurious because of volume contraction. In most instances, the primary physician should be able to distinguish among the variety of causes on clinical grounds, aided by a few simple laboratory studies.

PATHOPHYSIOLOGY AND CLINICAL PRESENTATION

An absolute increase in red cell mass may represent abnormal stem cell proliferation (as in polycythemia vera), a response to chronic hypoxemia (as in chronic lung disease), or a manifestation of renal disease or extrarenal malignancy.

Polycythemia Vera is a *myeloproliferative* disorder affecting all marrow elements; it results from clonal proliferation of a multipotent hematopoietic stem cell. Not only is red cell mass increased, but so are leukocyte and platelet counts. Other consequences include *extramedullary hematopoiesis, splenomegaly, hyperuricemia,* a hypercellular bone marrow, and often myeloid metaplasia and *myelofibrosis.* The condition is uncommon, with an incidence in the United States of four to five cases per million per year, or about 1,000 new cases annually. However, the prevalence is higher because survival is prolonged in the majority of patients. The peak age at onset is 50 to 60 years. Some patients have a relatively benign course, with red cell volume controlled by occasional phlebotomy, but others experience a much more malignant illness characterized by recurrent thrombosis and evolution toward myeloid metaplasia, myelofibrosis, and acute leukemia. Prior exposure to myelosuppressive therapy is a risk factor for malignant transformation.

It is not surprising that the presence of true polycythemia is often unsuspected because symptoms develop gradually and are frequently vague and rather nonspecific. In early stages, the patient may be entirely asymptomatic, with an elevated hematocrit as the only manifestation. As the disease progresses, the white blood cell (WBC) and platelet counts also rise, and symptoms and signs ensue as the red cell volume expands. Most symptoms are attributable to *hyperviscosity, hypervolemia*, and the resultant sluggish blood flow, which develop when the hematocrit rises above 55%. Disturbed hemostasis ensues, exacerbated by defective platelet function. Patients may present with either *thrombosis* (often in uncommon sites, such as hepatic, mesenteric, or retinal veins) or *bleeding* in the form of epistaxis, menorrhagia, easy bruisability, or oozing from the gums. The patient with advancing disease has a deep red appearance; peripheral cyanosis and ecchymoses may be noted. Blood pressure is usually normal, but *neurologic symptoms* are common (e.g., headache, dizziness, vertigo, tinnitus, "fullness" of the head, and blurred vision). Patients may complain of angina pectoris or claudication when coexisting atherosclerotic disease is present. Generalized *weakness*, fatigue, sweating, and lassitude are frequently reported. Gastrointestinal complaints may predominate (e.g., fullness, belching, epigastric or left upper quadrant discomfort); hepatomegaly is present in 40% and *splenomegaly* in 70%. A classic symptom is *pruritus* after bathing, believed to be caused by abnormal histamine release. Also, gouty joint symptoms occur in the context of marked secondary hyperuricemia caused by increased cell turnover.

Typically, the serum hemoglobin concentration is above 18.5 g/dL in men and above 16.5 g/dL in women, or an unexplained increase in hemoglobin concentration of 2 g/dL is present. In about 60% to 70% of cases, the WBC count rises above 12,000/mm^3. More than half of patients experience an increased platelet count. The red cells appear normochromic and normocytic unless iron deficiency develops, in which case the red cells may appear microcytic and hypochromic. The erythrocyte sedimentation rate is frequently very low. *Erythropoietin* levels are never elevated (in contrast to erythropoietin levels in other forms of polycythemia) and are often low. Leukocyte alkaline phosphatase concentrations are increased in 80%, as are vitamin B$_{12}$ levels, a consequence of an increase in vitamin B$_{12}$–binding proteins.

Reactive Erythrocytosis (Secondary Polycythemia). Chronic hypoxemia triggers *erythropoietin* production, which in turn stimulates marrow production of red cells. The increase is usually an appropriate physiologic response to tissue hypoxia and occurs when the arterial oxygen tension (Pao$_2$) continually falls below 55 mm Hg or, more precisely, when the arterial oxygen saturation (Sao$_2$) drops below 92%. Residence at a *high altitude* and *severe pulmonary disease* are common causes of chronic hypoxemia. Other etiologies include *cyanotic heart disease* with right-to-left shunt, heavy cigarette *smoking* (associated with excessive levels of carboxyhemoglobin), and a *hemoglobin variant* that poorly releases oxygen to tissues.

Pathologic Secondary Erythrocytosis. When *erythropoietin* production is increased in the absence of tissue hypoxia, then pathologic secondary polycythemia may ensue. Renal disease and a host of extrarenal malignancies have been implicated. Such instances of inappropriate erythropoietin production are unusual, but their occurrence can be an early clue of underlying disease. In about 1% to 3% of renal cell carcinomas, erythrocytosis is a manifestation, occurring at a time when cure is possible. Focal glomerulonephritis, hydronephrosis, renal artery stenosis, and polycystic kidney diseases are occasionally associated with elevations in erythropoietin and erythrocytosis. The mechanism is thought to involve a reduction in blood flow to renal tissue involved in erythropoietin production. Huge uterine myomas, cerebellar hemangiomas, and hepatomas are also causes, although the mechanisms are unclear; up to 10% of patients with hepatoma in one series had erythrocytosis. In rare instances, an increase in circulating androgens is associated with polycythemia.

Relative (Spurious) Erythrocytosis. This term denotes a heterogeneous set of conditions, characterized by an increase in hematocrit without an increase in red cell mass. The most common and usually self-evident cause is *dehydration.* More controversial is a group of patients who appear to have a normal to increased erythrocyte mass and a low to normal plasma volume (also referred to as *Gaisböck's syndrome* or *stress erythrocytosis*). There is some debate as to the actual existence of such a state, but it has been reported in obese, smoking, middle-aged, hypertensive men. Such men manifest an increased risk for thromboembolization.

DIFFERENTIAL DIAGNOSIS

Patients with erythrocytosis can be separated on the basis of their underlying pathophysiology into three diagnostic categories: (a) polycythemia vera; (b) secondary erythrocytosis; and (c) relative (spurious) erythrocytosis. Secondary erythrocytosis can be subdivided into physiologic and pathologic varieties (Table 80.1).

Polycythemia Vera
Secondary polycythemia
 1. Physiologic (systemic hypoxia)
    a. High altitude
    b. Right-to-left shunt
    c. Heavy smoking
    d. Severe pulmonary disease
    e. Abnormal hemoglobin with high O$_2$ affinity
 2. Pathologic (no systemic hypoxia)
    a. Renal cell carcinoma
    b. Uterine myoma
    c. Cerebellar hemangioma
    d. Hepatoma
    e. Hydronephrosis
    f. Cystic kidney disease
    g. Renal artery stenosis
Relative Polycythemia
 1. Marked volume depletion
    a. Protracted vomiting
    b. Persistent diarrhea
    c. Excessive diuretic use
    d. Renal
 2. High-to-normal erythrocyte mass, low-to-normal volume: hypertensive, obese, middle-aged, male smoker

Table 80.1. Differential Diagnosis of Polycythemia

WORKUP

The cause of erythrocytosis can usually be identified clinically, with the aid of a few well-selected laboratory tests. The first task is to rule out decreased plasma volume and then to determine if the true increase in hematocrit is a physiologic response or a pathologic process.

History. The history should first be checked for risk factors for volume depletion (e.g., diuretic use, vomiting, diarrhea) and for precipitants of chronic hypoxemia (e.g., residence at a high altitude, known cyanotic heart disease, smoking more than two packs per day, chronic lung disease). Inquiry into familial occurrence of polycythemia helps identify an abnormal hemoglobin, and a history of renal disease is also useful for recognition of pathologic secondary erythrocytosis. Important clues for polycythemia vera are easy bruising, bleeding, and thrombosis, especially if the clotting involves an unusual site (e.g., retina, hepatic or portal vein, mesenteric vasculature). Symptoms of hyperviscosity should be reviewed, although most are nonspecific (e.g., lassitude, headache, sweating). It is common to ask about pruritus worsened by bathing, a classic symptom of polycythemia vera. Any report of abdominal discomfort should be noted, as it might be a manifestation of the organomegaly associated with polycythemia vera.

Physical Examination. Postural signs should be checked for evidence of volume depletion (see Chapter 24). The integument is noted for plethora, cyanosis, clubbing, and ecchymoses. A comprehensive cardiopulmonary examination is essential and should include a search for signs of chronic lung disease (see Chapter 40), structural heart disease with a right-to-left shunt (see Chapter 21), hepatic enlargement, splenomegaly, and abdominal and pelvic masses. Splenomegaly can be an important clue for polycythemia vera because it is not found in most other forms of erythrocytosis; however, its absence does not rule out the diagnosis, particularly in the early phases of the disease.

Laboratory Evaluation. Testing should begin with a *complete blood cell count, platelet count*, and *peripheral blood smear examination* because two thirds of patients with polycythemia vera have an elevated WBC count (usually to 12,000 to 25,000/mm^3, and occasionally 50,000 to 100,000/mm^3), with increased numbers of immature forms and basophils; moreover, half have elevated platelet counts in the range of 450,000 to 1 million per cubic millimeter. Large, bizarre platelets and megakaryocytic fragments may be seen on the blood smear. In polycythemia vera, cell morphology becomes abnormal with progression of disease. For example, in the setting of myeloid metaplasia, anisocytosis and poikilocytosis with tear drop forms, ovalocytes, elliptocytes, and nucleated red blood cells may be seen. A microcytic, hypochromic smear may be noted if concurrent iron deficiency is present (found in about 10% of cases and sometimes obscuring the diagnosis). In secondary and spurious forms of erythrocytosis, the WBC count, platelet count, and blood smear are normal, which helps to differentiate these conditions from polycythemia vera.

Distinguishing Polycythemia Vera from Pathologic Secondary Erythrocytosis. Because no single test is pathognomonic for polycythemia vera, testing for the condition should be limited to patients with a reasonable pretest probability of having the disease. Patients should manifest at least one or two of the characteristic features in addition to an elevated hematocrit, such as generalized pruritus after bathing, splenomegaly, persistent leukocytosis, persistent thrombocytosis, or atypical thrombosis. Proper patient selection, in conjunction with utilization of newer testing modalities, is markedly improving laboratory confirmation of polycythemia vera.

Traditionally, either direct measurement of *red cell mass* or an estimation based on *red cell volume* was considered necessary for diagnosis; however, this measurement is expensive and often not readily available, and it does not distinguish between polycythemia vera and pathologic secondary erythrocytosis, the most important differentiation that needs to be made. Increasingly, determinations of serum *erythropoietin* levels and assays of *in vitro growth of erythroid colonies* are being used to make this important distinction. A high erythropoietin level virtually rules out polycythemia vera and suggests secondary erythrocytosis, as erythropoietin production should be suppressed in polycythemia vera. A low erythropoietin level strongly supports the diagnosis of polycythemia vera while ruling out pathologic secondary erythrocytosis (which is driven by excess erythropoietin production). If the erythropoietin level is normal (which can occur in mild disease, after phlebotomy, and with secondary disease), then erythroid stem cells are obtained for *in vitro* testing. In polycythemia vera, erythroid stem cells manifest colony growth in the absence of exogenous erythropoietin, a characteristic unique to this form of erythrocytosis.

Measurement of erythropoietin levels and erythroid colony assays are replacing the *traditional consensus diagnostic criteria* for polycythemia vera: (a) an elevated total red cell volume, a normal arterial oxygen saturation, and splenomegaly; or (b) in the absence of splenomegaly, an elevation in at least two of the following: *platelet count* (>400,000/mm^3), *WBC count* (>12,000/mm^3), *leukocyte alkaline phosphatase level, serum B$_{12}$ level*, or unbound *B$_{12}$-binding capacity*.

Testing for Secondary Polycythemia (Reactive Erythrocytosis). Although history and physical examination will often suffice, an *arterial blood gas* or *arterial oxygen saturation* determination can be important in the assessment of less obvious cases. A Pao$_2$ below 55 mm Hg and an Sao$_2$ below 92% indicate significant hypoxemia. The Sao$_2$ should be measured directly rather than calculated from the Pao$_2$ because false-negatives occur in smokers. When a strong family history of polycythemia is present, one should obtain a *hemoglobin electrophoresis* in search of a mutant hemoglobin with an abnormally high oxygen affinity. *Cardiac ultrasonography with Doppler* (and bubble study if available) is indicated when structural heart disease with right-to-left shunt is suspected.

Testing for Causes of Pathologic Secondary Erythrocytosis. One should look for signs and symptoms of renal lesions and tumors, especially renal cell carcinoma. *Renal ultrasonography* or *IV pyelography* with nephrotomograms is a reasonable screening test for such lesions; a positive study result is followed by contrast-enhanced *computed tomography* of the abdomen. *Abdominal ultrasonography* is a useful screening test for hepatoma, and *pelvic ultrasonography* can help confirm a large uterine myoma when one is suspected on physical examination.

Testing for Relative Erythrocytosis. A postural decline in blood pressure and rise in pulse usually suffice for a diagnosis of dehydration, but a ratio of *blood urea nitrogen* to *creatinine* above 20 can provide supporting evidence if desired. Only when the clinical evidence is insufficient to distinguish relative erythrocytosis from other forms should a *determination of red cell mass* be ordered. The calculation of red cell mass is rather elaborate and requires a laboratory experienced in the test. A radioisotope label (chromium 51) is administered to tag the red cells so that the mass can be calculated. The patient's body habitus needs to be taken into account when the result is interpreted. Tall, muscular persons will have a greater red cell mass than short, fat persons because blood volume is greater in muscle than in fat. A normal red cell mass is diagnostic of relative erythrocytosis.

SYMPTOMATIC THERAPY

When possible, treatment should be directed at the underlying cause (e.g., correction of a right-to-left shunt, removal of a erythropoietin-secreting tumor). *Cessation of cigarette smoking* (see Chapter 54) is an important goal; in patients with relative erythrocytosis or reactive polycythemia resulting from heavy smoking and high carboxyhemoglobin levels, the hematocrit will begin to fall within a week and return to normal 3 to 4 months after smoking is terminated. For selected patients with severe chronic obstructive pulmonary disease, *long-term oxygen therapy* may help normalize the arterial oxygen saturation (see Chapter 47).

The risks associated with erythrocytosis (hyperviscosity, thrombosis, impaired hemostasis) begin to rise substantially as the hematocrit moves into the 55% to 60% range. When the condition cannot be treated etiologically in prompt fashion, *phlebotomy* should be performed. Phlebotomy improves oxygen delivery, relieves hyperviscosity symptoms, and prevents the thromboembolic and hemorrhagic complications of polycythemia. The target hematocrit is in the low to middle 40s, the level at which tissue oxygenation is optimal in normovolemic patients. Phlebotomy is especially useful in patients with polycythemia vera and pathologic secondary erythrocytosis. Even in cases in which the rise in red cell mass represents a physiologic accommodation to chronic hypoxemia, phlebotomy may be indicated if the erythrocytosis becomes excessive (hematocrit >60%) and threatens oxygen delivery. Reducing the hematocrit below 55% improves exercise tolerance in patients with severe chronic obstructive pulmonary disease.

Phlebotomy is conducted by removing up to 500 mL of blood as often as every 2 to 3 days to achieve a hematocrit below 55%. For patients who cannot tolerate such large losses of volume (e.g., the elderly), phlebotomy is limited to removal of no more than 250 mL once or twice a week. Iron deficiency may ensue but should not be corrected in cases of polycythemia vera or pathologic secondary erythrocytosis because such treatment may stimulate a fulminant recurrence of red cell production. In patients with cardiopulmonary disease, a modest amount of iron replacement to correct microcytosis is probably beneficial because microcytic erythrocytes increase blood viscosity and decrease oxygen delivery. The severely erythrocytic patient who is to undergo surgery requires phlebotomy to prevent compromised hemostasis. Preoperative phlebotomy should be followed by administration of a volume expander to correct volume depletion.

Treatment of Polycythemia Vera. Control of polycythemia vera with phlebotomy alone is usually possible in cases in which the platelet count and WBC count remain relatively normal. Phlebotomy has been shown to increase median survival from 2 to 12 years by reducing the risk for thrombosis. The frequency of treatments is a function of the hematocrit and symptoms. Most symptoms can be alleviated by reducing the hematocrit to around 50%; however, continued frequent phlebotomy is

recommended until a normal hematocrit is achieved (middle 40s in men, low 40s in women). A maintenance schedule can then be set up based on monthly monitoring.

Bothersome *pruritus* can be controlled by the use of histamine blockers. The combination of a histamine $_1$ blocker (e.g., 60 mg of *fexofenadine* every morning; 4 mg of *chlorpheniramine* daily at bedtime) and a histamine$_2$ blocker (e.g., 400 mg of *cimetidine* three times daily) will often suffice. Secondary *hyperuricemia* occurs in this disease and can lead to acute gout; *allopurinol* (300 mg administered once daily) prevents gouty attacks and should be considered when the uric acid level rises above 9 to 10 mg/dL.

Myelosuppressive therapy deserves consideration when phlebotomy proves inadequate, thrombocytosis develops, or extramedullary hematopoiesis ensues. The optimal treatment is yet to be identified; a longitudinal investigation by the Polycythemia Vera Study Group has compared P 32, alkylating agents, and hydroxyurea. Although P 32 and *alkylating agents* (e.g., chlorambucil) are effective, they are also leukemogenic over time; as such, they are reserved for elderly patients. *Hydroxyurea* appears to be preferred, as it is less likely to cause malignant transformation but can suppress the disease. Its disadvantages include the need for frequent administration and the ingestion of a large number of pills, and remissions are far less sustained than with P 32. Patients who fail hydroxyurea therapy can be given a treatment of P 32, especially if they are elderly; it will induce a 6- to 24-month remission and is less leukemogenic than alkylating agents.

Thrombosis and bleeding are the most important complications of polycythemia vera. Prophylactic therapy with *aspirin* and other antiplatelet agents has failed to halt thrombosis. The most effective approach to limiting such risk appears to be phlebotomy with volume expansion. Development of thrombosis is an indication for *oral anticoagulation*, but the risk for bleeding is increased in patients with polycythemia vera who are taking warfarin.

In the later stages of the illness, painful splenic infarction or congestive splenomegaly may necessitate splenectomy. Transition to leukemia is associated with a lack of responsiveness to chemotherapy and a very poor prognosis.

PATIENT EDUCATION AND INDICATIONS FOR REFERRAL

Patient education is essential to encourage smokers to give up cigarettes (see Chapter 54) and patients with chronic obstructive lung disease to follow a maximal program for improving oxygenation (see Chapter 47). The patient's understanding of the basis of the disease and its prognosis should help in achieving compliance (see Chapter 1). When polycythemia vera is a strong diagnostic consideration, the patient should be referred to a hematologist for confirmatory testing and design of a treatment program. Referral is also appropriate when the diagnosis is difficult and measurement of red cell mass or bone marrow biopsy is being considered.

CHAPTER 81 EVALUATION OF BLEEDING PROBLEMS AND ABNORMAL BLEEDING STUDIES

The problems of bleeding encountered in the office setting range from abnormal results on screening studies to easy bruising, petechial rashes, and recurrent episodes of unexplained frank blood loss. Sometimes, the only manifestation is a low platelet count, prolonged prothrombin time (PT), or a delay in the bleeding time. When the volume of blood loss is small, rate of bleeding is slow, and risk for serious hemorrhage is low, evaluation may take place in the outpatient setting. The workup involves examination of the intrinsic and extrinsic clotting systems in addition to an evaluation of blood vessels, platelet function, and platelet quantity to identify which part of the hemostatic apparatus is at fault. Often, a careful history and physical examination, supplemented by a few simple laboratory studies, can yield a clinically meaningful answer and guide therapy. An important objective is to determine if the problem is inherited or acquired. At times, an anatomic lesion coexists with a bleeding diathesis; the clinician always needs to address this possibility, especially when the bleeding originates from the lung, gastrointestinal tract, vagina, or urinary tract (see Chapter 42, Chapter 63, Chapter 111, and Chapter 129, respectively).

PATHOPHYSIOLOGY AND CLINICAL PRESENTATION

Hemostasis is achieved by the interplay of the coagulation cascade, platelets, and vessel wall. The platelets provide the initial primary hemostatic plug in response to vascular injury, followed secondarily by generation of fibrin at the site of damage. Blood coagulation is a carefully controlled process, limited by endogenous anticoagulants. Normal hemostasis represents a delicate balance between coagulant and anticoagulant factors. Any upset in this system of checks and balances may result in bleeding or thrombosis.

Disorders of primary hemostasis involve the platelets or vessel wall and present as spontaneous bleeding or bleeding into superficial tissues (skin and mucous membranes, including the lining of the bowel and genitourinary tract). The appearance of petechiae and slow oozing after trauma, rather than brisk bleeding, are typical. Menorrhagia or epistaxis may be a presenting complaint.

Disorders of secondary hemostasis involve the clotting factors or the fibrinolytic system and lead to bleeding that is characteristically deep and visceral, causing such problems as hemarthrosis, retroperitoneal hemorrhage, and deep hematomas.

Qualitative Platelet Disorders

Platelet function defects can be classified according to the step in platelet activity that is affected: adhesion, aggregation, activation, secretion, or acceleration of coagulation. Patients with isolated qualitative platelet defects have a prolonged bleeding time in conjunction with normal-appearing platelets that are adequate in number.

Defective Adhesion. The most important condition of impaired adhesion is von *Willebrand's disease*, which is inherited in an autosomal dominant pattern and associated with decreased secretion or abnormal synthesis of a glycoprotein polymer (von Willebrand's factor) needed for platelet adherence to a site of vascular endothelial injury. The release of von Willebrand's factor in the classic form of the disease can be stimulated by desmopressin (DDAVP). Rarer forms of the disease are not corrected by DDAVP. Cryoprecipitate can also correct the problem. In addition, because of a deficiency of factor VIII procoagulant, the partial thromboplastin time (PTT) is prolonged. Platelet agglutination fails to occur in the presence of the antibiotic ristocetin, a laboratory characteristic of this disease that is useful for its detection. Mucous membrane bleeding is a frequent manifestation. The severity of bleeding is variable and most severe among homozygous persons, who may bleed from the gastrointestinal tract; hemarthrosis is rare. Acquired forms of the disease also exist, which occur in the context of lymphoma, other malignancies, and connective tissue disease.

An acquired adhesion defect occurs when high doses of *semisynthetic penicillins* or *cephalosporins* are taken; these agents can coat the platelet surface and reduce binding to glycoprotein.

Defective Activation and Secretion. Patients with activation problems have impaired production or an impaired response to prostaglandin-dependent activators such as thromboxane A_2, which attracts platelets and constricts vessels. *NSAIDs* affect platelet activation and secretion by inhibiting cyclooxygenase, which helps convert arachidonic acid to thromboxane. In addition, NSAIDs inhibit the release of adenosine diphosphate, which is needed for platelet aggregation. Irreversible inhibition of cyclooxygenase occurs with even small, single doses of aspirin and persists for the life span of the platelet (7 days). Reversible inhibition is seen with the use of other NSAIDs and omega-3 fatty acids (found in oily fish). Severe bleeding does not result, but an underlying bleeding diathesis may be aggravated. In patients with *storage pool disease*, the adenosine diphosphate and serotonin contents of platelet granules are reduced or released prematurely, as occurs in patients who have undergone *cardiopulmonary bypass*. Bleeding is typically mild, and the bleeding time is only mildly prolonged.

Defective Aggregation. Patients with a rare hereditary defect in platelet aggregation, *Glanzmann's thrombasthenia*, are missing a bridging protein called glycoprotein IIb/IIIa. The platelets of such persons cannot bind to fibrinogen and thus fail to aggregate by way of fibrinogen cross-links. *Clot retraction is abnormal*; the bleeding time is markedly prolonged. Serious bleeding can occur. Patients taking high doses of *semisynthetic penicillins* or *cephalosporins* also demonstrate reduced binding to fibrinogen.

Defective Acceleration of Coagulation. When platelets bind factors V and X on their surface, the rate of prothrombin conversion is greatly accelerated. Patients whose platelets cannot bind these clotting factors have a mildly prolonged PT, normal bleeding time, and normal platelet aggregation.

Mixed or Unknown Defects in Function. A number of conditions are associated with poorly defined but potentially important qualitative defects in platelet function. *Uremia* is the most important and is believed to be related to a dialyzable toxin. In addition to dialysis, correction of anemia and administration of DDAVP, conjugated estrogens, and cryoprecipitate can reduce the prolongation in bleeding time. *Dysproteinemias* and *myeloproliferative diseases* also produce complex defects in platelet function, as can high parenteral doses of b-lactam *antibiotics.*

Quantitative Platelet Defects

A normal platelet count ranges from 150,000 to 300,000/mm^3. *Thrombocytosis* (by definition, counts >400,000) may lead to impairment of platelet function, occasionally causing mucous membrane bleeding or hemorrhage following trauma or surgery. Bleeding from thrombocytosis most often occurs in the setting of myeloproliferative disease. *Thrombocytopenia*, defined as a platelet count below 100,000, is associated with a prolonged bleeding time. The diagnosis requires confirmation with a peripheral smear because spurious forms occur caused by *in vitro* clumping of platelets in response to citrate or small amounts of circulating cold agglutinin.

The risk for serious bleeding from true thrombocytopenia does not occur until the platelet count falls well below 50,000. Easy bruising is seen with counts of 30,000 to 50,000; spontaneous bruising, menorrhagia, and prolonged bleeding with trauma arise as the count drops below 20,000. Below 10,000, spontaneous epistaxis, gastrointestinal and genitourinary bleeding, and an increased risk for central nervous system hemorrhage occur. A petechial rash of the lower legs may be an initial manifestation. The lesions differ from those of vasculitis in that they are painless, flat, nonpruritic, and without an erythematous blush. Hemorrhagic bullae in the buccal mucosa are another characteristic finding. Bleeding may begin from the gastrointestinal or urinary tract. Thrombocytopenia develops when platelet destruction is increased (trauma, immune injury, disseminated intravascular coagulation, thrombotic thrombocytopenic purpura), production is decreased (marrow failure), or abnormal pooling occurs (hypersplenism).

Increased Destruction is the most common cause of thrombocytopenia. The primary mechanism is immunologic, occurring in association with drugs, viruses,

lymphoproliferative disorders, and connective tissue diseases as well as idiopathically.

Idiopathic Thrombocytopenic Purpura ranks among the major causes of platelet destruction. Although a platelet-bound immunoglobulin G (IgG) antibody has been detected in 80% of cases and found useful for diagnostic purposes, its pathophysiologic significance remains to be determined. Free antibody in the serum is less common and highly variable. The condition is most common in young adults, children, and women. In adults, the condition is more chronic, being characterized by a waxing and waning course with few spontaneous remissions. It may present as bleeding in the context of aspirin or NSAID use, as an incidental finding on routine blood count, or as menorrhagia, epistaxis, or purpuric rash following a viral infection. The physical examination findings are otherwise normal, and the spleen usually is not palpable, although it may be slightly enlarged. No lymphadenopathy, hepatomegaly, or sternal tenderness is present, which helps to distinguish it from immune thrombocytopenia of other causes (HIV infection, connective tissue disease, lymphoproliferative disease). Mild fever is sometimes noted.

Immune Thrombocytopenias associated with *chronic lymphocytic leukemia* and *systemic lupus erythematosus* follow clinical patterns similar to that of idiopathic thrombocytopenic purpura. In addition, lymphadenopathy and splenomegaly are found in the majority of patients with chronic lymphocytic leukemia, and 25% have hepatomegaly also. In systemic lupus erythematosus, arthritis and arthralgias are reported in 90%, skin rash in 70%, lymphadenopathy in 60%, and renal disease in 50%. Platelet counts below 100,000 are not frequent, being reported in about 15% of cases. *HIV infection* is also associated with an immune thrombocytopenia, affecting 10% of asymptomatic carriers and 30% of patients with AIDS.

Drug-induced Thrombocytopenia that results in increased destruction is idiosyncratic and immune-mediated. *Heparin* (less likely with the low-molecular-weight preparations), histamine$_2$ blockers, *quinidine, sulfonamides*, and *penicillins* are common precipitants, although *any* drug may be responsible. A rapid fall in the platelet count to levels below 10,000 can occur, and acute hemorrhage may ensue. A prompt return of the count to safe levels is typical as soon as the responsible drug is withheld.

Thrombotic Thrombocytopenic Purpura causes platelet consumption, rather than outright destruction, as hyaline-platelet complexes form in small vessels, trapping platelets. No consumption of clotting factors or fibrin deposition is seen, as it is in disseminated intravascular coagulation. The cause is unknown. Ironically, use of the platelet aggregation inhibitor *ticlopidine* has been associated with thrombotic thrombocytopenic purpura. In most instances, an immune mechanism is postulated. Microangiopathic hemolytic anemia ensues, fever develops, and microvascular damage to the kidneys and central nervous systems may become manifest. The lactic dehydrogenase level can rise markedly. The combination of *anemia*, a peripheral smear showing *schistocytes*, and *thrombocytopenia* in conjunction with fever, *neurologic symptoms*, and *renal dysfunction* comprises the clinical syndrome. Patients with the acute fulminant form of the disease are unlikely to present in the outpatient setting, but those with the chronic relapsing form may do so.

Decreased Production. The bone marrow may be suppressed by drugs, depressed after a viral infection, or replaced by tumor. Thrombocytopenias associated with conditions causing *marrow failure* or a *myelophthisic process* usually occur in the context of a generalized pancytopenia (see Chapter 80). On occasion, individual *drugs* cause selective *inhibition of platelet production.* Chlorothiazide, tolbutamide, and ethanol are among the best documented. Megakaryocyte production is reduced in *megaloblastic anemia*, and quick recovery is noted with replacement therapy. Transient thrombocytopenia may follow influenza, hepatitis, rubella, and other viral diseases. The thrombocytopenia of HIV disease involves viral invasion of megakaryocytes in addition to increased peripheral destruction.

Increased Pooling can be seen in disorders associated with an abnormally enlarged spleen. Splenomegaly results in excessive trapping and a fall in the number of circulating platelets.

Defects of the Intrinsic Pathway

These conditions prolong the *PTT* (the PT remains normal) by impairing the synthesis or functioning of intrinsic pathway clotting factors. Detection may be difficult because the PTT will not become prolonged until the reduction in the concentration of a functioning intrinsic clotting factor exceeds 75%. Fortunately, many clotting factor deficiencies do not cause serious bleeding, but the most common ones, the hemophilias, do.

Deficiencies of Factor VIII and IX. *Hemophilias A* and *B* represent deficiencies of factors VIII and IX, respectively. They account for more than 80% of patients with an inherited bleeding diathesis and, because they are X-linked, affect only males. The risk for bleeding depends on the degree of factor deficiency. Patients with concentrations as low as 5% of normal experience little bleeding, except after surgery or major trauma; those with concentrations 1% to 5% of normal may bleed after minor trauma; those with concentrations below 1% of normal undergo spontaneous hemorrhage, typically into muscle and weight-bearing joints. Bleeding can also occur into the central nervous system, genitourinary tract, and retroperitoneum. As noted, detection may be difficult if factor levels are in excess of 25% of normal because the PTT will be normal. Chromosomal mapping is being developed to help detect female carriers. Relatively early prenatal detection is available by DNA analysis of chorionic villi tissue, provided tissue is also available from other affected family members. Fetal blood may be sampled for the determination of antihemophilic factor levels later in pregnancy by ultrasonographically guided aspiration.

Factor XI Deficiency occurs mostly among Ashkenazi Jews, inherited as an autosomal recessive disorder. A severe insult such as major trauma or surgery is needed to precipitate bleeding.

Other Deficiencies of intrinsic pathway factors may cause a prolongation of the PTT but do not lead to clinical bleeding, even in the setting of major surgery or serious trauma.

Inhibitors. The *lupus anticoagulant* is an IgG antibody elicited in the setting of connective tissue disease and phenothiazine use. Bleeding complications are rare, but a hypercoagulable state is sometimes seen in patients with this anticoagulant that leads to an increased risk for venous thrombosis and spontaneous abortion (see Chapter 22). Both the PTT and PT are prolonged because the antibody is directed against phospholipids used in both assays. Hemophiliacs who have had multiple transfusions of antihemophilic factor have close to a 15% risk for the development of antihemophilic factor inhibitors, IgG antibodies against the replaced factors. Such antibodies are also noted in patients with connective tissue or lymphoproliferative disease, those who are pregnant, and persons of advanced age.

Defects of the Extrinsic Pathway

The major clotting factors of the extrinsic pathway (II, VII, X) depend for their synthesis and modification on a healthy liver and an adequate dietary intake of vitamin K. Some vitamin K also derives from bacterial production by gut flora. Hereditary deficiencies of extrinsic pathway factors are rare. Most bleeding traced to the extrinsic pathway is the consequence of impaired vitamin K production or liver disease. Causes include *hepatocellular insufficiency, cholestasis* (which impairs absorption of lipid-soluble vitamin K), *poor dietary intake*, and use of *broad-spectrum antibiotics* that kill normal gut flora. The characteristic laboratory finding is a prolongation of the PT. Prolongation of the PT also occurs with warfarin anticoagulant therapy. *Warfarin* inhibits the vitamin K–dependent postsynthetic modification of factors II, VII, IX, and X; this prevents them from being able to bind calcium and achieve biologic activity (see Chapter 83).

Vascular Defects

Vascular defects are characterized by *purpuric bleeding* into the skin and mucous membranes in the absence of a detectable clotting factor or platelet abnormality. Ecchymoses and petechiae are the predominant manifestations. The most common form occurs as a result of aging, so-called *senile purpura*. Atrophy of connective and fatty tissues makes the vessels fragile and subject to ecchymotic bleeding, especially in areas of constant sun exposure (face, neck, dorsum of hands, forearms). The skin fragility and easy bruising seen with *Cushing's syndrome* are believed to have a similar basis, the catabolic effects of prolonged corticosteroid excess. *Scurvy* causes defective collagen synthesis; affected patients may present with gingival bleeding or hemorrhage into subcutaneous tissue and muscle. Perifollicular bleeding is characteristic. *Purpura simplex* is a mild condition seen in otherwise healthy women; they experience ecchymoses mostly in the lower extremities (sometimes colorfully referred to as "devil's pinches"), especially during menstrual periods. Most cases are believed to be acquired, and some have been linked to the use of NSAIDs.

Hereditary Disorders of connective tissue (e.g., *Marfan syndrome, Ehlers-Danlos syndrome*) produce structural defects in supporting connective tissue and major vessels. Bleeding ranges from easy bruising to serious hemorrhage. In *Rendu-Weber-Osler disease*, the developmental anomaly is *telangiectasis* formation because of a lack of vessel support and contractility. Bleeding from these thin, convoluted networks of venules and capillaries can result from minor trauma or occur spontaneously. The telangiectatic lesions are violaceous, flat, and usually no larger than a few millimeters, and they range in shape from pinpoint to spidery. They occur on the mucous membranes, face, trunk, and palmar and plantar surfaces. Lesions also arise in major viscera, which leads to a risk for serious hemorrhage. The

clinical course is often one of repeated hemorrhagic episodes.

Pharmacologic Agents can induce purpuric bleeding in the absence of demonstrable platelet or clotting factor abnormalities. *Drug-induced vascular purpura* is thought to have an autoimmune mechanism, with antibodies directed at the endothelial surface, although the responsible antibodies have yet to be identified. Drugs in this category include *procaine penicillin, thiazides, quinine, iodides, sulfa drugs*, and *coumarins.* The bleeding ceases when the drug is withdrawn.

Immune Complex Formation can result in minor purpuric bleeding, as sometimes occurs with *systemic lupus, rheumatoid arthritis*, and *Sjögren's syndrome.* In *amyloidosis*, deposition of amyloid protein in the skin and subcutaneous tissue leads to vascular fragility, especially about the orbits and upper torso. The "raccoon eyes" appearance of such patients is characteristic.

Mixed Defects

A number of conditions impair the hemostatic apparatus at multiple levels. Chronic renal failure, dysproteinemias, chronic liver disease, and consumption coagulopathies are the most important examples.

Uremia interferes with platelet function and causes deficiencies in the production of clotting factors. Prolonged oozing from arterial and venipuncture sites is common. Dialysis and correction of the anemia help reduce the bleeding tendency, which ranges from purpura and mucous membrane bleeding to gastrointestinal hemorrhage.

Dysproteinemias, including cryoglobulinemia, macroglobulinemia, and myeloma, can lead to damage of the endothelial surface as immune complexes and paraproteins precipitate from the serum. The sludging and hyperviscosity commonly associated with these conditions also result in capillary anoxia. Impaired clotting factor and platelet activity and endothelial damage cause a multifactorial bleeding diathesis.

Chronic Liver Disease precipitates bleeding by a number of routes. Patients with severe hepatocellular failure can no longer make adequate amounts of vitamin K–dependent clotting factors, even with the administration of vitamin K. In addition, fibrinogen production suffers, and the fibrinogen that is made is defective. Patients with portal hypertension may become thrombocytopenic from platelet sequestration in the spleen, although in itself this rarely causes bleeding. However, varices are common in such patients, which increase the risk for gastrointestinal hemorrhage (see Chapter 63).

Disseminated Intravascular Coagulation occurs in the setting of illness that causes exposure of blood to tissue thromboplastin (e.g., snake bite, extensive burn, serious infection, cancer). Activation of the extrinsic pathway in the microcirculation consumes clotting factors and platelets; it leads to bleeding that ranges from minor petechiae to hemorrhage. The condition is rarely encountered in the office setting.

DIFFERENTIAL DIAGNOSIS

The causes of a bleeding diathesis can be organized according to the subdivisions of the hemostatic apparatus: platelet function, platelet number, intrinsic pathway, extrinsic pathway, and vessels (Table 81.1). Differential diagnosis proceeds by identifying which segment of the clotting system is at fault.

Table 81.1. Differential Diagnosis of Bleeding by Mechanism

WORKUP

When a patient presents with easy bruising or bleeding, the clinician needs to ascertain the likelihood of an underlying defect in hemostasis. Bleeding from multiple sites, easy bruising, spontaneous bleeding, ecchymoses greater than 3 cm in diameter, or prolonged bleeding after a surgical or dental procedure strongly suggest a bleeding diathesis. Before embarking on a detailed evaluation in the office, one should be sure that no serious hemorrhage or major volume depletion is present. Inquiry is required into dyspnea, light-headedness, marked postural fatigue, and observed quantity of blood loss. A quick check of postural signs, skin color, and skin temperature will provide added objective evidence of intravascular volume status and degree of anemia. Once the presence of or risk for severe hemorrhage has been ruled out, the outpatient evaluation can commence.

The next task is to ascertain which segment(s) of the hemostatic system are at fault. This determination, along with an assessment of whether the condition is acquired or hereditary, can greatly help focus the evaluation (Table 81.2).

Table 81.2. Differentiating Platelet, Coagulation, and Vascular Disorders

History

One needs a detailed history of the bleeding problem, including its onset, precipitants, location, clinical course, prior history, associated family history, and drug history. Inquiry into past surgery, childbirth, menstruation, nosebleed (both nostrils), dental extraction, trauma, laceration, and injection can provide important information. Especially important is the history of a transfusion requirement after minor trauma or surgery when such transfusion would ordinarily not be required.

On the other hand, not all patients with a history of easy bruising have a bleeding diathesis. Easy bruising is common and often occurs in otherwise normal patients. Bruises that occur on the limbs and are less than 3 cm in diameter are likely to be harmless and caused by inapparent trauma in the absence of recalled injury.

Likewise, minor bleeding up to 2 days after a molar extraction is within normal limits. However, ecchymoses occurring spontaneously on the trunk or measuring greater than 3 cm in diameter on the limbs are more worrisome.

As noted earlier, bleeding that is transient, superficial (confined to the skin and mucous membranes), and spontaneous or immediately posttraumatic suggests a platelet problem or vascular fragility. In contrast, patients with serious clotting factor problems characteristically report bleeding that is deep (into tissues or viscera), delayed, and prolonged. A past medical history or family history of abnormal bleeding is strong presumptive evidence of a hereditary disorder, but its absence does not rule it out. For example, 30% of hemophiliacs give no family history of bleeding. In a patient with a suspected hereditary cause, gender should be noted because many hereditary bleeding disorders are sex-linked, especially those involving clotting factors.

A thorough review of *medications* is essential. The use of medications capable of interfering with platelet function (aspirin, NSAIDs, semisynthetic penicillins, cephalosporins, dipyridamole), platelet number (thiazides, alcohol, quinidine, methyldopa, sulfa, phenytoin, barbiturates), or coagulation factor synthesis (warfarin) should be noted.

The presence of a recent or *concurrent illness* that might affect hemostasis ought to be given particular attention, including chronic liver disease, uremia, viral infection, connective tissue disease, myeloproliferative states, and paraproteinemias.

Physical Examination

After taking the vital signs and checking for significant volume depletion, one can proceed with a systematic examination. The general appearance is noted for cushingoid habitus and marfanoid appearance. On examination of the skin, the size, number, and location of any *purpuric lesions* should be recorded, and note should be made of whether they are *petechial* (<3 mm) or *ecchymotic* (>3 mm). Purpura represents bleeding into the skin, usually the result of vessel breakage or leakage. Petechial lesions occur with thrombocytopenia, qualitative platelet disorders, and vascular defects. Petechial rashes are also a hallmark of vasculitis, but the lesions in vasculitic cases are characteristically palpable, tender, and pruritic, and are surrounded by an erythematous flush. One can readily distinguish petechiae from nonpurpuric erythematous skin lesions by noting their failure to blanch when compressed with a glass slide. *Blanching* lesions must not be dismissed too hastily because they may be *telangiectases*, which are an important clue to Rendu-Weber-Osler syndrome. Ecchymoses occurring in areas subject to trauma are a common finding in normal people; however, ecchymotic lesions greater than 6 cm in the absence of major trauma are likely to represent an underlying bleeding abnormality. The skin is also noted for signs of chronic liver disease (spider angiomas, jaundice).

The mucous membranes are examined for bleeding, the lymph nodes for enlargement, the abdomen for hepatosplenomegaly, and the joints and muscles for hematomas and hemarthroses. Rectal and pelvic examinations are conducted for evidence of bleeding. In a patient with thrombocytopenia, careful examination for splenomegaly is important because it may be the only clue of sequestration. Percussion of the Traube space (the area of resonance over the stomach) for dullness, combined with splenic palpation with the patient in the right lateral decubitus position, is the best means of detecting splenomegaly by physical examination (sensitivity of 46%, specificity of 97%).

Laboratory Studies

Although the history and physical examination often provide important clues regarding etiology, laboratory investigation helps to classify the cause of the bleeding more definitively. Primary hemostasis is assessed by *platelet count* and *bleeding time.* The *PT* best assays the extrinsic clotting system, and the PTT, the intrinsic one.

Platelet Count is usually performed by an automated particle-counting machine on a sample of blood collected into a tube containing the anticoagulant ethylenediaminetetraacetic acid (EDTA). Falsely low counts occur when platelets clump on exposure to EDTA, a common phenomenon when blood is processed at low temperatures. It can be prevented by warming the blood slightly before processing, using another anticoagulant, or performing a finger-stick platelet count. The presence of a cold agglutinin in the blood will also cause clumping and a falsely low level, as will antibody that produces rosettes of platelets about white cells. A confirmatory look at the peripheral smear is always helpful. Finding platelets on examination of a peripheral smear is good presumptive evidence of adequate quantity.

Bleeding Time is a sensitive but nonspecific test of qualitative platelet function; values are also abnormal in thrombocytopenia, uremia, von Willebrand's disease, and afibrinogenemia. Even anemia may produce a prolonged bleeding time, correctable by transfusion of red cells alone. The test often gives false-positive readings, demonstrated by the high rate of normal findings on follow-up platelet aggregation studies.

The Ivy method is the standard technique for performance of the test. A cut is made in a relatively avascular area of the forearm, with use of a template to ensure an incision of 1 cm in length and 1 mm in depth, while venous return is obstructed with a blood pressure cuff inflated to 40 mm Hg. Blotting paper is applied to the edge of the incision; a normal result is cessation of blotter-detected oozing by 9 minutes. Recent aspirin or current NSAID use will produce a modest prolongation in the bleeding time, although this usually does not represent a significant risk for bleeding unless a preexisting bleeding diathesis is present.

Prothrombin Time and Partial Thromboplastin Time assay the extrinsic and intrinsic clotting factor cascades, respectively, in addition to the common pathway. The PT assesses factor VII and common pathway factors X, V, prothrombin, and fibrinogen. The PTT reflects levels of kininogen, prekallikrein, and factors VIII, IX, XI, and XII, in addition to those of the common pathway. Its sensitivity is limited; clotting factor deficiency in excess of 75% is needed to prolong the PTT. The PT is slightly more sensitive, becoming prolonged when factor VII falls by 55% to 65%. However, bleeding is rare in the absence of such reductions. PTT prolongations not associated with bleeding include those caused by deficiencies of factor XII, kininogen, or prekallikrein, and the presence of an inhibitor.

Screening for an inhibitor is carried out by mixing equal volumes of the patient's plasma and normal donor plasma. If the prolongation in PT or PTT is corrected, then no inhibitor is present and the workup proceeds to determine the missing clotting factor. If it is not corrected, then this is strong suggestive evidence of the presence of an inhibitor, and identifying it is the next step. The PT and PTT do not assess the final factor XIII-dependent cross-linking of fibrin; urea clot solubility testing is required. Testing for fibrinolysis also must be performed separately.

Testing for a Qualitative Platelet Defect. In the setting of bleeding consistent with defective initial hemostasis (see above) and a normal platelet count, normal PT, and normal PTT, one should consider determining the bleeding time, provided that no explanation is readily evident (e.g., recent aspirin or NSAID use, uremia, and so forth). An abnormal study is followed by *in vitro* testing of platelet function. *Aggregation testing* is conducted by adding an aggregating substance such as adenosine diphosphate, epinephrine, collagen, or thrombin to a platelet-rich plasma sample. If the bleeding time and the PTT are prolonged, then *ristocetin-induced agglutination* of platelets can be performed to check for von Willebrand's disease. Aggregation is normal in von Willebrand's disease, but the platelets fail to agglutinate. Aggregation and ristocetin studies are best ordered in consultation with a hematologist.

Testing for the Cause of Thrombocytopenia. First, pseudothrombocytopenia must be ruled out. Then the task turns to differentiating increased destruction from decreased production and sequestration. Examination of the *peripheral blood smear* is helpful in this regard. A pancytopenia strongly suggests marrow failure. The presence of large immature platelets on the peripheral smear in a patient with an isolated thrombocytopenia points to increased destruction. Isolated thrombocytopenia is almost always caused by increased destruction. If uncertainty persists, a *bone marrow examination* can provide further clarification of the mechanism. A hypocellular marrow in the setting of pancytopenia indicates marrow failure; an increase in megakaryocytes argues for increased destruction. Sequestration is best determined by examining for an enlarged spleen.

Increased destruction may be immune or nonimmune. Immune destruction is by far the more common, but before ordering elaborate tests for antibodies, one should consider a few preliminary investigations that may obviate the need for more sophisticated studies. For example, simply withdrawing all potentially offending drugs (especially those most likely to be responsible, such as quinidine, gold, trimethoprim/sulfamethoxazole) and monitoring the platelet count may suffice for the diagnosis of a medication-induced condition. Testing for the presence of HIV infection (enzyme-linked immunosorbent assay and Western blot), connective tissue disease (antinuclear antibody), or mononucleosis (heterophile) is indicated when clinical evidence is suggestive. In the absence of such common precipitants and in the setting of an otherwise normal complete blood cell count (mild lymphocytosis included), one should consider idiopathic thrombocytopenic purpura. Whole blood is tested for the presence of *platelet-bound IgG autoantibodies* (serum may contain little of the antibody). Detection is complex, and controversies abound concerning the meaning of findings.

To check for consumption of platelets, a peripheral smear (with an examination for red cell schistocytes) is useful. Their presence suggests a microangiopathic

condition, such as occurs with thrombotic thrombocytopenic purpura and disseminated intravascular coagulation. The PTT is normal in the former and abnormal in the latter.

Preoperative Screening for a Bleeding Disorder

The most important component of preoperative screening is the history. The absence of abnormal bleeding during a previous surgical procedure or trauma is strong evidence of normal hemostasis. Current medication use also needs to be carefully reviewed, especially NSAIDs, salicylates, and drugs known to precipitate thrombocytopenia. Although the platelet count, PT, PTT, and bleeding time are frequently determined, the yield is low in patients with unsuspected deficits. In particular, little if any correlation is found between bleeding time and risk for surgical bleeding. Routinely obtaining a preoperative bleeding time in a patient with no known or suspected bleeding abnormality is of no proven value.

The PTT, PT, and platelet count continue to be ordered routinely, but their value in the absence of a condition known to compromise hemostasis remains unproven. In a study of 829 consecutive and otherwise healthy patients undergoing PT and PTT screening before orthopedic surgery, unexpected abnormalities were found in about 8%. None had an impact on patient management.

SYMPTOMATIC MANAGEMENT AND PATIENT EDUCATION

Patients with a clinically insignificant laboratory abnormality deserve detailed reassurance that their hemostasis is adequate. For example, the patient with a minor prolongation of bleeding time on preoperative testing yet no prior history of abnormal bleeding is unlikely to have anything more serious than recent salicylate exposure. Functional hemostasis will usually be preserved and no special precautions or further action (other than repeating the bleeding time) need be taken. However, the patient with a clinically important bleeding diathesis requires some basic advice, even as evaluation proceeds. The nature of the advice depends on the type of bleeding abnormality at hand.

Vascular Defects. Patients with purpura simplex and senile purpura can be reassured. Occasionally, these patients take large doses of vitamins C and K in the hope of lessening their easy bruising; such self-treatment measures are without proven efficacy and only add unnecessary expense. NSAIDs may exacerbate the cosmetic problem and can be withheld if the easy bruising disturbs the patient, but they ought not to be avoided if the case of an important indication for their use. Patients with recurrent bleeding from more serious vascular disease (e.g., hereditary hemorrhagic telangiectasia) should be advised to avoid any agent that might compromise hemostasis. Episodes of bleeding respond to compression if the rest of the hemostatic system is kept intact. Patients with vascular defects often have an iron deficiency from recurrent bleeding; the resulting anemia responds well to oral iron (see Chapter 82).

Platelet Disorders. Patients with a known qualitative platelet disorder and a history of bleeding should be counseled to avoid salicylates and NSAIDs. Patients with no history of abnormal bleeding before NSAID use can probably continue on the agent, provided the bleeding is clinically unimportant and the indication for drug use is compelling. However, the drug should be stopped in anticipation of a major surgical procedure.

Patients with platelet counts below 50,000 are at risk for posttraumatic bleeding and should be advised to put off surgery, dental extraction, and contact sports until the problem is corrected. The use of stool softeners and a soft toothbrush is recommended. Those with counts below 20,000 are at risk for serious spontaneous bleeding and require hospitalization. While workup is in progress to identify a cause, all but the most essential medications should be halted, with substance exposures (solvents, insecticides, alcohol) limited and NSAIDs and salicylates prohibited.

In most instances, treatment of thrombocytopenia should be etiologic and carried out in consultation with a hematologist. A few exceptions are worth noting: Thrombocytopenia associated with HIV infection is an indication for prompt initiation of *antiretroviral therapy* (see Chapter 13). Idiopathic thrombocytopenic purpura is an indication for immediately starting *high-dose steroid therapy* (e.g., 1 mg of prednisone per kilogram per day), especially if the patient is symptomatic. Prednisone can be tapered after 1 to 2 weeks if the platelet count normalizes; if it does not, then splenectomy may be needed. In both instances, hematologic consultation is still warranted, but it should not delay the implementation of initial therapy.

Clotting Factor Problems. Most patients on warfarin who exhibit bleeding from excessive anticoagulation need to hold their dose for only a few days to allow the PT to drift back into a safe therapeutic range (see Chapter 83). Large doses of vitamin K should not be used to correct the PT unless anticoagulation is no longer desired because it is difficult to resume anticoagulation quickly in a patient who has recently received large doses; smaller doses are less problematic. An urgent need to correct the PT without impairing future anticoagulation efforts can be met by administering fresh-frozen plasma.

Patients with a poor intake or malabsorption of vitamin K can be given oral vitamin K supplements (2.5 to 10 mg/d) or parenteral doses (10 to 25 mg IM); in addition, the underlying cause of the malabsorption should be treated (see Chapter 64). Patients with severe hepatocellular failure will not respond to vitamin K because synthetic function has been compromised (see Chapter 71).

Hemophilia. The patient with hemophilia and the patient's family face lifelong problems. A detailed discussion of the management of such patients is beyond the scope of this chapter, but basic management includes specifying guidelines for permissible physical activity and teaching proper first aid. If the degree of bleeding has been only mild to moderate, then one can encourage participation in noncontact sports and other activities that entail little risk for injury. The goal is to allow as much normal activity as possible. First aid treatment of an acute hemarthrosis should be learned by the family. One immobilizes the joint and applies ice packs to reduce pain and swelling. Splinting and elastic bandages can help ensure that a position of good joint function is maintained.

Pain control is important. Aspirin and related nonsteroidal agents must be avoided. Acetaminophen and codeine work well when given in adequate doses for short periods of time. The primary physician should not try to aspirate a hemarthrosis; the risk for causing further bleeding and introducing infection is high.

Administration of *factor VIII concentrate* has been the mainstay of therapy, used for episodes of acute bleeding and before surgery and dental work. Carefully obtained and elaborately treated concentrate preparations have greatly reduced the risk for transfusion-related HIV infection, and *recombinant preparations* are now available, although more expensive. *DDAVF* is being used in place of factor VIII to treat patients with mild to moderate hemophilia or von Willebrand's disease and is proving effective for both episodes of acute bleeding and prophylaxis. If future studies support these encouraging results, desmopressin should offer hemophiliacs an alternate means of acute treatment.

Genetic counseling is an important component of hemophiliac care. Definitive identification of women who are carriers of the hemophilia gene has been difficult, but DNA analysis techniques offer hope of improved identification to facilitate genetic counseling. Early prenatal diagnosis is also available (see above).

INDICATIONS FOR ADMISSION AND REFERRAL

Bleeding problems carry the potential for serious harm and bear very careful evaluation and monitoring. If the severity of the condition is in doubt, prompt hospital admission should be considered. Patients who manifest volume depletion, gross bleeding, bleeding from multiple sites, or a change in mental status require emergency admission. The person who otherwise appears well but has a dangerously low platelet count (<20,000), an absence of platelets on smear, or a markedly prolonged bleeding time is best evaluated and monitored in the hospital. Hemophiliacs with acute bleeding require emergency transfusion of factor VIII.

Referral or consultation with a hematologist can be helpful when a patient with clinical bleeding is suspected of having a qualitative platelet disorder. Proper test selection and interpretation will be facilitated. Referral is also indicated for patients with unexplained, clinically significant clotting factor deficiencies, severe thrombocytopenia, or suspected hemophilia or von Willebrand's disease.

CHAPTER 82 MANAGEMENT OF COMMON ANEMIAS

Most of the anemias encountered in the outpatient setting are sufficiently mild or chronic to allow time for the careful design of a cost-effective treatment program. The ease with which a number of anemias (e.g., deficiencies of iron, folate, and vitamin B$_{12}$) can be corrected sometimes leads to empiric therapy or self-treatment without adequate workup for the underlying cause. The skillful application of appropriate treatment is based on a thorough etiologic evaluation (see Chapter 79). Once the cause is understood, attention can be turned to treatment modalities. Increasingly prominent among treatment options is erythropoietin therapy, with an expanding list of indications, so that an understanding by the primary care physician of evidence-based applications is necessary. Those caring for patients with sickle cell anemia who are subject to painful crises need to be familiar with the first line of treatment so as to prevent such disabling episodes.

IRON-DEFICIENCY ANEMIA

Iron-deficiency anemia is extremely common, occurring in about 10% to 15% of premenopausal women; it may also be a manifestation of gastrointestinal blood loss. Proper management necessitates identifying the underlying cause (see Chapter 79). Ascribing the anemia to a trivial cause (e.g., menstruation, hemorrhoids) and treating it empirically without a thorough workup for more serious disease (e.g., bowel malignancy) can seriously compromise outcome. A response to iron replacement should not be taken as a sign of a benign cause. The physician must determine whether inadequate intake, poor absorption, increased loss, or a combination of factors is responsible for the anemia. Knowing the most economical, effective, and best-tolerated forms of supplemental iron facilitates design of an optimal replacement therapy program.

Clinical Presentation and Course

In menstruating women, the balance between dietary iron intake (1 mg/d) and loss (15 mg/mo) is precarious. Low-grade anemia, especially when losses from pregnancy (approximately 500 mg) are not made up, is common. However, the many vague symptoms in otherwise healthy menstruating women that are attributed to "low iron" have not been found to correlate with degree of anemia or respond to correction of anemia in controlled studies (see Chapter 79).

Iron-deficiency anemia is usually slow in onset, so that compensatory changes such as increases in 2,3-diphosphoglycerate and cardiac output minimize symptoms. When blood loss has been rapid or the anemia severe (hemoglobin level below 7 g/dL), patients are likely to become symptomatic, especially if cardiopulmonary reserve is limited. Replacement therapy is required in such cases, regardless of underlying cause. The degree of anemia does not correlate with the seriousness of the cause.

Pica (defined as a craving for ice, starch, clay, or any other substance) is particularly common in patients with severe iron deficiency, but often goes unreported. Up to 50% of iron-deficient patients may exhibit pica, with pagophagia (the craving for ice) accounting for the vast majority of cases. No correlation has been found between the presence of pica and the cause of iron deficiency. Symptoms resolve with treatment.

The occasional patient with severe iron deficiency who presents with glossitis, angular stomatitis, koilonychia, or esophageal web improves after correction of the deficiency. Whether the *menorrhagia* sometimes seen with iron deficiency is corrected by iron is a subject of debate. Patients who have undergone *subtotal gastrectomy* and gastrojejunostomy have up to a 60% chance of incurring iron deficit because of a loss of acid-secreting capacity, rapid gastric emptying, and bypass of the duodenum. *Pregnancy* is almost certain to produce iron deficiency because a net loss of more than 500 mg of iron occurs. Iron deficiency from chronic gastrointestinal blood loss has been documented in *long-distance runners.*

Unless the cause of the iron deficiency is removed, recurrence rates are high, even when treatment is prescribed. In a series of 100 cases, 29 relapses were noted: In 24 instances, inadequate iron was being taken; in 12, blood loss continued in excess of iron therapy; and in four patients, malabsorption was documented.

Principles of Management

As noted above, the importance of identifying and treating the underlying cause cannot be overemphasized, especially when the anemia is found in male patients or the elderly. Even in menstruating women, the probability of finding silent but important gastrointestinal disease is substantial. Correcting iron deficiency without attending to the underlying cause can mask an important clue to treatable disease and compromise timely treatment.

Indications. Symptoms are often minimal and the morbidity from a mild anemia is low, so that treatment in such situations is less important than discovery of the underlying cause. Moreover, as noted previously, correction of the iron deficit is not certain to alleviate the host of vague symptoms often attributed to it. Nevertheless, replacement therapy makes sense when (a) the patient is symptomatic and has a limited cardiopulmonary reserve; (b) the anemia has become moderately severe (hemoglobin level of 8 to 9 g/dL); (c) the patient is pregnant; (d) the patient has undergone a subtotal gastrectomy and gastrojejunostomy; (e) continued heavy blood loss is anticipated; or (f) the patient is recovering from megaloblastic anemia.

Absorption occurs best under conditions of low pH in the proximal small bowel, such as 1 to 2 hours before a meal or at bedtime. Antacid use reduces absorption, as does food intake; the phytates and phosphates in food bind iron. When iron tablets are taken with meals, absorption drops by more than 50%. Absorption also varies according to the severity of the deficit. About 20% of an oral dose is taken up initially, but absorption falls to 5% after 1 month of replacement therapy, even though the anemia remains incompletely corrected. Ascorbic acid improves absorption in achlorhydric patients.

Side Effects. Upper and lower gastrointestinal symptoms are the principal side effects of oral iron therapy; they can be severe enough to interfere with treatment. The upper gastrointestinal effects are especially troublesome and include *nausea, vomiting, epigastric cramping*, and *acid reflux.* Onset is usually within an hour of iron intake. Upper gastrointestinal symptoms are proportional to the amount of ionized iron delivered to the stomach and proximal small bowel, and they decrease with a reduction in dose. Many patients mistakenly attribute their symptoms to the type of iron preparation used and switch to another; however, most often it is the amount of iron released in the upper digestive tract that accounts for symptoms. Dose reduction is all that is required. The lower gastrointestinal side effects of *constipation* and *diarrhea* are reported by about 25% of users, but these are less a function of the amount of iron available for absorption than are upper gastrointestinal side effects. Constipation usually responds to dietary fiber or a stool softener.

The IM administration of iron has been associated with the development of *sarcomas* at injection sites and should be avoided. Fatal *anaphylactic reactions* and *asthma* have been associated with all parenteral forms of iron administration. If parenteral iron must be given, it should be administered by the IV route, first a very small test dose and then a slow drip; a syringe with epinephrine should be drawn up at the same time and kept on hand.

Preparations. Ferrous iron is required for oral use; ferric iron is poorly absorbed. The most cost-effective approach to oral iron replacement is use of generic *ferrous sulfate.* It is the least expensive (as little as 10% of the cost of other preparations) and provides the most elemental iron. All commonly used ferrous salts (i.e., sulfate, *gluconate, citrate*) have equivalent rates of absorption, differing principally in the amount of elemental iron released. Choice is a matter of cost and side effects. The severity of gastrointestinal upset is predominantly a function of the amount of iron released rather than the type of ferrous salt used. This is the reason for the increased frequency of gastrointestinal upset associated with the use of ferrous sulfate, which releases the most elemental iron. Some preparations contain ascorbic acid to facilitate absorption, but ferrous sulfate provides sufficient iron to make absorption-enhancing measures unnecessary in most instances. *Slow-release* and *enteric-coated* preparations have been touted as producing fewer side effects and requiring only once-daily administration. However, they dissolve slowly and can bypass the proximal small bowel (where most absorption takes place) before dissolving to a significant degree. There is *no* evidence they are worth the extra cost, which can be several times that of unadulterated ferrous sulfate. An ingenious but expensive ferrous sulfate formulation utilizes a *gastric delivery system* that is activated by stomach secretions; as a result, the capsule floats and remains within the stomach for a few hours after food has passed. The capsule slowly releases iron during this period, so that iron absorption is enhanced by two to three times, gastrointestinal upset is minimized, and the necessary frequency of dosing is

reduced.

Parenteral iron has a very limited role. It should be used only in patients who have had an adequate trial of oral iron and have shown a genuine intolerance to all available preparations. Patients with inflammatory bowel disease may require parenteral iron because of the irritant effect of oral iron and the need to take large doses to keep up with blood loss. Parenteral iron has also been suggested for patients with malabsorption, but most are able to absorb a sufficient amount of oral iron. Parenteral iron is best given by the *IV* route (see above).

Dosing. The *recommended oral dose* for iron deficiency is 300 mg of ferrous sulfate three times daily. As noted, absorption is maximized by dosing 1 to 2 hours before a meal or at bedtime. Although taking iron with a meal reduces absorption, it also lessens disagreeable gastrointestinal symptoms, such as nausea and epigastric discomfort. For alleviation of gastrointestinal side effects, reducing frequency of dosing is less effective than reducing the dose taken.

Drug-Drug Interactions. The *effect of iron on absorption* of other drugs needs to be kept in mind. When iron is ingested simultaneously, the absorption of *levodopa, methyldopa, tetracycline*, and *fluoroquinolone antibiotics* is reduced by up to 90%. A similar but more variable effect on thyroxine has been noted. Iron intake should be delayed for several hours after intake of these other medications, and monitoring of their efficacy should be stepped up during iron therapy.

Drugs that neutralize or inhibit acid secretion (e.g., *antacids, histamine$_2$ blockers, proton pump inhibitors*) may reduce iron absorption because a low pH is required in the proximal small bowel for optimal uptake. Taking iron with orange juice (rich in ascorbic acid) or using an ascorbic acid–containing preparation can help in situations in which suppression of gastric acid is needed.

Duration of Therapy. The response to iron is apparent within 10 days of initiatiation of therapy; a reticulocytosis is first noted, followed by a rise in the hemoglobin concentration of 0.1 to 0.2 g/dL daily. Therapy for several weeks is required to bring the hemoglobin level back up to normal, and replenishing iron stores may take months. However, speed is not an issue unless blood loss is rapid, in which case blood transfusion rather than iron therapy is the treatment of choice. The response to parenteral iron therapy is no more rapid than that seen with oral preparations.

Patient Education and Prevention of Iron Deficiency

To maximize compliance, patients need to be instructed about the best means of minimizing gastrointestinal side effects. Starting with a small dose of ferrous sulfate (e.g., 300 mg/d) and building to 900 mg/d avoids initial intolerance. Taking iron just after eating may also help. It needs to be made clear that therapy has to be continued on a regular basis for weeks and often months.

The prevention of iron deficiency is most important in those with increased needs (i.e., pregnant women and young children). The average American diet contains 12 mg of iron per 2,000 calories. Twenty percent is absorbed by markedly iron-deficient patients and 5% to 10% by others; thus, about 0.6 to 1.2 mg is taken up under normal circumstances each day. The daily requirement for men and postmenopausal women is 0.5 to 1.0 mg, so that dietary intake should suffice. However, the requirement for menstruating women is 1.5 mg/d, and that for pregnant women is 2.5 mg/d. Iron-rich foods can be added to the diet to avoid the need for iron supplements. Liver, oysters, and heavily iron-enriched cereals (containing >45% of the recommended daily iron allowance) are the best dietary sources, providing more than 5 mg of iron per serving. Lean beef, veal, moderately iron-fortified cereals (containing >25% of the daily allowance), and beans are good sources, providing 3 to 5 mg of iron per serving. Fish, chicken, egg yolks, raisins, and fortified breads and pasta are fair sources, providing 1 to 3 mg per serving. Green vegetables are rich in iron, but the iron is less readily available for absorption because it is bound to the phosphates and phytates present in these foods.

When diet alone seems inadequate and needs are very high, as in pregnancy, a once-daily dose of 150 to 300 mg of ferrous sulfate is recommended to avoid significant iron deficiency. It must be emphasized that most people who eat a balanced diet do not require iron supplements. Taking widely promoted supplements that contain iron, vitamins, and minerals is expensive and unnecessary in most instances. Excessive iron is associated with increased risks for malignancy and atherosclerotic disease. Those taking expensive vitamin preparations should be advised that much simpler, less costly, yet equally efficacious preparations are available.

VITAMIN B$_{12}$ DEFICIENCY

Vitamin B$_{12}$ deficiency can result from inadequate intake, impaired absorption, increased requirements, or faulty utilization. Poor intake is distinctly rare, occurring mostly in ultrastrict vegetarians who refrain from eating eggs and dairy products as well as meat. Many cases of vitamin B$_{12}$ deficiency are secondary to pernicious anemia; the lack of intrinsic factor compromises absorption. Absorption can also be impaired by achlorhydria, disease of the terminal ileum, bacterial overgrowth resulting from stasis, and gastrectomy. Faulty utilization is uncommon; it occurs with genetic defects in the synthesis of transcobalamin, the plasma protein that transports vitamin B$_{12}$.

Clinical Presentation and Course

Irrespective of cause, vitamin B$_{12}$ deficiency may lead to slowly evolving *megaloblastic anemia, glossitis*, and *neuropathy.* Macrocytosis is usually the first hematologic manifestation and can precede anemia by as much as 1 to 2 years. Hypersegmentation of neutrophils is another early hematologic finding. Because of the body's large vitamin B$_{12}$ storage capacity, the onset of clinical manifestations may take months to years. Although megaloblastic anemia and glossitis also occur with folic acid deficiency, the neuropathy is distinctive. Traditionally, neurologic symptoms were thought to be a late development, associated with a vitamin B$_{12}$ level below 100 pg/mL. However, careful studies have documented vitamin B$_{12}$–responsive neuropsychiatric deficits in the absence of such marked vitamin B$_{12}$ deficiency, anemia, or machine-determined macrocytosis (although hypersegmentation and macrocytosis were often noted on examination of the peripheral smear).

Classically, the neurologic syndromes include those of peripheral neuropathy and subacute combined degeneration (symmetric paresthesias in the hands and feet, and progression to ataxia resulting from loss of vibratory and position sense as the posterior columns of the spinal cord become involved). However, cortical involvement is also prevalent and may present as memory loss (simulating dementia), disorientation, depression, hallucinations, agitation, personality change, perversions of taste and smell, irritability, or central visual scotomas. If left untreated, many neurologic deficits can become permanent.

In pernicious anemia, coincident thyroid disease, rheumatoid arthritis, vitiligo, or gastric cancer may be present. *Achlorhydria* after histamine stimulation is characteristic. The diagnosis is usually made by the Schilling test, with the use of exogenous intrinsic factor to help document its absence (see Chapter 79).

Principles of Management

Prompt recognition and treatment are essential to minimize the risk for permanent neurologic damage. Early disease produces reversible demyelination; if uncorrected, it progresses to nerve death and permanent neurologic dysfunction. Thus, in a patient with neurologic symptoms suggestive of vitamin B$_{12}$ deficiency, prompt diagnosis (see Chapter 79, Chapter 167, and Chapter 169) and treatment are paramount. Parenteral therapy is preferred (except in the rare patient with poor intake) because most vitamin B$_{12}$ deficiency is secondary to impaired absorption. However, the use of large oral doses (>100 µg/d) may result in sufficient absorption of vitamin B$_{12}$ in some cases. *Cyanocobalamin* is the most commonly used parenteral formulation, although *hydroxycobalamin* is better bound to serum proteins and less rapidly excreted, so that less frequent administration is possible. In practice, either form of vitamin B$_{12}$ suffices.

Replacement Regimens. A host of initial replacement regimens are available, all of which are adequate. For example, in a program commonly used for pernicious anemia, a patient is initially treated with 100 to 1000 µg of IM cyanocobalamin or hydroxycobalamin daily for 1 to 2 weeks, after which the same dose is given twice weekly for another month, and then once a month for the remainder of the patient's life. If neurologic symptoms are present, a twice-monthly follow-up dose is recommended for 6 months.

Some argue that 1,000-µg doses are unnecessary because only 100 µg can be effectively metabolized at one time, with the remainder promptly excreted in the urine. However, because of their low cost and safety, maintenance doses of 1,000 µg are often given. Others note that monthly injections after initial replacement are unnecessary, finding that an injection once every 3 to 4 months suffices for many patients. The optimal program can be individualized, although it is probably best to continue with a monthly regimen in patients with neurologic sequelae. More important than the interval of therapy is its indefinite continuation, which must be ensured. Relapse of symptoms is common in the absence of continued therapy. Compliance with a monthly injection program is often poor; having the visiting nurse or family

member give the injection is helpful and far less inconvenient than a monthly office visit.

Vitamin B_{12} deficiency can be prevented in the elderly, in whom gastric atrophy, hypochlorhydria, and food-cobalamin malabsorption (see Chapter 79) are frequent findings, with a daily oral intake of 25 to 1,000 µg of cyanocobalamin. About 1% is absorbed.

Response to Treatment can be dramatic, with marked reticulocytosis noted within 72 hours and a rapid improvement in neurologic deficits, especially those that are mild or of short duration. However, neurologic problems that have been present longer may take 6 to 12 months to improve, and deficits that persist after 12 to 18 months of therapy are probably permanent, which underscores the importance of a timely diagnosis for successful therapy.

During recovery, serious *hypokalemia* can develop in patients who have had a severe depletion of vitamin B_{12} as potassium is taken up by new red cells. The serum potassium level should be monitored, and supplements should be provided if it falls below normal. Concurrent folic acid supplementation is not needed. In fact, the inappropriate use of a large pharmacologic dose of oral folate (e.g., 5 mg) alone may partially and nonspecifically correct the anemia and mask an underlying vitamin B_{12} deficiency, which puts the patient at risk for an acute, marked deterioration of neurologic function if vitamin B_{12} is not given. There is no harm in having the patient take folate in addition to vitamin B_{12}, but this is rarely necessary unless the diet is extremely poor.

Other Treatment Modalities. Patients with a vitamin B_{12} deficiency caused by bacterial overgrowth or disease of the terminal ileum require treatment directed at the underlying bowel problem. Oral *antibiotic therapy* with tetracycline or amoxicillin provides temporary relief from bacterial overgrowth. More definitive treatment of inflammatory bowel disease may be indicated (see Chapter 73).

Unnecessary Vitamin B_{12} Therapy. Many well-intentioned physicians have used parenteral vitamin B_{12} as a nonspecific therapy for patients bothered by fatigue or other vague symptoms. In one study of a rural health clinic, 10% of all patients attending the clinic were found to be receiving such treatment regularly, 6% in the absence of appropriate indications for its use. Many persons without a vitamin B_{12} deficiency report symptomatic benefit from monthly injections, probably as a consequence of a strong placebo effect. Even after being told that it is unnecessary, a large proportion remain reluctant to halt such therapy or stop temporarily, only to seek out a physician willing to restart it. Although giving vitamin B_{12} entails little direct risk, its use can be misleading and should be abandoned in favor of a more comprehensive and etiologic approach to the patient's underlying problems, be they those of anxiety, depression, somatization, or an underlying medical problem (see Chapter 8, Chapter 226, Chapter 227, and Chapter 230). Patients taking vitamin B_{12} injections unnecessarily should be counseled on the need to explore the underlying cause of their symptoms.

FOLIC ACID DEFICIENCY

Causes. Most folic acid deficiency results from inadequate intake, although occasionally increased need or impairment of absorption or utilization is encountered. *Dietary deficiency* is in part a consequence of the limited capacity to store folate; within 3 months of initiation of an inadequate diet, megaloblastic changes and anemia can develop. Foods rich in folate include green vegetables (asparagus, lettuce, spinach, broccoli), liver, yeast, and mushrooms. Excessive boiling of vegetables in water can remove a substantial amount of available folic acid. *Alcoholism* is responsible for many cases of inadequate intake.

Impaired absorption is seen in the context of ileal disease (e.g., tropical and nontropical sprue, heavy infestation with *Giardia*), short-bowel syndrome, and phenytoin use. *Increased demand* takes place in the setting of pregnancy, severe hyperthyroidism, hemolytic anemia, malignancy, and florid psoriasis. *Utilization* is *hindered* by the use of methotrexate; triamterene and trimethoprim have similar although less marked effects on dihydrofolate reductase. Patients undergoing hemodialysis experience substantial folic acid *loss*, so that replacement therapy is necessary.

Clinical Presentation. Folate deficiency is one of the megaloblastic anemias. It is sometimes accompanied by glossitis. Anemia occurs within 3 to 4 months of the onset of deficiency. Diagnostic features include a low serum folate level (<15 ng/mL) and a marked reticulocytosis in response to physiologic doses (200 µg per) of folic acid. The response to treatment with folic acid is prompt. No neurologic deficits are associated with folic acid deficiency, but elevations in serum homocysteine occur, which are associated with premature arterial occlusive disease and a heightened risk for venous thrombosis (see Chapter 31 and Chapter 35).

Treatment for most patients involves orally administered pharmacologic doses of folic acid (1 to 2 mg/d). Most forms of folic acid deficiency, even malabsorptive types, can be overcome by oral therapy. Four to five weeks of treatment usually reverse the anemia and replenish body stores. When the underlying cause persists (e.g., malabsorption, malignancy, psoriasis, hemodialysis), long-term therapy is indicated. Patients taking methotrexate can be given folinic acid, which bypasses inhibition of dihydrofolate reductase. As noted above, the nonspecific use of folic acid to treat a megaloblastic anemia is ill-advised because it may mask an underlying vitamin B_{12} deficiency and precipitate neurologic symptoms. If alcoholism is the basis of the folate deficiency, then the drinking problem requires careful attention in its own right (see Chapter 228). Patients with folate deficiency will benefit from dietary counseling and perhaps a referral to the nutritionist.

ERYTHROPOIETIN DEFICIENCY STATES AND PREOPERATIVE ANEMIA

Erythropoietin Deficiency States. Anemias secondary to erythropoietin deficiency states (e.g., end-stage renal disease) have been among the most refractory to treatment. Erythropoietin replacement therapy, made possible by the advent of recombinant human erythropoietin, represents a major advance in the management of such anemias. Randomized, controlled trials have established the cost-effective application of such treatment in a number of settings. In dialysis patients with regular transfusion requirements, an almost universal elimination of such requirements, a normalization of the hematocrit, and an improved quality of life with thrice-weekly IV injections of recombinant erythropoietin (150 U/kg) have been demonstrated. Side effects are few but include increases in blood pressure and iron deficiency. Concurrent iron supplementation is often necessary. Erythropoietin has also proved cost-effective in other situations associated with severe anemia and reduced serum erythropoietin levels (e.g., HIV infection, malignancy, cancer chemotherapy). Erythropoietin has made more aggressive therapy possible and has markedly reduced transfusion requirements.

Preoperative Anemia. A reduced requirement for allogeneic transfusions has become a major objective for patients undergoing elective surgery. The donation of autologous blood has become a standard practice in many settings. The presence of anemia before surgery is a major predictor of the need for intraoperative or postoperative transfusion. The increasing desire to reduce exposure to allogeneic blood has stimulated a demand for autologous transfusion and an interest in the contribution of erythropoietin therapy. Weekly preoperative erythropoietin therapy can limit transfusion requirements (and so the need for allogeneic blood) and facilitate the donation of autologous blood. A preoperative program of two to four weekly SQ doses of erythropoietin (averaging 300 to 600 U/kg) plus autologous blood donation appears to limit the risk for exposure to allogeneic blood significantly. The best candidates for such preoperative measures appear to be patients with a preoperative hematocrit in the range of 33% to 39% who are to undergo surgery entailing an expected blood loss of 1 to 3 L. Once-weekly erythropoietin administration is the most cost-effective mode of administration in this setting. Work is ongoing (including better methods for procurement of autologous blood) to bring the costs of this approach down to the range of that for allogeneic transfusion.

SICKLE CELL DISEASE

The need to treat sickle cell disease is especially pressing in patients with painful crises. Vascular occlusion may result from hemolytic episodes induced by sickling; this leads in turn to the chest pain syndrome and stroke, which can be life-threatening, and to asplenia. Transfusion requirements can be high. Theoretically, the ideal approach to therapy would be to block sickling (hemoglobin S polymerization), reduce the intracellular hemoglobin concentration, and induce the formation of hemoglobin F.

Direct Inhibition of Sickling and Reduction of Intracellular Hemoglobin Concentration. To date, no sufficiently safe and effective drugs are available that directly inhibit sickling. Reducing the intracellular hemoglobin concentration is a less direct means of inhibiting sickling; the rate of sickling is proportional to the concentration of hemoglobin S. To achieve a lower intracellular concentration, efforts have focused on increasing intracellular water. This is accomplished through the inhibition of potassium loss with low-dose *clotrimazole* therapy, which blocks one set of potassium channels. The results of initial studies are promising, but confirmation and safety of long-term use remain to be demonstrated. *Magnesium* supplements have been shown to block other modes of potassium egress from red cells and are being studied in sickle cell disease.

Increasing Hemoglobin F. Hemoglobin F inhibits the polymerization and sickling of hemoglobin S. Efforts to encourage the synthesis of hemoglobin F have led to use of the myelosuppressive drug *hydroxyurea* in the treatment of sickle cell disease. Although the mechanism by which hydroxyurea increases hemoglobin S

synthesis remains unknown, it has proved effective in national prospective, randomized trials in reducing hemolysis, which necessitates transfusion, and the number and severity of painful crises and episodes of chest pain syndrome. Paradoxically, the increase in hemoglobin F is only short-lived, yet the effect of the drug persists, which correlates with its suppression of neutrophil and reticulocyte counts. The major concern with the long-term use of hydroxyurea is that it is associated with induction of malignancy. This concern has stimulated searches for alternatives. Results with erythropoietin are mixed; butyric acid and its analogues are also being studied for their effects on hemoglobin F synthesis. Gene therapy is likely to be applied in the future to manage this classic genetic disease.

CHAPTER 83 OUTPATIENT ORAL ANTICOAGULANT THERAPY

ELAINE M. HYLEK AND ROBERT A. HUGHES

Oral anticoagulant therapy with coumarin derivatives effectively prevents thromboembolism in a variety of conditions, ranging from venous thrombosis to atrial fibrillation to transient ischemic attacks. Oral platelet inhibitors help prevent thrombosis and restenosis of coronary arteries. This expanded range of applications for oral anticoagulants makes their proper use an important responsibility of the primary care physician. To optimize patient care, physicians must know (a) the indications for warfarin and antiplatelet therapy, (b) how to initiate and maintain patients on oral anticoagulants in the outpatient setting, (c) common complications, and (d) the drugs and conditions that interfere with or potentiate the anticoagulant effect. This chapter focuses primarily on coumarin derivatives and aspirin (see Chapter 30 for a discussion of the use of other antiplatelet agents).

WARFARIN

Mechanism of Action

Warfarin and other coumarin derivatives act by inhibiting the action of vitamin K in the g-carboxylation of glutamic acid residues on coagulation factors II, VII, IX, and X. Without g-carboxylation, these proteins cannot participate in coagulation. The warfarin-induced decline in active, carboxylated coagulation factors is a function of the half-life of each factor, which varies from 5 hours for factor VII to 72 hours for factor II. The prothrombin time (PT) may be prolonged after only 2 to 3 days of therapy, but this represents primarily depression of factor VII. The full antithrombotic effect of warfarin is achieved only after 5 to 7 days, with depletion of factor II.

Indications

Therapy is indicated in conditions associated with a high risk for thrombus formation and subsequent embolization. These include the following:

- Atrial fibrillation (see Chapter 28 and Chapter 33)
- Valvular heart disease and prosthetic heart valves (see Chapter 33)
- Systemic embolization (see Chapter 171)
- Deep venous thrombosis (see Chapter 35)
- Pulmonary embolization (see Chapter 35)
- Dilated cardiomyopathy and left ventricular thrombus (see Chapter 32)
- Following myocardial infarction in selected patients (see Chapter 31)

Atrial Fibrillation is highly prevalent, found in 5% of people over 60 and nearly 10% of people over 80. It increases the risk for stroke more than fivefold; the patient in atrial fibrillation has a 5% average annual risk for stroke. Patients with atrial fibrillation secondary to valvular heart disease are at even greater risk.

Prosthetic Heart Valves increase the risk for systemic emboli, especially stroke. The risk is higher with caged-ball and tilting-disk valves, and with valves in the mitral rather than aortic position. Anticoagulation is continued indefinitely. Patients with bioprosthetic valves need only short-term (e.g., for 3 months) anticoagulation unless another indication, such as atrial fibrillation or a history of systemic embolism, is present.

Deep Venous Thrombosis and Pulmonary Embolism are indications for anticoagulation. A 3- to 6-month course may suffice when risk factors are reversible or time-limited, such as surgery, temporary immobilization, or estrogen use. Patients with a first event who are found to be heterozygous for activated protein C resistance (factor V Leiden) but no other risk factors should also receive a 3- to 6-month course of treatment. Patients with a first episode of idiopathic deep venous thrombosis should be treated for at least 6 months. In patients with recurrent deep venous thrombosis or pulmonary embolism, a known hypercoagulable state, or homozygosity for factor V Leiden, anticoagulation should be continued indefinitely.

Dilated Cardiomyopathy puts patients at risk for embolization. When this condition was accompanied by atrial fibrillation, the annual risk for embolic events in the absence of anticoagulation exceeded 15% in one cohort study. Without atrial fibrillation, the risk is in the 1% to 5% range. The absence of randomized trials demonstrating risk reduction with anticoagulation precludes definitive recommendations. Potential benefits and risks must be weighed for individual patients.

Myocardial Infarction. Some patients may benefit from anticoagulation following myocardial infarction. *Anterior Q-wave infarction*, particularly with evidence of *mural thrombosis*, or atrial fibrillation warrants anticoagulation. Otherwise, there is no evident advantage for warfarin over aspirin in chronic stable angina or in the secondary prevention of myocardial infarction.

Contraindications

Contraindications to the use of oral anticoagulants need to be considered in the context of urgency of anticoagulation, risk and seriousness of potential complications, and duration of therapy (see Table 83.1). Patients with *previous central nervous system bleeding*, recent *neurosurgery*, or *frank bleeding* should not receive warfarin. Important relative contraindications include *active peptic ulcer disease, chronic alcoholism, blindness* (unless in supervised situations), *bleeding diathesis*, and *severe hypertension.* When taken in *early pregnancy*, coumarins may cause birth defects; when they are used at *delivery*, fetal hemorrhage can occur. Heparin should be used in place of warfarin during early pregnancy and childbirth. Embarking on oral anticoagulant therapy is unwise when follow-up cannot be readily maintained, when laboratory facilities for accurately measuring the PT are inadequate, or when the patient is unreliable.

Absolute Contraindications
Previous central nervous system bleeding
Recent neurosurgery
Active frank bleeding
Early pregnancy and delivery

Relative Contraindications
Active peptic ulcer disease
Chronic alcoholism
Bleeding diathesis
Severe hypertension

Table 83.1. Contraindications to Anticoagulant Therapy with Warfarin

Initiating and Monitoring Therapy

Initiation. Patients with *acute pulmonary* embolization or acute systemic embolization should be admitted to the hospital for immediate administration of *IV heparin* to halt clot propagation. Warfarin should be started on the first day of heparin therapy and overlapped with heparin for at least 4 days to ensure adequate reduction in prothrombin levels. Heparin can then be discontinued once the *international normalized ratio* (INR; see below) exceeds 2.0 on two consecutive days. Warfarin

treatment should be initiated with sequential 5-mg doses and daily measurement of the INR. Studies have shown that such initial 5-mg doses (in comparison with initial 10-mg doses) are less likely to induce excessive anticoagulation and are equally effective in lowering levels of prothrombin.

For patients with *deep venous thrombosis*, SQ administration of *low-molecular-weight heparin* is an effective alternative to IV administration of unfractionated heparin for initial anticoagulation (see Chapter 35). It allows for a shortened hospital stay or an entirely at-home anticoagulant treatment program, which reduces costs. Warfarin therapy is instituted in the same fashion as IV heparin therapy.

Patients who are in less urgent need of immediate full anticoagulation (e.g., *stable atrial fibrillation*) can be safely started on warfarin alone as outpatients. A generally accepted approach to initiating outpatient warfarin therapy is to give 5 mg daily, measure the INR at 5 to 7 days, and adjust the dose accordingly. The starting dose should be set at 2.5 mg daily in patients who weigh less than 110 lb, are older than 75 years, or are at increased risk for bleeding. Warfarin is best taken on an empty stomach at a specific time each day. Administration at bedtime allows for changes to be made in the dosage on the same day the INR is measured. The Food and Drug Administration has approved several generic warfarins; the same generic or brand formulation should be used consistantly to avoid patient confusion and INR fluctuaion.

Monitoring. The intensity of anticoagulation is measured with the *PT test* and expressed as the *prothrombin time ratio* (PTR), which is the ratio of the patient's PT to the control PT of the laboratory. Standardization of the PTR across laboratories is necessary to account for the different sensitivities of the various thromboplastin reagents used in the assay. The *INR* has replaced the PTR as the universally accepted measurement of anticoagulation intensity. To calculate the INR, the PTR is raised to the power of the international sensitivity index (ISI) of the specific reagent used (i.e., PTRB^{ISI}).

It can take up to 3 months to achieve a stable warfarin dosage. Once stabilized, the INR can be checked every 3 to 4 weeks. The variability in the warfarin dose response mandates frequent monitoring. Changes in the warfarin requirement may be precipitated by a change in diet, particularly the intake of foods with a high content of vitamin K (e.g., most leafy vegetables), or by medications that interfere with the hepatic clearance of warfarin. Many commonly used drugs potentiate the anticoagulant effect of warfarin and should prompt close monitoring (see below). In about 75% of patients, dosage adjustments over time are unnecessary.

Patients with *lupus anticoagulants* (one of the *antiphospholipid antibodies* that can cause hypercoagulability and thromboembolization; see Chapter 35) pose a particular problem in monitoring because these antibodies can interfere with the PT assay. Both overestimation and underestimation of the degree of anticoagulation can result. Consultation with a hematologist is needed to design the anticoagulation monitoring program for such a patient.

Recommended Intensity of Therapy. After initiation of therapy, dosage should be adjusted to maintain the therapeutic range. Extensive study supports the use of lower ranges of anticoagulation intensity (INR target range of 2.0 to 3.0) for most groups of patients. Efficacy is maintained while the risk for hemorrhagic complications is reduced. Only those patients at highest risk for thromboembolism (e.g., mechanical prosthetic heart valves) should receive anticoagulation in an INR range of 2.5 to 3.5.

Adjustment of Dose. The dose can be adjusted in numerous ways when the INR is out of range. One method designed to maximize safety and avoid wide swings in the INR is based on 10% changes in the weekly dose unless the INR is grossly out of range. For example, if the patient is taking 7.5 mg/d, the weekly dose is 52.5 mg. If the INR is too low, the weekly dose is increased by 10%, so that on 2 days of the week the patient takes 10 mg, and 7.5 mg on the other 5 days. The INR is then measured weekly for the next 2 weeks, with continued adjustment in dose if necessary.

Outpatient anticoagulation requires facilities for accurate INR measurement and reliable collection of blood samples, and the ability to contact patients promptly. Careful monitoring and follow-up are essential for a safe and successful outpatient anticoagulation program. At the beginning of therapy, patients should attend an educational session with a nurse who can instruct them in the use of warfarin, answer questions, test their understanding, and provide informative booklets for them to take home. Patients who fail to keep an appointment for an INR test should be contacted immediately. A computer system can provide reminders so that no patient is lost to follow-up. Commercial laboratory services are sometimes employed to draw samples at home for patients who have difficulty coming to the office. Home monitoring devices are under development.

Duration. In the absence of hemorrhagic complications, anticoagulation should be continued indefinitely in patients with atrial fibrillation, valvular heart disease, systemic embolization, or mechanical prosthetic heart valves. Patients with recurrent deep venous thrombosis, recurrent pulmonary embolism, or a known hypercoagulable state should also receive anticoagulants indefinitely. Those with a single episode of deep venous thrombosis caused by a self-limited risk factor and no known hypercoagulable state can stop their warfarin after 3 to 6 months (see Chapter 35).

Complications

Reports of the incidence of *hemorrhagic complications* in patients on long-term anticoagulant therapy have varied widely, depending on the definition of bleeding used and the INR target under study. Several series have demonstrated that hemorrhage severe enough to require hospitalization or transfusion should occur in fewer than 5% of patients who are carefully monitored. The rate of intracranial hemorrhage among patients managed in a structured setting was 0.6% annually. *Risk factors* for hemorrhagic complications include an *INR higher than 4.0, recent initiation of anticoagulation*, and *wide fluctuation in the INR. A history of gastrointestinal bleeding* is a risk factor; peptic ulcer disease *per se* is not. Older patients generally experience a higher incidence of complications, but this may be mediated through other risk factors more common among the elderly.

Patients experiencing urinary, gastrointestinal, or gynecologic bleeding while on anticoagulant therapy should undergo a diagnostic evaluation to identify any underlying pathologic lesion. In several series, a lesion responsible for the bleeding was detected in more than 50% of patients.

Hemorrhagic necrosis of the skin (more common among women) and *cyanotic toes* (more common among men) occur rarely, even with INRs in the therapeutic range. The mechanism may be a transient inhibition of endothelial vitamin K-dependent antithrombotic proteins (proteins S and C) in patients congenitally deficient in such factors.

Effects of Drugs and Concurrent Illnesses

Potentiation. Drugs that potentiate the effect of warfarin may do so by preventing the synthesis or absorption of vitamin K, displacing warfarin from binding sites, inhibiting microsomal degradative enzyme activity, increasing catabolism of clotting factors, or impairing platelet function (Table 83.2). The risk for bleeding is particularly high with concurrent use of NSAIDs. In the elderly, a 13-fold increase in hemorrhagic peptic ulcer disease results from taking NSAIDs plus warfarin. Substitution of daily *acetaminophen* for NSAIDs reduces the risk for bleeding from gastric injury, but it raises the risk for excessive anticoagulation by potentiating the effects of warfarin; close INR monitoring and warfarin dose adjustment are critical with daily use of acetaminophen.

Effect	Mechanism	Drug
Prolongation of PT	Inhibits clearance	Metronidazole
		Trimethoprim sulfamethoxazole
		Cimetidine[a]
		Omeprazole[a]
		Sulfinpyrazone[a]
		Disulfiram
		Anabolic steroids
	Inhibits vitamin K	Cephalosporins, 2nd, 3rd generation
		↓Thyroxine
	Increases metabolism of clotting factors	
	Unknown	Erythromycin
		↑ Tamoxifen
		↑ Phenytoin
		↑ Isoniazid
		↑ Ketoconazole
		↑ Piroxicam
Reduction of PT	Increases warfarin clearance	Barbiturates
		Carbamazepine
		Rifampin
	Reduces warfarin absorption	Cholestyramine
	Increases synthesis of clotting factors	Estrogens
	Unknown	Penicillins

[a]Causes only minimal prolongation of prothrombin time (PT).
Adapted from Hirsh J. Oral anticoagulant drugs. N Engl J Med 1991;324:1865, with permission.

Table 83.2. Common Drugs That Interact with Oral Anticoagulants

Hepatocellular failure results in impaired synthesis of clotting factors and albumin; cholestasis makes for less efficient absorption of vitamin K. Both conditions are capable of prolonging the INR and potentiating the effects of warfarin.

Inhibition. Anticoagulant effects are decreased by agents that induce microsomal enzymes, decrease the absorption of warfarin, or increase the synthesis of clotting factors or binding proteins (see Table 83.2). Moreover, coumarins cause a decrease in the metabolism of tolbutamide and phenytoin by competing for the same degradative enzymes. The INR should be measured when any change in a drug program is made, and it should be followed closely thereafter.

Reversal of Anticoagulation and Elective Interruptions in Therapy

Rapid Reversal. Serious bleeding, a dangerously high INR (>20), or a need for urgent surgery are among the circumstances in which rapid reversal of oral anticoagulation is indicated. Administration of *fresh-frozen plasma* provides rapid correction of the INR but involves exposure to blood products and a large colloid load. Alternatively, administration of *vitamin K* (which stimulates hepatic synthesis of the clotting factors inhibited by warfarin) is also effective but somewhat slower, taking 12 to 48 hours to reduce the INR to a safe level. IV, SQ, and oral preparations are available. The *high-dose IV preparation of vitamin K* (1 to 10 mg) is the most potent and most rapidly acting of the various formulations, but it is also the most likely to overshoot, impair repeated anticoagulation, and subject the patient to the risk for an acute anaphylactic reaction (a rare but serious complication). *Low-dose IV vitamin K* (0.1 to 0.5 mg) appears only slightly less effective and is less likely to overshoot. The same holds for *sc vitamin K* (1 to 3 mg), but systemic absorption can be erratic, leading to treatment failure. *Oral vitamin K* (2.5 mg) can reverse INRs of less than 10 but may require slightly more time to work than parenteral forms.

Interruptions. The decision to discontinue anticoagulant therapy in the context of nonemergent bleeding or elective surgery needs to be individualized. The risk for embolization must be balanced against the risk for hemorrhage. The risk for embolization is substantial and greatest for persons with acute deep venous thrombosis or acute arterial embolization who have been taking warfarin for less than 1 month. A somewhat lesser risk is associated with recurrent deep venous thrombosis, nonvalvular atrial fibrillation with previous arterial embolization, placement of a mechanical heart valve, and deep venous thrombosis after more than 1 month of warfarin. The risk for postoperative bleeding can be minimized by withholding anticoagulation for about 4 days before elective surgery to allow the INR to drift below 1.5, the level at which most surgery can be carried out with little risk for hemorrhage.

When patients are at high risk for thromboembolization, *perioperative heparin* must be considered. A 2-day preoperative course is of low risk when stopped 6 hours before surgery. Postoperative heparinization, begun 12 hours after surgery (without a loading bolus), is associated with a 3% daily risk for major hemorrhage and should be reserved for those patients at highest thromboembolic risk whose risk for postoperative bleeding is acceptable. If the risk for bleeding is unacceptably high in such persons, then a *vena cava filter* should be considered preoperatively.

Patient Education

Before initiation of outpatient therapy, the patient and designated family member(s) need to (a) understand the risks and benefits of warfarin; (b) become familiar with the requirements for taking warfarin responsibly (e.g., avoidance of NSAIDs and excessive amounts of alcohol); (c) be able to recognize signs of abnormal bleeding (e.g., melena); and (d) be versed in the triage protocol for hemorrhagic complications. Instruction of the patient by a nurse trained in anticoagulation management, supplemented by an information booklet appropriate to the patient's educational level, constitute the essentials of the patient education effort. Any patient who is incapable of understanding the instructions or is deemed unreliable should not be placed on therapy because the risks for hemorrhage probably outweigh any possible benefits. The one exception is the patient who can be closely supervised by family members or health care professionals.

The physician should know the tablet color coding of the warfarin brand the patient is using. This helps ensure that proper doses are being taken. Constancy of brand should be advised, both to minimize dosing errors and to ensure consistency of anticoagulant effect.

ANTIPLATELET THERAPY

Aspirin inhibits platelet aggregation by irreversibly acetylating and inactivating platelet prostaglandin H synthase and its cyclooxygenase activity. The major side effect of aspirin is gastrointestinal hemorrhage. Newer platelet-active drugs, *ticlopidine* and *clopidogrel*, inhibit adenosine diphosphate–induced platelet aggregation and do not interfere with the prostaglandin protective effect on the gastric mucosa. The cost of ticlopidine and its association with agranulocytosis has reduced its use as an alternative to aspirin. Clinical studies of clopidogrel are ongoing.

Indications

Aspirin has been shown to be effective in the treatment and prevention of atherothrombosis.

Current indications for aspirin therapy include the following:

- Primary and secondary prevention of myocardial infarction (see Chapter 18 and Chapter 31)
- Chronic stable angina (see Chapter 30)
- Unstable angina (see Chapter 20)
- Acute myocardial infarction
- Transient cerebral ischemia and ischemic stroke (see Chapter 171)
- Acute ischemic stroke
- Coronary stent implantation (combined with clopidogrel or ticlopidine for at least 14 days; see Chapter 30)

The minimum effective dose of aspirin for these indications ranges from 80 to 160 mg/d.

Aspirin as an Adjunct or Alternative to Warfarin

As Adjunct. Patients with mechanical prosthetic heart valves, specifically those with caged-ball or caged-disk valves, or others with additional risk factors for thromboembolism can optimally be managed by adding aspirin therapy (80 to 100 mg/d) to warfarin, with an INR target range of 2.5 to 3.5.

As Alternative. For most conditions in which anticoagulation is indicated, aspirin has been found to be either ineffective or equivocally effective. Among patients with atrial fibrillation, only those deemed to be at low risk for stroke or for whom warfarin is contraindicated are appropriate candidates for aspirin therapy (see Chapter 28 and Chapter 33).

CONCLUSIONS AND RECOMMENDATIONS

Warfarin

- Warfarin is highly effective in preventing thromboembolism. The recommended intensity of anticoagulation for most indications is an INR of 2.0 to 3.0. Patients with metallic prosthetic heart valves should be given aspirin in addition to warfarin, with a target INR of 2.5 to 3.5.
- Only patients felt to be at low risk for stroke or those in whom anticoagulant therapy is contraindicated should be treated with aspirin for prophylaxis against stroke in atrial fibrillation.
- Patients with temporal risk factor–related deep venous throm-bosis or pulmonary embolism should be treated with warfarin for 3 to 6 months. Patients with idiopathic deep venous thrombosis or pulmonary embolism should be treated for at least 6 months. Patients with recurrent thrombosis or an ongoing hypercoagulable state or who are homozygous for activated protein C resistance should be treated indefinitely with warfarin.
- Rapid reversal of anticoagulation therapy is indicated for severe bleeding, an INR above 20, and urgent surgery. Administration of fresh-frozen plasma achieves reversal within hours. Vitamin K accomplishes the same in 6 to 48 hours, depending on dose and route of administration.
- The decision to discontinue anticoagulant therapy in the context of nonemergent bleeding or elective surgery needs to be individualized. The risk for embolization must be balanced against the risk for hemorrhage.

- Reversal of oral anticoagulation for elective surgery can be accomplished simply by withholding warfarin for 4 days or until the INR is below 1.5, the level at which the risk for hemorrhage becomes minimal in most forms of surgery. For high-risk patients, perioperative heparinization must be considered.
- Anticoagulant therapy mandates frequent monitoring, life-style changes, and commitment by the patient and health care team to optimize its safety and efficacy.

Aspirin

- Aspirin should be used by all persons at risk for atherothrombosis. Aspirin can reduce the risk for vascular events, including myocardial infarction, stroke, and transient ischemic attack.
- Aspirin combined with clopidogrel or ticlopidine should be used for at least 14 days after coronary stent implantation.

CHAPTER 84 APPROACH TO THE PATIENT WITH LYMPHOMA

The lymphomas are a diverse group of malignancies, with non-Hodgkin's lymphoma about twice as common as Hodgkin's disease and increasing at a rate of 4% annually. Together, they account for more than 60,000 new cases of cancer per year in the United States, having doubled in incidence during the past 20 years. Multiple subtypes are found, each with specific immunologic and pathologic characteristics and a distinctive clinical presentation and therapeutic response. Non-Hodgkin's lymphoma strikes much later than Hodgkin's disease; peak incidence is in the fifth decade, compared with the second decade for Hodgkin's disease (although a second peak occurs in the fifth decade). The prognosis for non-Hodgkin's lymphoma is less favorable in terms of long-term cure, although survival and responsiveness to therapy are substantial. Cure is possible for many patients with Hodgkin's disease.

Although the treatment of these conditions is the province of the oncologist, the primary physician has an important role in diagnosing and staging the disease, coordinating plans for management, and delivering follow-up care on an outpatient basis. Because they are likely to conduct the initial evaluation, it is essential that primary physicians be prepared to discuss with patients and their families the meaning of findings. Even after referral, the primary physician often encounters requests for advice, being the physician the patient knows best. Consequently, a serious working knowledge of the clinical presentation, prognosis, staging methods, and treatment options is important for the primary physician if the patient is to be served well.

HODGKIN'S DISEASE

Pathology, Clinical Presentation, and Course

The histology of Hodgkin's disease incorporates four categories: lymphocyte predominance, nodular sclerosis, mixed cellularity, and lymphocyte depletion. *Lymphocyte predominance* occurs in 10% to 15% of patients, *nodular sclerosis* in 20% to 50%, *mixed cellularity* in 20% to 40%, and *lymphocyte depletion* in 5% to 15%. In about 15% of cases, classification is difficult and requires expert interpretation of the histology. In all instances, the *sine qua non* of diagnosis is the pathognomonic *Reed-Sternberg cell*.

The condition originates in the lymph nodes. Conceptually, Hodgkin's disease is *unicentric* in origin and progresses by contiguous extension along lymphatic pathways. Consequently, the adenopathy tends to be asymmetric. This pattern of evolution is in contrast to that of non-Hodgkin's lymphomas, which are multicentric and generally at more advanced stages at initial presentation. Most patients present with disease above the clavicle. Fewer than 15% present with disease originating below the diaphragm, although any node may be involved (including those of the mediastinum, axilla, or groin). Typically, the nodes are firm and nontender; although often matted, they may be discrete and even freely movable. Subsequent spread to the spleen is a regular occurrence and is the first manifestation of disease below the diaphragm, followed by involvement of the liver and bone marrow. Fever, weight loss, night sweats, or alcohol-induced pain may develop and almost always represents advanced disease.

The differential diagnosis of Hodgkin's disease includes infectious mononucleosis, HIV infection, and other nonbacterial adenopathies in the young (see Chapter 12). In the elderly, other malignancies are a common diagnostic consideration; they are particularly suspect in the presence of a fever of unknown origin. Excisional biopsy rather than needle aspiration is needed for diagnosis.

Classification by Stage. Because prognosis and treatment are so dependent on the extent of disease, classification by stage plays a central role in Hodgkin's disease. The *Ann Arbor staging system* of classification is the one most widely referred to. In it, *stage I* is defined as disease confined to a single node-bearing area or localized involvement of a single extranodal site. *Stage II* involves two or more contiguous node-bearing areas on the same side of the diaphragm or more than one nodal region in conjunction with localized involvement of an extralymphatic organ on the same side of the diaphragm. *Stage III* is nodal involvement on both sides of the diaphragm, with or without involvement of the spleen or a local extranodal organ or site. Additional subcategories have been developed for patients with intraabdominal disease. *Stage III1* represents disease confined to the upper abdomen; it is generally microscopic. *Stage III2* designates disease extending into the pelvis with grossly involved nodes or bulky retroperitoneal tumor. *Stage IV* represents diffuse visceral disease (liver, lung parenchyma, bone marrow).

The special category designated *E* (for extranodal) was created because of data indicating that involvement of an organ contiguous with a lymph node–bearing area is associated with a distinctly better prognosis than is hematogenous visceral involvement. Nonetheless, the prognosis is not as good as it would be without any organ involvement. *S* denotes disease in the spleen.

Approximately 20% of patients have *fever, night sweats*, or *significant weight loss* (>10%). These systemic symptoms are incorporated into the staging system because they are important determinants of prognosis. When absent, the designation is *A*; when any of the three is present, the designation is *B*. Patients with pruritus only are no longer included in the B group. Early (I and II) and advanced (III and IV) stages of Hodgkin's disease are relatively equally distributed in terms of frequency. More sophisticated staging by pathologic and clinical procedures generally tends to advance the stage of disease.

The *prognosis* of Hodgkin's disease has improved dramatically with the advent of careful staging and improved radiation technology and chemotherapy programs. Overall 5-year survival is 80%; when all stages of disease are combined, 65% experience 5-year relapse-free survival (Table 84.1). The principal determinants of outcome are stage, patient age, presence or absence of symptoms, and tumor bulk. Histology is also a factor, although not as important as the others.

STAGE	DEFINITION	RELATIVE INCIDENCE (%)	THERAPY	CURE (%)
I	Confined to single node-bearing area.	30	Radiation	70–90
II	Confined to two contiguous node-bearing areas on one side of diaphragm	25	Radiation	
III	In nodal areas on both side of diaphragm	25	Radiation and chemotherapy	50–60
IV	Visceral lesions (liver, lung) not in continuity with nodes	20	Chemotherapy	
Special categories				
E	Visceral extranodal disease in continuity with nodes (e.g., lung mass extending out from hilum)		Radiation +/− chemotherapy	
B	Symptoms of fever, weight loss, or sweats		Chemotherapy +/− radiation

Table 84.1. Hodgkin's Disease: Stages, Relative Incidences, and Prognosis

Staging

Staging (Table 84.2) is critical to the design of a therapeutic program and an estimation of prognosis. *Clinical staging* involves an assessment of the history and the findings on physical examination and radiology. The history should ascertain the presence of fever, night sweats, or weight loss. Careful palpation of all lymph nodes and assessment of liver and spleen size are important, although enlargement discovered by physical examination does not necessarily indicate involvement by the disease. One half of patients with a palpable spleen do not have histologic splenic involvement, and one fourth with normal-sized spleens do.

STUDY	INDICATION
Radiographic Studies	
Chest roentgenogram	All patients; CT if mediastinal or hilar disease
Chest CT	If x-ray findings abnormal or if results would change therapy
Lymphangiogram	Only if (a) no clinical evidence of infradiaphragmatic disease, (b) no mass or lung disease, or (c) no advanced stage signs or B symptoms
Abdominal CT	Complements lymphangiogram; same indications
Surgical Studies	
Laparoscopy	Preferable to laparotomy in presence of B symptoms, to identify liver pathology
Laparotomy	Stage I or II disease and no symptoms
Hematologic Studies	
Bone marrow biopsy	Only if clinical stage IIB or more

CT = computed tomography.

Table 84.2. Staging Procedures for Hodgkin's Disease

About 90% of patients are thought to have stage I or II disease at the time of initial clinical staging. However, most treatment decisions require *pathologic staging* (which includes biopsy) because up to two thirds of patients who present with clinical stage I or II disease are found to have disease below the diaphragm on pathologic staging. About half of patients with B symptoms will manifest disease below the diaphragm at laparotomy, compared with 25% of patients with A symptoms. The principal staging procedures include chest radiography, computed tomography (CT), lymphangiography, and bone marrow biopsy. Staging laparotomy is indicated in selected instances.

Chest Radiography and Computed Tomography. All patients should undergo *chest radiography* because some of the most common forms of Hodgkin's disease involve the mediastinum. Even if the chest radiographic findings are abnormal, *CT of the chest* is indicated because it provides enhanced sensitivity for detection and definition of mediastinal, hilar, and paravertebral adenopathy. The need for chest CT in a patient with totally normal findings on the chest x-ray film depends on whether the result will alter therapy or prognosis. CT is more sensitive than chest radiography for the detection of disease in the mediastinum and adjacent structures.

Complementary information about disease below the diaphragm is provided by *CT of the abdomen* and lymphangiography. CT is best for demonstrating the number and size of nodes in the retroperitoneum and pelvis. It also may show evidence of hepatic or splenic involvement, although no radiologic test (including *magnetic resonance imaging* and *radionuclide scanning*) is sensitive enough to rule out splenic involvement. Abdominal CT provides anatomic information about nodes in areas not well visualized by lymphangiography (mesenteric, subhepatic, perisplenic, celiac, and periaortic regions). CT cannot detect microscopic disease and gives less information than the lymphangiogram about nodal architecture. Magnetic resonance imaging offers no advantage over CT.

Lymphangiography can provide complementary information about the structure of retroperitoneal nodes and is capable of detecting disease in nodes that are not enlarged. The sensitivity of lymphangiography by itself is low, with a false-negative rate of 20%. However, when strict radiologic criteria for nodal involvement are used, the specificity reaches 95%, with a false-positive rate below 5% noted. Thus, a positive study result is helpful, but negative findings on the lymphangiogram do not rule out disease below the diaphragm. Moreover, even with a positive result, the test does not detect involvement of the liver or spleen, which is an important determinant of therapy. The test is important to perform in patients with clinical stage I or II disease without B symptoms, particularly those patients in whom laparotomy is scheduled, to identify the lymph nodes to be removed. About 25% of patients classified clinically are reclassified on the basis of lymphangiogram results. The dye load associated with lymphangiography carries a small risk for pulmonary insufficiency related to extravasation of dye into the lung parenchyma, and it should not be performed in persons with severe lung disease.

Bone Marrow Biopsy. Biopsy of the marrow is a useful staging procedure in patients with systemic symptoms or disease beyond stage II; results are positive in up to 20% of such patients. Because disease in the marrow is often focal, multiple biopsies are necessary to avoid sampling error. Marrow aspiration is never useful. A positive result on a marrow study classifies the disease as stage IV and makes laparotomy unnecessary. Patients with clinical stage I or IIA disease have never been reported to have positive findings on marrow biopsy, but stage IIB is associated with marrow involvement in 9% of patients.

Staging Laparotomy and Laparoscopy. Removal of the spleen is reserved for patients in whom the result will change the approach to therapy (e.g., asymptomatic patients with clinical stage I or II disease who are being considered for radiotherapy alone). The procedure has the advantage of allowing a more precise definition of the extent of disease and frequently results in reclassification and implementation of a different treatment program. It includes wedge biopsy of the liver, splenectomy, and examination of the lymph nodes in contiguous chains, exclusive of mesenteric nodes. The surgery is associated with a low mortality rate (0.5% to 1.0%) and negligible early morbidity. However, patients who receive radiation and chemotherapy after splenectomy are at increased risk (up to 28% in the first 6 years) for fulminant sepsis, with its attendant 50% mortality. Those who undergo splenectomy but do not receive chemotherapy appear to be much less vulnerable to serious infection. Because of the risk for infection, only those who will have their treatment program altered by the results of laparotomy should undergo the operation. Immunizations for pneumococcal disease and other potentially life-threatening infections should be conducted before splenectomy.

Laparoscopy has been advocated as a less invasive means of identifying liver involvement in patients with a high probability of disease below the diaphragm (e.g., those with B symptoms). Liver biopsy specimens are taken from suspected areas under direct visualization. Laparoscopy is superior to percutaneous liver biopsy (20% yield vs. 5%), but its yield does not match that of open biopsy performed during staging laparotomy. Few patients with hepatic involvement are free of systemic complaints; on the other hand, neither hepatomegaly detected by physical examination or scan nor elevated alkaline phosphatase levels identify patients likely to have positive findings on biopsy.

Radionuclide Scanning. Conventional liver/spleen and bone scans lack sufficient sensitivity or specificity to warrant their routine use in staging. Results of *gallium 67 scanning* may be positive in areas of disease involvement, and occasionally previously unknown disease is discovered. Its main use is to detect residual disease in the mediastinum after treatment of bulky mediastinal disease.

Overall Approach. The history is reviewed for characteristic systemic symptoms; the physical examination focuses on lymph node–bearing areas. Chest radiography and CT are performed, as is lymphangiography and abdominal CT in patients who are clinically in stage I or II. If the patient is clinically in stage I or II and would be treated by radiation alone, a staging laparotomy should be performed to identify occult disease below the diaphragm. Until it becomes possible to predict more accurately who is likely to have occult disease in the abdomen, one must rely on the laparotomy. When systemic symptoms are present, a laparoscopy and bone marrow biopsy can be performed as preliminary studies; if either result is positive, the need for laparotomy is obviated. Lymphangiography produces too many false-negative results to be relied on without intraabdominal evaluation, and even if the result is positive, it fails to provide information about the liver and spleen, which is necessary for selecting radiation therapy, chemotherapy, or both.

Prognostic Scoring

Although staging is the single most important determinant of prognosis, staging has not been sufficient to predict fully the outcome of treatment, especially in persons presenting with advanced (i.e., stage III and IV) disease. Clinical, biologic, and demographic data have been examined by regression analysis to identify independent predictors of prognosis. Partially validated scoring systems have emerged from such analyses. One of them, derived from the International Prognostic Factors Project, is based on a serum level of *albumin* below 4.0 g/dL, a *hemoglobin* concentration below 10.5 g/dL, *male sex*, *age* older than 45 years, *stage IV* disease, *white cell count* above 15,000/mm^3, and *lymphocytopenia* (<600 cells per milliliter or <8% of white cells). Patients with two features have a nearly 20% greater chance of being free of progression of disease than do patients with three features. Separate work on biologic factors of possible prognostic value find potential for *CD30* levels, number of *activated cytotoxic T cells*, presence of *CD15* in biopsy specimens, and presence of *interleukin-16*.

To be maximally useful in choice of therapy, prognostic systems will have to become better at identifying patients at greatest and least risk. Although effective, therapy for Hodgkin's disease can have morbid consequences. Carefully matching disease prognosis with aggressiveness of therapy is essential to maximize outcomes and minimize the risks of treatment.

Treatment

Although selection of a treatment regimen is the responsibility of the oncologist, it is important for the primary physician to be cognizant of the major treatment

regimens and their outcomes. Treatment is a function of disease stage, not of cell type. Therapy for Hodgkin's disease achieves a substantial cure rate in all stages (Table 84.1).

Stages I and II. *Radiation therapy* is the treatment of choice. For patients with stage IA or IIA disease, *local* and *extended-field radiotherapy* to contiguous node-bearing areas and adjacent regions has resulted in an 85% to 90% cure rate. *Total nodal radiation therapy* has been used in stages IB and IIB, delivered at a dose of 3,500 to 4,500 rads during a 3- to 4-week period through a portal referred to as the "mantle" for chest radiation and the "inverted Y" for intraabdominal lymph nodes. Patients with stage IB and IIB disease have a 70% to 75% chance of cure with such radiation therapy. However, to be curative, radiation therapy must be performed with great precision, and the extent of disease must be well documented. One study found that 37% of treatment portals did not cover the entire extent of disease. *Side effects* of radiation therapy include dental problems and increased risks for *thyroid cancer* (20-year latency), *hypothyroidism* (50%), radiation *pneumonitis* (6% to 20%), accelerated *coronary artery disease* and *myocardial infarction*, and a *second solid tumor* (incidence approximately 1% annually). The risk for *leukemia* is also increased in patients receiving high doses of radiation to the bone marrow.

Chemotherapy is added to radiation when a large mediastinal mass (exceeding one-third the diameter of the chest) is present, and is substituted for radiation if the patient fails to respond or relapses. Some have argued that because success rates with chemotherapy are so great, all patients with early-stage disease should receive it. The debate continues, but radiation therapy remains the treatment of choice.

Stages III and IV. *Combination chemotherapy* is the cornerstone of treatment. The Mustargen, Oncovin, prednisone, procarbazine (*MOPP*) program was the prototype. Doxorubicin (Adriamycin), bleomycin, vinblastine, dacarbazine (*ABVD*) is currently in wide use. Combination regimens are designed to address issues of tumor resistance and drug toxicity. Hybrids and alternation of combinations have also proved effective. All are based on the identification of agents with individually distinctive mechanisms of antitumor activity. Their side effects are nonadditive, which helps to limit the amount of drug-related morbidity. Response rates for stage III and IV disease are in the 80% range, and complete remission of disease is the rule. For patients with advanced disease who experience remission, the chance of cure is 50%. By manipulation of dosages and schedules of drugs, most such chemotherapy can be delivered conveniently on an outpatient basis. In most instances, chemotherapy is administered for 6 months, at which time restaging is carried out; in the absence of residual disease, therapy is discontinued. No benefit is derived from a "maintenance program."

Choice of program remains a subject of much debate among oncologists. Of particular concern is the 20% rate of failure to respond, which has led to the use of seven-drug and alternating four-drug regimens. Problems occur with both, especially the need to prolong therapy beyond 6 months, which greatly increases the risk for toxicity. Some authorities argue that the real cause of failure to respond is the inability to administer adequate doses. In the absence of a definitive means of identifying the very high-risk patient (see above), balancing response rates with treatment-related adverse effects remains an art form that requires an oncologist experienced in the treatment of Hodgkin's disease.

Adverse effects of combination chemotherapy include sterility, secondary malignancy, and increased susceptibility to infection, in addition to those associated with individual drugs (see Chapter 88). MOPP produces *sterility* in almost all male patients. Sperm banking is indicated before initiation of therapy. Close to 90% of women over age 26 become infertile, but most younger women are able to have children; however, premature menopause is common. The incidence of sterility is significantly lower with ABVD. The risk for *leukemia* is increased for up to 10 years after chemotherapy (peak is at 5 years), especially when the program includes an alkylating agent (as in MOPP). In a comprehensive analysis of leukemia in treated Hodgkin's disease, the relative risk was 9.0 over that for radiation therapy and did not increase with concomitant radiation. Risk did increase with dose and duration of chemotherapy, stage of disease, age, and splenectomy. Leukemia risk is thought to be lower with ABVD. Despite the risk for leukemia, the gain in survival afforded by combination chemotherapy greatly outweighs its adverse effects.

Other chemotherapy-related side effects include severe *emesis, bone marrow suppression*, and *neuropathy* (see Chapter 88). The risk for overwhelming *pneumococcal sepsis* associated with splenectomy can be lessened by the use of polyvalent *pneumococcal vaccine*. The vaccine is often given before splenectomy but can be administered after surgery; antibody response is just as adequate after splenectomy. However, antibody production is blunted if chemotherapy is begun within 10 days of vaccination. As noted above, the risk for overwhelming sepsis approaches 30%, with a 50% fatality rate.

Radiation is sometimes employed for stage III patients. Those with stage III1A disease appear to do equally well with radiation or chemotherapy. When patients with stage IIIA disease have a large mass of mediastinal tumor, radiation is often added to their program.

Treating Relapses. Relapse occurs in 20% to 35% of patients. The probability of responding to repeated treatment ("salvage" therapy) is a function of the length of the initial remission and approaches 95%, even if the original chemotherapeutic regimen is used. A non–cross-resistant regimen, such as ABVD, can be used either in place of the original program or in some form of combination with it. Relapse-free survival of 45% at 10 years has been noted for patients retreated after an initial remission of more than 12 months; however, overall survival falls to 24% because of complications of retreatment (e.g., second malignancy). For those with an initial remission of less than 12 months, the survival after retreatment is about 10% at 10 years. The use of *autologous bone marrow transplantation* in drug-resistant patients has provided new options. Retreatment after transplantation produces remission in 50% and extended disease-free periods in a fourth to a half of those who respond.

Monitoring Therapy

Periodic examination of involved nodes is the simplest means of judging response to therapy. Many laboratory parameters have been developed but offer little advantage over physical examination and chest radiography. The need for periodic restaging is a judgment to be made in consultation with the oncologist. Patients receiving MOPP require close surveillance (see Chapter 88). Patients being treated with radiation should be watched for bone marrow suppression and, when lung fields are involved, radiation pneumonitis and thyroid dysfunction.

The likelihood of *late relapse* (36 months or more after completion of therapy) is small, but large enough to warrant continued monitoring. The risk for late relapse is low, but patients with stage I disease show the highest rates, perhaps because of failure to irradiate all involved nodes. Also at risk for recurrence are patients presenting with a large mediastinal tumor; local recurrence is typical. Gallium scanning has proved useful in such cases, although biopsy confirmation is necessary because false-positives do occur. Most relapses are detected by history, physical examination, or chest radiography; abdominal CT may also help detect late disease. Careful late follow-up is warranted, even after 3 years, because response to retreatment is good.

Patient Education and Indications for Consultation and Referral

Many patients will greet the diagnosis of Hodgkin's disease with dread, equating it with a fatal outcome. Without raising false hopes, the physician can point to the excellent 5-year survival rates and the high percentage of patients who are disease-free after 10 years. Patients who have undergone splenectomy should be advised to undergo vaccination with polyvalent pneumococcal vaccine before starting chemotherapy or radiation. Because chemotherapy can cause permanent sterility, it is important to review this prospect with the patient before treatment is begun. Pretherapy sperm storage has been advocated. Young women (under age 26) can be counseled in encouraging terms because they have been found capable of bearing phenotypically normal children.

Once the diagnosis is confirmed and clinical staging is completed, referral to the oncologist for a discussion of pathologic staging and design of a treatment program is indicated. During the period of initial treatment, the patient will be followed closely by the oncologist, but the primary physician can and should serve to coordinate care and provide support to the patient and family.

NON-HODGKIN'S LYMPHOMAS

The non-Hodgkin's lymphomas represent a diverse group of malignancies originating from lymphocytes. About 85% arise from B cells, with the remainder deriving from T cells. The wide range of histologic appearances that characterize the non-Hodgkin's lymphomas is believed to represent arrest of maturation at different stages of cellular development. The etiology remains unknown, but risk factors include viral infection, mutation of oncogenes, connective tissue disease, prior Hodgkin's disease, and immunodeficiency states.

Classification, Prognosis, and Clinical Presentation

Classification and Prognosis. In contrast to the histopathologic characteristics of Hodgkin's disease, those of the non-Hodgkin lymphomas are major determinants of prognosis and response to therapy, whereas stage at the time of presentation is of less importance. A host of histologic classification schemes have been put

forward. The most widely accepted is the one referred to as the *Working Formulation* (Table 84.3). It relates histology to prognosis, with nodal architecture, degree of differentiation, and cell type being the important determinants.

GRADE AND CELL TYPE	FREQUENCY (%)	SURVIVAL (Y)
I. Low-Grade Lymphoma	39% total	5-7 years
A. Small lymphocytic	4	
B. Follicular, small cleaved cell	25	
C. Follicular, mixed, small cleaved cell	9	
II. Intermediate-Grade Lymphoma	41% total	2-5 years
D. Follicular, predominantly large cell	4	
E. Diffuse small cleaved cell	8	
F. Diffuse mixed, small, large cell	7	
G. Diffuse large cell, cleaved/noncleaved	22	
III. High-Grade Lymphoma	20% total	0.5-2 years
H. Diffuse large cell; immunoblastic	9	
I. Lymphoblastic	6	
J. Small noncleaved cell (Burkitt's, non-Burkitt's)	5	

Adapted from Rosenberg SA. National Cancer Institute-sponsored study of classifications of non-Hodgkin lymphomas summary and description of a working formulation for clinical usage. Cancer 1982;49:2186, with permission.

Table 84.3. Working Formulation of Non-Hodgkin's Lymphomas

Three *histopathologic categories* emerge: *low-grade* (indolent), *intermediate-grade* (aggressive), and *high-grade* (highly aggressive). Survival for patients with untreated low-grade disease extends for years; for those with intermediate-grade disease, it declines to several months; and for high-grade disease, it is measured in weeks. However, the response to therapy often follows an inverse pattern, with some of the many aggressive tumors responding readily to therapy and exhibiting a potential for cure, whereas most low-grade lymphomas prove stubborn and typically relapse.

Clinical Presentation. Unlike Hodgkin's disease, non-Hodgkin's lymphomas are multicentric in origin and can appear in discontinuous lymph node chains. *Localized* and *regional* lymphomas (stages I and II, respectively; see below) account for fewer than 10% of cases. Most of the remainder present with *disseminated* disease (stage III or IV). Non-Hodgkin's lymphomas can occur in nodal sites, viscera, or both. Mediastinal disease is found in 20%. *Extranodal disease* is often solitary and likely to be confined to the organ of origin. Waldeyer's ring, the upper gastrointestinal tract, testes, and bone are the most commonly involved extranodal sites, accounting for up to 15% of cases. Extranodal disease can have a favorable prognosis, particularly in the absence of nodal involvement. Five-year survival rates are as high as 30% to 50% irrespective of pathologic type. A unique site of extranodal disease is the central nervous system, especially the epidural space, leptomeninges, and cerebral hemispheres. This form of lymphoma has a high association with HIV infection. The propensity for the development of central nervous system lymphoma is also related to histologic type (lymphoblastic), distribution (marrow spread), and age (younger patients).

Presentation is affected by tumor grade. Patients with high-grade disease are likely to present with a rapidly growing, symptomatic mass confined to a single nodal or extranodal site. Low-grade disease typically manifests as slowing enlarging nodes at multiple sites. Fever, night sweats, and weight loss are more common in non-Hodgkin's lymphoma than they are in Hodgkin's disease.

Anemia is a common consequence of lymphoma. Mechanisms include immune hemolysis, hypersplenism, and marrow infiltration. In some patients, the lymphoma cells circulating in the blood may be sufficiently numerous to appear on a peripheral blood smear. In others, a *leukemic phase* may develop and account for the appearance of malignant cells on peripheral smear.

Immune dysfunction occurs in many patients, which should not be surprising given that most lymphomas are B-cell disorders. Humoral immunity is particularly impaired, leading to hypogammaglobulinemia, monoclonal gammopathies, hemolytic anemias, and immune destruction of platelets.

Staging

The staging system for lymphoma is identical to that used for Hodgkin's disease, with the exception that there are no categories for symptoms or designations for contiguous visceral involvement or splenic disease. As noted above, stage is less a determinant of prognosis and treatment selection than it is for Hodgkin's disease, but it still plays some role in the selection and intensity of treatment. Pending a better staging system, the Ann Arbor scheme (Table 84.4) continues to be used for non-Hodgkin's lymphoma, although distinctions between stages have less meaning. For patients with low-grade disease, the main issue therapeutically is whether their disease is localized or disseminated. For more aggressive forms of disease, extent of disease is less important.

GRADE AND STAGE	TREATMENT	LONG-TERM REMISSION (%)*
Low-Grade		Unknown
Early stage	Radiation	
Late stage	Controversial (single or multiagent chemotherapy, interferon,† radiation,† watchful waiting†)	
Intermediate-Grade		
Early stage	Multiagent chemotherapy +/- radiation	85-95
Late stage	Multiagent chemotherapy	60-80
High-Grade		
All stages	High-dose multiagent chemotherapy, autologous marrow transplantation†	20-40

*Long-term remission is not synonymous with cure; cure rates actually increase with advancing grade of disease.
†Investigational method.
Adapted from Longo DL, DeVita VT Jr, Jaffee ES, et al. Lymphocytic lymphomas. In: DeVita VT Jr, Hellman S, Rosenberg SA, eds. Cancer: principles and practice of oncology 5th ed. Philadelphia: JB Lippincott Williams and Wilkins, 1997:2261, with permission.

Table 84.4. Treatment of Non-Hodgkin's Lymphomas

Although the approach to staging is in part determined by tumor histology (see below), some generalizations are appropriate. A thorough *physical examination* of all node-bearing areas is essential, including such sites as the epitrochlear nodes, Waldeyer's ring, and the preauricular area. The liver and spleen are commonly enlarged when involved and should be carefully checked. Radiologic investigations are especially important in patients thought to have local or regional disease. *Chest radiography* and *CT* of the *chest, abdomen*, and *pelvis* are obtained. In many centers, CT of the abdomen and pelvis has replaced *lymphangiography* for nodal survey and has the added advantage of providing information about liver and spleen size. However, lymphangiography is a reasonable alternative where CT is unavailable. CT is considerably better at detecting disease in the pelvis and retroperitoneum.

Hematologic assessment is critical and includes examination of the *peripheral smear* and *bone marrow* (aspirate plus biopsy specimen). Bilateral or multiple bone marrow biopsies can identify occult stage IV disease. In a series of 131 patients, 27% had positive biopsy findings when more than one marrow site was sampled. Aspiration is inadequate because the false-negative rate is 30%; a solid bone marrow specimen is essential.

Much of the staging workup depends on clinical or histopathologic findings. For example, patients with intermediate-grade disease found in the area of Waldeyer's ring are at increased risk for gastrointestinal involvement and need to undergo endoscopy if the clinical picture is suggestive. Patients with a high-grade histologic pattern are almost certain to have advanced disease at the time of presentation and need not undergo extensive study. *Lumbar puncture* should be considered in patients at risk for central nervous system spread (i.e., those with marrow involvement, lymphoblastic histology, young age, or HIV infection).

Several staging procedures are unnecessary. *Laparotomy* is *not* indicated because the yields from CT and bone marrow biopsy are so high that rarely do the findings from laparotomy influence clinical decision making. *Gallium scanning* is also not very helpful.

Therapy

Chemotherapy is the predominant mode of treatment for non-Hodgkin's lymphoma ([Table 84.4](#)) because most patients already have widespread disease at the time of initial clinical presentation. It may be administered as a single agent or as a complex multidrug regimen. Radiation plays a role in the management of localized disease. As noted, histology and stage are, respectively, the primary and secondary determinants of response to therapy. Absence of bulky disease, minimal extranodal disease, absence of B symptoms, young age, and female gender are other predictors of response to therapy and prolonged survival.

Low-grade (Indolent) Disease. The curability of low-grade disease remains a subject of controversy. Most forms of therapy produce responses and remissions, but relapses are the rule. The rare patient with true early-stage disease is typically treated with *radiation*. For patients with more advanced indolent disease, treatment is controversial. Most histopathologic types appear to respond with complete remission to *combinationchemotherapy, high-dose single-agent therapy*, radiation, or *combined-modality therapy*, but relapse is common after 2 years. Remission after retreatment is common, but cure has never been reported (except for those with the follicular mixed cell type), and the benefit of aggressive chemotherapy versus watchful waiting remains to be demonstrated. Overall, median survival is about 10 years, regardless of type of therapy used. Some centers use aggressive chemotherapy plus radiation, followed by *autologous bone marrow transplantation* in selected patients who relapse. The approach must still be considered investigational until long-term results are available, but they appear to be encouraging. Another approach is the use of *interferon alfa* plus combination chemotherapy, which appears to give better results than chemotherapy alone. *Isotope-labeled monoclonal antibodies* are also under investigation.

Intermediate-grade (Aggressive) Disease. Among patients with *localized disease, combination chemotherapy* [e.g., with CHOP (cyclophosphamde, hydroxydaunomycin, Oncovin, prednisone)] with or without *local radiation* to the involved area provides 5-year disease-free results in as many as 85% to 95%. Besides histopathology and stage, outcome is adversely affected by advancing age, B symptoms, marrow involvement, elevations in lactate dehydrogenase, a large abdominal mass, and multiple extranodal sites. In patients who fail to respond or who relapse after an initial response, secondary therapy is employed, consisting of non–cross-resistant drugs such as bleomycin and doxorubicin.

Advanced-stage disease has been treated with more *aggressive combination chemotherapy*, which provides complete remissions in 80% and long-term survival in up to 70% of patients who can tolerate full therapy. However, drug-related toxicity and serious complications are far more frequent with the more aggressive programs, so that dose reductions are often necessary that compromise outcomes and result in long-term survival rates of only 30%. High-level expression of the *BCL-2* oncogene is associated with a poor prognosis. The survival of patients who relapse is improved with *high-dose chemotherapy* and *autologous bone marrow transplantation*.

High-grade (Highly Aggressive) Disease. *Intensive chemotherapy* utilizing multidrug regimens is indicated for patients with symptomatic or rapidly progressive disease. For localized disease, the addition of *radiation* therapy improves absolute rates of survival by more than 13 percentage points. Tumor burden, lactate dehydrogenase levels, *p53* gene mutations, and interleukin-6 levels correlate with prognosis. High-dose chemotherapy in combination with *autologous bone marrow transplantation* has proved superior to standard-dose therapy in persons with diffuse large-cell disease. Lymphoblastic and some Burkitt's lymphomas are treated with regimens similar to those for acute leukemia. Response rates with multidrug therapy approach 95%, with a median survival in excess of 2 years. For some subgroups, combination chemotherapy may result in cure for 20% to 40% of patients.

Investigational Therapies include the use of monoclonal antibodies, autologous bone marrow transplantation, and interferon. Because most lymphomas are of B-cell origin, identification of a specific antigen allows a *monoclonal antibody* against the tumor cell to be developed. Monoclonal antibodies have induced remissions but are associated with the development of immune responses against the immunoglobulin in some patients. Another approach is to perform *autologous bone marrow transplantation*, sometimes after treating the marrow with monoclonal antibodies to purge it of tumor cells. The best candidates for transplantation appear to be those who are responsive to chemotherapy and are in a second remission. Five-year disease-free results have been reported in 30% to 60% of carefully selected patients, but risk is high, with up to 10% of patients dying of complications associated with the procedure. Clinical trials with *interferon* are under way; partial remissions have been achieved.

Monitoring Therapy

Monitoring patients on chemotherapy requires close surveillance (see [Chapter 88](#)). Bone marrow suppression is the leading complication. Relapse or recurrence generally develops in the areas of previous disease (in contrast to Hodgkin's disease, in which relapse is extranodal or visceral). Relapse typically occurs within 12 to 18 months of initiation of treatment. Watching for the development of neurologic symptoms is particularly important in those with a predisposition to central nervous system spread (see above).

Patient Education

The encouraging results of chemotherapy, particularly in patients with aggressive advanced disease, provide new hope. As with Hodgkin's disease, the patient can be given a fairly accurate assessment of the prognosis after careful histologic study and staging have been carried out. Often, the prognosis is far better than the patient's fearful expectations and can be shared profitably. Even elderly patients are candidates for treatment of life-threatening disease.

A detailed review of possible adverse effects of therapy (e.g., sterility, infection; see [Chapter 88](#)) must be reviewed, as must the experimental nature of those therapies for which data on long-term outcomes are lacking. A key question remaining is what constitutes the best approach to advanced stages of indolent disease.

Indications for Referral

These malignancies are potentially curable. Referral to the oncologist should be made early, when the diagnosis is first suspected. Management of the patient with Hodgkin's disease or lymphoma needs to be a cooperative venture from the start, with the primary physician working closely with the oncologist experienced in lymphoma. Selection of a treatment modality requires the judgment of an oncologist who is knowledgeable about available protocols, which are constantly undergoing revision. The primary physician monitors response and adverse effects, maintains continuity, and provides psychological support.

CHAPTER 85 APPROACH TO THE PATIENT WITH METASTATIC TUMOR OF UNKNOWN ORIGIN

A malignancy is designated as a tumor of unknown origin (TUO) after meeting several criteria: (a) the tissue is histologically confirmed to be malignant and a primary tumor of the organ is ruled out; (b) routine screening fails to identify the primary source; and (c) a very late metastasis (as occurs in breast cancer, melanoma, and renal cell carcinoma) is also ruled out.

A TUO poses several problems, ranging from the utility of pursuing further workup to the efficacy of empiric therapy for disease that is already widely metastatic. Any decision to conduct a more extensive evaluation or treat empirically must include a consideration of the low probability that a treatable cancer is present. Moreover, the evaluation of a TUO can prove expensive and uncomfortable. However, within this very heterogeneous group are a few very responsive malignancies that can be effectively treated if recognized.

Guided by the principle of looking only for treatable disease, the primary physician should be able to conduct the major part of an effective workup in the outpatient setting and work closely with the oncologist in presenting thoughtful treatment options to the patient.

CLINICAL PRESENTATION AND NATURAL HISTORY OF DISEASE

Clinical Presentation. Common sites of metastatic presentation are the lung, mediastinum, liver, bone, and lymph nodes. Others include the bone marrow, brain, spinal cord, peritoneum, and retroperitoneum. In the *lung*, a TUO may present as a solitary nodule, multiple nodules, or recurrent pleural effusion (see Chapter 43 and Chapter 44). When a TUO presents in the mediastinum, it often does so as a catastrophic secondary complication, such as dysphagia, stridor or respiratory difficulty, or superior vena cava syndrome. In *bone*, a TUO may appear as a lytic or blastic lesion of the axial skeleton, long bones, or skull. Sometimes, the patient reports bone pain or has a pathologic fracture. Often, a TUO is discovered as an incidental radiographic finding. *Bone marrow* invasion may be heralded by pancytopenia or a myelophthisic picture.

An isolated hard *lymph node* is another important presentation of a TUO. Asymmetric cervical, axillary, or inguinal disease is characteristic. Axillary nodes that histologically manifest adenocarcinoma are most commonly associated with ipsilateral breast cancer, even in the presence of normal findings on a breast examination and mammogram. The presence of carcinoma in an inguinal node may represent local spread from carcinoma of the vulva, prostate, perineum, endometrium, or ovary, or it may represent systemic involvement by lymphoma. Metastasis from testicular cancer usually does not present as inguinal adenopathy except in cases of previous pelvic and retroperitoneal node dissection.

Liver involvement is usually discovered when results of liver function tests are abnormal (e.g., isolated elevation of alkaline phosphatase), a hepatic nodule is detected on physical examination, or a focal defect is noted on abdominal ultrasonography or liver scan. When a primary is discovered, the most frequent sites of origin prove to be the pancreas, liver, bowel, and stomach. Tumor that has spread to the *peritoneum* can lead to malignant ascites. Involvement of the *retroperitoneum* is usually a silent consequence of spread by lymphomas and genital cancers. *Brain* metastasis may be asymptomatic, but the new onset of a focal deficit or headache is suggestive. *Spinal cord* involvement may present urgently with symptoms of cord compression (see Chapter 167).

A number of newly appreciated treatment-responsive tumors that often present as TUOs have been defined. Most manifest a poorly differentiated or undifferentiated histologic appearance. For example, *poorly differentiated carcinoma* of *neuroendocrine origin* (determined by electron microscopy) is quite responsive to treatment (60% response rate) and typically involves the mediastinum, peripheral lymph nodes, and retroperitoneum. *Extragonadal germ cell cancers* are another subset of poorly differentiated carcinomas that respond to treatment. They too manifest as disease of the mediastinum, retroperitoneum, or lymph nodes. Other features are patient age of less than 50 years and elevations in serum human chorionic gonadotropin (HCG) or a-fetoprotein (AFP) levels. *Adenocarcinoma of the peritoneum* causing malignant ascites in a woman with no known primary responds to treatment for ovarian carcinoma, even when no ovarian disease can be found; median survival increases to 23 months. Atypical presentations of *prostate cancer* may include a poorly differentiated or undifferentiated histology and little clinical evidence of a primary lesion.

Natural History and Clinical Course. Because a TUO represents metastatic disease, it should not be surprising that overall median survival is usually no more than 3 to 4 months; about 25% survive 1 year, and fewer than 10% are alive after 5 years. Overall survival is not improved by treatment when all TUO patients are considered as a group, although outcomes for responsive clinical and histopathologic subgroups can be improved considerably with treatment (see below).

DIFFERENTIAL DIAGNOSIS

Based on data from autopsy studies, pancreatic carcinoma leads the list of causes of cancer of unknown origin, accounting for about 25% of cases. Cancers of the lung, kidney, colorectum, and prostate cancer together account for another 30%. From the perspective of workup and management, a consideration of potentially treatable cancers is most important (Table 85.1); this is aided by a differential diagnosis according to region of presentation (Table 85.2). In older men, the most common treatable malignancy is prostate cancer; in younger men, it is testicular carcinoma. In women, breast and ovarian cancers lead the list. Other important causes are cancers of the nasopharynx, oropharynx, and lung (small-cell type). As noted, even patients with a poorly differentiated or undifferentiated histology may have a treatable cancer, such as lymphoma, neuroendocrine carcinoma, extragonadal germ cell cancer, peritoneal carcinomatosis, or carcinoma of the prostate. Although a number of other subtly presenting tumors (e.g., pancreatic carcinoma, melanoma) are probably responsible for many TUO presentations, they are not sufficiently responsive to treatment to warrant listing.

Potentially curable, even when metastatic
  Gestational trophoblastic tumors
  Germ cell cancer, gonadal (e.g., testicular carcinoma)
  Hodgkin's disease
  Non-Hodgkin's lymphoma
  Squamous cell carcinoma of the oropharynx
  ? Poorly differentiated carcinoma of neuroendocrine type*
  ? Poorly differentiated carcinoma of extragonadal germ cell origin

Very responsive to treatment, although not curable when metastatic
  Prostate cancer
  Breast cancer
  Small-cell carcinoma of the lung
  Ovarian carcinoma
  Endometrial cancer
  Thyroid cancer
  Poorly differentiated carcinoma of neuroendocrine type*
  Poorly differentiated carcinoma of extragonadal germ cell origin*
  Peritoneal carcinomatosis*

*Presents as tumor of unknown origin with poorly differentiated or undifferentiated histology.

Table 85.1. Treatable Malignancies That May Present as a Tumor of Unknown Origin

Table 85.2. Treatable Causes of Metastic Disease by Site of Presentation

SITE OF PRESENTATION	SOURCE OF PRIMARY
Lung and mediastinum	Lung (small cell), Breast, Hodgkin's disease, Extragonadal germ cell, Neuroendocrine, Germ cell (testicular)
Bone	
Osteoblastic lesions	Prostate, Lung (small cell), Hodgkin's disease
Osteolytic or mixed lesions	Breast
Liver	Breast, Lung (small cell)
Brain	Breast, Lung (small cell), Lymphoma
Bone marrow	Breast, Lung (small cell), Prostate
Lymph nodes	
High cervical	Squamous cell cancer, Hodgkin's disease, lymphoma, Neuroblastoma
Axillary	Breast (ipsilateral), Lung (small cell)
Inguinal	Prostate, Ovary, Endometrium, Lymphoma
Retroperitoneal	Lymphoma, Hodgkin's disease, Testis, Prostate, Ovarian, Neuroendocrine, Extragonadal germ cell

WORKUP

Searching for Treatable Disease

When faced with a TUO, the priority is to search for treatable disease. Conducting the workup on the basis of probability rather than on responsiveness to therapy (Table 85.3) may lead to searches that have little impact on outcome. The expense and discomfort incurred by the many diagnostic studies ordered in search of likely but poorly responsive disease can be avoided if the physician adopts the discipline of searching for malignancies that respond to treatment (Table 85.1, Table 85.2, Table 85.3 and Table 85.4). In similar fashion, once a metastatic lesion has been identified, it is *not necessary to stage* the patient for other sites of metastases because the incurable nature of the tumor has already been revealed. Thus, the patient who presents with a pulmonary nodule and is found to have breast cancer as a primary source does not require a liver scan to document the presence of liver disease. Treatment in patients with cancer is determined first and foremost by stage of disease, but once metastases have been identified, the tumor is sufficiently staged.

Table 85.3. Common Cancers and Their Responsiveness to Therapy

TUMOR	RESPONSE RATE (%)
Responsive	
Breast	40–60
Ovary	60–70
Prostate	60–70
Head, neck	50–70
Testicular	80–100
Lymphoma	80
Lung (small cell)	80
Marginally Responsive	
Neurosecretory	30–50
Sarcoma	30
Colon, other GI tumors	10–15
Melanoma	10–15
Hepatoma	20
Unresponsive	
Renal	
Lung (non-small-cell)	
Brain	

GI, gastrointestinal.

Table 85.4. Diagnosis of Some Treatable Cancers Presenting as Tumor of Unknown Origin

MALIGNANCY	DIAGNOSTIC FEATURES OR STUDIES
Squamous cell, nasopharynx, oropharynx	PE (nodule, plaque), CT or MRI, blind biopsy
Lymphoma	PE (adenopathy), immunohistochemical stains
Ovarian cancer	PE (ascites or mass), pelvic CT or MRI, AFP, HCG, peritoneal implants
Prostate cancer	PE (nodule), PSA, prostate ultrasonography, immunohistochemical stains
Breast cancer	PE (breast nodule), receptor studies
Testicular cancer	PE (testicular nodule), ultrasonography, serum AFP, HCG
Extragonadal germ cell cancer	PE (adenopathy), CT (lung nodules, mediastinal mass, retroperitoneal mass), immunohistochemical studies, serum AFP, HCG
Neuroendocrine carcinoma	PE (adenopathy), CT (retroperitoneal nodes, mediastinal nodes), EM

PE, physical examination; CT, computed tomography; MRI, magnetic resonance imaging; AFP, α-fetoprotein; HCG, human chorionic gonadotropin; PSA, prostate-specific antigen; EM, electron microscopy.

Histologic Diagnosis

The importance of *biopsy* and histologic diagnosis cannot be overstated. Before other investigations are initiated in search of a treatable cancer, a thorough *histologic assessment* of tissue from the metastatic site should be conducted. Because immunohistochemical,electron microscopic, and receptor studies may need to be performed on the sample, adequate tissue must be obtained and processed properly. One portion is quick-frozen for immunohistologic study, another placed in formalin for hematoxylin and eosin staining, and a third placed in glutaraldehyde for electron microscopy. Cytologic sampling is usually insufficient because it does not provide architectural information, which can be critical for diagnosis. Moreover, cytologic preparation may misrepresent nuclear and cytoplasmic abnormalities, which can be induced by inflammation or drugs. Therefore, in patients with serositis and pleural or peritoneal effusions, the cytologic diagnosis should be confirmed by tissue diagnosis.

The histologic assessment begins with diagnosis of the tumor by cell type (adenocarcinoma, lymphoma, small-cell carcinoma of the lung, sarcoma, squamous cell carcinoma, melanoma, undifferentiated). *Special stains*, such as the one for *mucin* (found in cancers of the prostate and kidney), may be utilized. The histologic designation of *adenocarcinoma* does not definitively establish the primary source of the tumor. A glandular malignancy can develop in any organ. The histologic distinction between adenocarcinoma of the ovary, stomach, lung, or breast is sometimes possible by pathology laboratory methods, but other approaches may be needed, including clinical assessment (see below).

The histologic designation of *undifferentiated carcinoma* presumes a level of anaplasia that precludes reliable identification of the origin of the malignancy. If this is encountered, *immunohistochemical staining* is used to search for diagnostically important intracellular substances, such as prostate-specific antigen (PSA) and prostatic acid phosphatase for prostate cancer, and AFP and HCG for germ cell tumors. The technique may also detect substances useful in differentiating a carcinoma from a lymphoma, melanoma, or germ cell tumor. Immunohistochemical analysis has become the ancillary test of choice in the workup of undifferentiated carcinoma.

Electron microscopy can be useful when immunohistochemistry is inconclusive. Subcellular structures are examined for evidence of differentiation from which one can infer the cell line of origin (i.e., its histogenesis). Such a review of ultrastructure can help classify a cell as epithelial, mesenchymal, mesothelial, or melanocytic in origin, and subclassify within each category according to characteristic ultrastructural features (e.g., melanosomes, membrane-bound secretory granules, elongated microvilli, lysosomes, large bundles of tonofilaments, membrane-bound mucin vacuoles). However, because of problems with sampling and cell preservation, the sensitivity and specificity of electron microscopy are not high. The sample must be cut into very small cubes (which makes for sampling errors) and preserved in glutaraldehyde promptly (any delay in processing or use of a fixative other than glutaraldehyde can distort cell architecture).

Other studies include testing for the presence of *estrogen* and *progesterone receptors*, which helps to identify breast cancer, although these receptors are also found

in ovarian and endometrial cancers. *Cytogenetic studies* are a promising diagnostic technique and likely to enhance tumor identification as the methodology matures. Among the growing list of molecular diagnostic methodologies is *polymerase chain reaction* technology, which allows specific nucleic acid sequences to be detected.

Clinical Assessment

All patients should undergo a careful *physical examination* that concentrates on the detection of treatable malignant disease (i.e., cancer of the breast, uterus, or ovaries in women; cancer of the prostate or testicles in men; lymphoma in all patients). Depending on the site of metastasis, other elements of the physical examination may also prove useful (see below and Table 85.4).

Similarly, *laboratory studies* are guided by the same principle of looking for treatable cancer rather than conducting an extensive workup for all possible primary tumors. An unfocused search can lead to the ordering of many unnecessary, uncomfortable, or expensive tests. Studies should be directed at the detection of treatable cancer [e.g., *mammography* for breast cancer, *ultrasonography* for a testicular or prostatic cancer, *computed tomography* (CT) for ovarian disease]. The clinical presentation (see Table 85.2 and below) in conjunction with pathologic data can help guide the workup. Most routine blood chemistries are not helpful, although a few *serologic markers* (e.g., prostate-specific antigen, AFP, b-HCG subunit) can aid in searching for treatable disease (Table 85.4).

Pulmonary Nodules, Pleural Effusions, and Mediastinal Masses. An *open biopsy* procedure is generally necessary to obtain sufficient tissue for detailed histopathologic study and definitive diagnosis. A needle aspiration rarely suffices. Of particular importance is the identification of small-cell, neuroendocrine, and extragonadal germ cell cancers and lymphoma, which are among the more treatable malignancies that present as mediastinal or rapidly growing pulmonary mass lesions. In most other instances, identification of the primary does not affectoutcome. Detailed study by the pathologist can be very useful. *Electron microscopy* and *immunohistochemical studies* are essential, complemented by *serologic testing* for *AFF* and b-HCG subunit.

Pleural effusions caused by malignancy can be identified cytologically, but a *pleural biopsy* in conjunction with aspiration is more informative (see Chapter 43). A diagnosis of adenocarcinoma in cytologic fluids does not identify the primary source; one must look specifically for the source by immunohistochemical, receptor, and mammographic studies.

Mediastinal disease that produces symptoms of dysphagia, respiratory difficulty, or superior vena cava syndrome is almost invariably a consequence of primary lung cancer, metastatic breast cancer, or lymphoma. All can be rather well managed by local radiation therapy; thus, extensive evaluation and a search for the primary tumor are usually unwarranted. Clinically more silent mediastinal disease may be caused by neuroendocrine or extragonadal germ cell cancer, which can be identified by the methods noted earlier.

Osseous Metastases. The identification of an isolated bony lesion that is radiographically characteristic of neoplasia should be followed by a biopsy if tissue is not obtainable elsewhere. The appearance of the lesion on *plain film* should be noted to determine whether it is lytic, blastic, or mixed, which can help limit the differential diagnosis (Table 85.2) and focus the evaluation. If the bony lesion is difficult to sample, a *bone marrow biopsy* at the iliac crest represents a reasonable alternative. The vast majority of patients with bony metastases have multiple lesions that often invade the bone marrow. Should this not prove diagnostic, one can obtain a *bone scan* to identify other sites of tumor that may be more easily accessible to biopsy. Having established a histologic diagnosis of malignancy in the bone, the search for the primary should, as always, be confined to treatable disease. Tumors of the lung and kidney (usually not very treatable) prove to be the most common sources of skeletal metastases of unknown cause.

Liver Metastases are usually diagnosed by ultrasonography or *CT-guided needle biopsy*. Most are adenocarcinomas with gastrointestinal sources, although breast and lung are other important origins. Once a metastatic adenocarcinoma has been identified in the liver, further testing to identify the primary is usually unwarranted because few are sufficiently responsive to justify the workup. Symptomatic patients with hepatic metastases have a life expectancy of less than 6 months, but asymptomatic persons have a significantly longer survival.

Ascites. Malignant ascites is most likely to derive from metastatic cancer of the pancreas, stomach, or colon involving the peritoneal surface. However, a search for such cancers is of little value because little can be done to alter prognosis. However, in women, an important treatable cause of malignant ascites is diffuse peritoneal involvement by ovarian cancer. *Pelvic ultrasonography*, CT, or magnetic resonance imaging (MRI) and testing for the tumor marker serum *CA-125* are indicated, although peritoneal implants have been noted in patients without detectable ovarian disease. Serologic studies (HCG, AFP) and immunohistochemical study of the tumor may suggest this responsive lesion.

High Cervical Lymphadenopathy. Because enlargement of a high cervical node may result from a contiguous primary tumor in the nasopharynx or oropharynx or a lymphoma (two treatable cancers), intensive assessment is warranted. A careful examination of the nasopharynx, oral cavity (including base of the tongue), and larynx is essential, as is detailed examination of all lymph nodes. *CT* or *MRI* is helpful in the examination of the deeper submucosal and neck structures. If node biopsy reveals squamous cell or epidermoid histology but no primary is evident, then *blind biopsies* of areas likely to harbor nasopharyngeal tumor (base of the tongue, nasopharynx) are conducted. If the histopathology is adenocarcinoma, then sinuses or the salivary glands may be the primary source. Again, careful physical examination supplemented by CT or MRI may help reveal the primary. If histologic studies indicate a lymphoma or Hodgkin's disease, then the evaluation shifts to staging activities (see Chapter 84).

Axillary Adenopathy necessitates a careful breast examination and mammography. The diagnosis of breast cancer may be assisted by performing *estrogen* and *progesterone receptor assays* on nodal tissue obtained from the axilla. *Immunohistochemical study* for markers of lymphoma is also indicated. *Chest CT* may be warranted if small-cell histology is suggested.

Inguinal Adenopathy is approached diagnostically in much the same manner as cervical adenopathy, with an emphasis on local disease and lymphoma, because they are quite responsive to treatment (Table 85.3). Detailed pathologic study is essential and should include *immunohistochemical* and *receptor studies* of the tissue obtained at biopsy. Careful pelvic and anorectal examinations are performed, complemented by ultrasonographic study of the pelvis. If inguinal node biopsy identifies a lymphoma, then workup proceeds for staging (see Chapter 84).

Retroperitoneal Mass. An incidentally discovered retroperitoneal mass is likely to represent advanced-stage lymphoma or metastatic prostate, germ cell, or ovarian cancer. All are responsive to therapy and thus important to identify. Because it is difficult to obtain samples from this site, a search for a more accessible site is indicated. Careful physical examination of the peripheral nodes, prostate and testicles in men and pelvic organs in women is indicated. Ultrasonographic examination may help detect a small prostatic or testicular lesion. Ultrasonography may also help identify an ovarian tumor. Serum marker studies (AFP, b-HCG subunit, and prostate-specific antigen) aid the diagnostic effort.

Brain. The search focuses on breast, small-cell, and lymphomatous disease (see above). Consideration of brain biopsy is usually unnecessary unless no tissue is available peripherally. If a brain biopsy is performed, detailed immunohistochemical and receptor studies should be conducted.

Bone Marrow Invasion. When pancytopenia or a myelophthisic picture with leukoerythroblastic changes is encountered, marrow invasion should be considered and confirmed by *bone marrow biopsy* (see Chapter 79). The marrow examination includes a search for clusters of malignant cells, which may help in identification. Once their presence is confirmed, a search for the several treatable tumors can commence (Table 85.1).

TREATMENT

As emphasized above, the workup focuses intensively on identification of treatable cancers (Table 85.1 and Table 85.3). However, when the primary remains unknown (as in a substantial proportion of cases), the options for treatment become more problematic, with the choices being between empiric treatment and watchful waiting. Data on the efficacy and cost-to-benefit ratio of both approaches are limited. Interpretation of published outcomes data is often hindered by the absence of careful, detailed characterization of patients and their tumors. Only a few prospective, randomized, controlled trials have been performed, and although responses have been documented, median survival seems to improve little, if at all. Many optimistic reports suffer from selection biases. Consequently, any discussion with the patient and family must address the uncertain benefit of empiric treatment and its likely adverse effects. When patients with germ cell and neuroendocrine TUOs are excluded, response rates are in the range of 25% to 30%. With certain exceptions, only those who are symptomatic ought to be considered for treatment because the response is likely to be brief, side effects prominent, and chances of long-term benefit small.

Empiric Therapy. Of the two basic approaches to *empiric therapy*, one is to use "broad-spectrum" *chemotherapy* (e.g., Adriamycin and mitomycin C). These are

potent agents with a high potential for toxicity. Monitoring for marrow suppression is necessary. Treatment is halted if no response is noted after two courses. The other empiric approach is to treat based on a prudent estimate of the *most likely treatable tumor*, judged by cell type, age, sex, site, and so on (Table 85.1, Table 85.2, and Table 85.4). If the pathologic type is undifferentiated, treatment is directed toward the most responsive tumors in this class—namely, lymphoma and germ cell neoplasms. Metastatic adenocarcinoma in men can be treated as metastatic prostate cancer, and in women as metastatic ovarian or breast cancer, as these are the most treatable malignancies. Metastatic prostate cancer shows a very high response rate to hormonal therapy. Carcinoma of the breast shows a similar response rate to therapy; modalities include hormonal treatment for some patients and chemotherapy for others (see Chapter 122).

One of the more effective empiric therapies for TUO is *radiation* with or without node dissection in patients who have high cervical adenopathy and epidermoid or squamous cell histology. Treatment is conducted on the ipsilateral site, with cure rates of 20% to 35% reported. Adenocarcinoma of an inguinal node without a known primary may be treated by local radiation therapy bilaterally if no evidence of an anal or prostatic lesion is found on blind biopsy. Radiation may also provide reasonable *palliation* for patients with localized symptomatic disease, especially that which involves bone, mediastinum, or lymph nodes. Bony metastases are generally not treated systemically. When symptomatic, they are treated palliatively with local radiation therapy and, if necessary, stabilized orthopedically. In the absence of symptoms, a bony metastasis may be monitored unless a definitively responsive tumor, such as prostate or breast cancer, can be identified.

PATIENT EDUCATION AND INDICATIONS FOR REFERRAL

The finding of metastatic cancer is always very upsetting news, and even more perplexing when a source is hard to identify. However, an intelligently designed, selective search for treatable disease can provide considerable reassurance and hope. Such a diagnostic strategy should be shared with patient and family, both to provide hope and a sense of control over a difficult situation and to reduce irrational pressure to "find the cause" at all costs.

A search that proves unrevealing poses the issue of empiric therapy. Here, a thoughtful and frank consultation with the oncologist is indicated to review the options. The lack of adequate data on cost and benefit often make counseling difficult, but an experienced and wise oncologist can be of great help to the patient and family. The patient suspected of having a metastatic lesion of the spinal cord requires urgent hospital admission and prompt referral to the radiation oncologist.

CHAPTER 86 APPROACH TO STAGING AND MONITORING

Staging and monitoring are essential components of cancer management. Staging is performed to assess the extent of disease, and it is used to help determine prognosis and choice of therapy. Monitoring serves to detect the reappearance or progression of cancer and contributes importantly to updating prognosis and revising treatment plans. Staging and monitoring strategies are determined by tumor type, natural history, response to therapy, and characteristic pattern of spread. The frequency and duration of monitoring depend on the rate of disease recurrence.

The primary physician is in an ideal position to conduct much of the noninvasive staging and monitoring needed in the care of the cancer patient. To do so effectively requires an understanding of the limitations of the many available laboratory tests and radiologic procedures, so that important decisions about test and procedure selection can be made effectively and unnecessary expense and discomfort can be avoided.

TERMINOLOGY, PRINCIPLES, AND PROCEDURES OF STAGING

Cancer stage is defined by the anatomic distribution of disease. The task of staging is to identify the amount and distribution of tumor. Several staging systems are used to express the extent of disease. At times, there appear to be almost as many staging schemes as there are malignancies. Some are so tumor-specific and idiosyncratic that they make for considerable confusion. However, most incorporate designations for *local disease* (confined to a visceral site), *regional extension* (with or without involvement of contiguous lymph nodes), and *distant metastasis*.

The TNM System

To standardize staging, the *TNM system* has been proposed and used with increasing frequency. The *T* refers to *tumor*, the *N* to *nodes*, and the *M* to *metastases*. Numbers are added to designate subcategories, reflecting the size of the tumor (T1 to T5), the degree of nodal involvement (N0 to N3), and the absence or presence of distant metastases (M0 or M1).

Although varying slightly among tumors, the various subcategory designations have specific meaning. For the T categories, *Tis* indicates carcinoma *in situ*; *T1*, the smallest measurable tumor mass or tumor confined to mucosa or submucosa; *T2*, larger tumor mass or tumor extending directly to adjacent structures; *T3*, very large tumor or still further direct extension; *T4*, tumor of any size with very profound local tissue invasion and marked direct extension; and *T5*, extension beyond adjacent organs. As regards N categories, *NC* designates no nodal metastasis; *N1*, ipsilateral or regional involvement or movable regional nodes; *N2*, more extensive regional disease or fixed, matted nodes; *N3*, contralateral or distant nodal metastasis.

The TNM staging classification is increasingly preferred because of its consistency, comparability, and precision. Other staging systems commonly used for particular cancers have direct correlates to the TNM system and can be expressed in its terms (Table 86.1).

Table 86.1. TNM Staging and Correlation with Conventional Staging Systems for Cancers of the Lung, Breast, and Colon

Staging Principles and Procedures

A well-designed staging evaluation reflects the characteristic pattern of a malignancy and the speed of local and metastatic spread. Staging is performed both *clinically* (by means of history, physical examination, imaging procedures, and serum markers) and *pathologically* (by direct sampling of tissue). The two are complementary.

History and Physical Examination. Although much emphasis is placed on laboratory and radiologic procedures in clinical staging, the history and physical examination continue to play central roles in the determination of tumor mass, local spread, and metastasis. In almost every cancer workup, historical and physical data are required for intelligent staging and determination of the need for additional study. The failure to conduct acareful history and physical examination risks subjecting the patient to unnecessary or misguided studies.

Imaging Procedures. If, after a detailed history has been taken and a physical examination performed, it is deemed necessary to obtain further information noninvasively regarding the anatomic extent of disease, then one usually considers imaging studies. Among the most frequently ordered are computed tomography (CT), magnetic resonance imaging (MRI), ultrasonography, and radionuclide scanning (particularly the bone scan). Even the plain film of the chest or bone can sometimes provide diagnostic information. Limitations include lack of specificity and inability to detect very early lesions.

Computed Tomography and Magnetic Resonance Imaging represent important advances over older contrast and radionuclide studies. They provide not only improved detection of tumor but also better quantification of tumor burden. CT is the less expensive and more readily available of the two technologies, but MRI provides enhanced resolution in some areas, particularly the central nervous system. *Chest CT* has proved superior to conventional full-lung tomography for the detection of pleural, mediastinal, and parenchymal lesions. The test is particularly useful for staging patients with lung cancer and those with sarcomas and testicular cancers, malignancies with high rates of metastasis to the lung and mediastinum. *CT of the abdomen* enhances evaluation of the retroperitoneum by identifying enlarged lymph nodes that were previously difficult to detect noninvasively. A positive scan result can obviate the need for surgical exploration. CT has also improved the detection, sampling, and quantification of tumor in the pancreas, liver, adrenal gland, and kidney. Results of pelvic CT for the detection and staging of early ovarian and prostate cancers have been variable; the test often lacks sensitivity in the detection of early disease or early spread to pelvic nodes. *CT of the head* has virtually eliminated invasive and radionuclide staging studies of the central nervous system. Conducting the study with iodinated contrast further improves sensitivity.

Particularly in the central nervous system, *MRI* has contributed to the staging and monitoring of cancer. Compared with CT, it is more sensitive and offers a better assessment of the posterior fossa and spinal cord. Its increased cost is justified when enhanced sensitivity is required. In addition, MRI is being investigated as a means of staging of pelvic malignancies. Although early results have been disappointing, methodologic advances in imaging ovarian and prostate cancers may improve sensitivity. Sensitivities have been reported in the range of 40% to 50% for early disease and 60% to 70% for more advanced disease. It is too soon to recommend MRI for routine use in staging pelvic malignancies, but the literature should be followed closely.

Radionuclide Scanning remains the most sensitive means of detecting metastasis to *bone*. It is far superior to plain films, except in cases of myeloma. However, bone scan results can be nonspecific, so that confirmation by other means is sometimes necessary. In cancers with a high propensity for spread to bone (prostate,

breast, small-cell cancers), the bone scan has become an integral part of the initial evaluation. In other instances, it is used late in the course of disease to evaluate bone pain. *Liver* scans are still frequently ordered to stage gastrointestinal cancers, but they rarely detect disease that is not predicted on the basis of abnormal serum liver chemistries (e.g., elevated alkaline phosphatase) or clinical hepatomegaly. Furthermore, a large percentage of abnormal findings on hepatic scans represent secondary drug effects or incidental inflammatory disease. True-positive liver scans are found in fewer than 1% of patients with otherwise operable primary breast or colon cancer; routine liver scanning for metastases is unwarranted in these conditions. As noted, CT and MRI have largely ended the use of radionuclide *brain* scanning for the detection of central nervous system disease. The sensitivity and specificity of gallium scanning are inadequate because the radionuclide also readily enters inflamed tissue. Nevertheless, the test is recommended by some for staging melanoma and lymphoma. Because of the discomfort of the study, which requires frequent enemas, and its high false-negative rate, it has been relegated to infrequent use.

Ultrasonography has proved extremely useful for assessment of the prostate, ovaries, testes, liver, pancreas, kidneys, and thyroid. Ultrasonography accurately distinguishes solid from cystic masses, an important advantage in the evaluation of pelvic, testicular, renal, and thyroid masses. It can also help guide needle biopsy. Resolution for transabdominal studies wanes for lesions less than 1 cm in diameter. The results of about 20% of such studies are inadequate because of overlying bowel gas. Transrectal ultrasonographic techniques have improved the detection and staging of early prostate cancer. Ultrasonography appears to provide results comparable to those of MRI for the staging of early prostate disease, but at much lower cost.

Standard Radiographs, such as the *metastatic series*, have a high false-negative rate and are relatively insensitive, although false-positive rates are relatively low. *Contrast studies*, such as IV pyelography, venography, and angiography, are infrequently applied to staging, although they may aid in planning surgery. Conventional chest tomography has been supplanted by chest CT (see above), which has a lower false-negative rate.

Lymphangiography was developed primarily for the evaluation of retroperitoneal lymph nodes in the staging of Hodgkin's disease, but it has been similarly employed for lymphoma. The usefulness of the test for staging has declined because treatment no longer depends heavily on its findings (see [Chapter 84]). In lymphoma, the test has been replaced by abdominal CT, but it is still used for staging in Hodgkin's disease.

Serum Chemistries and Markers. An isolated elevation in *alkaline phosphatase* (liver fraction) indicates hepatic infiltration; it may be an early sign of metastasis to liver and often precedes a radiologically detectable lesion. Marked elevations in *prostate-specific antigen* suggest a large tumor burden and the likelihood of extracapsular spread of prostate cancer.

Surgical Staging is indicated when the results will alter therapeutic decision making. Clinical staging may underestimate the extent of disease by virtue of its limited ability to detect microscopic spread. However, invasive study should be conducted only when the choice of therapy will be affected; otherwise, the morbidity and risks incurred may not be justifiable.

Lymph Node Dissection was initially undertaken in patients with breast cancer, prostate carcinoma, and malignant melanoma in the hope of eliminating contiguous sites of disease. However, it has been demonstrated that lymphadenectomy at the time of surgery for the primary lesion does not extend survival, although it does serve as a prognostic and therapeutic determinant in cancers of the prostate and breast. Lymph node evaluation of distant disease has become a recognized staging procedure in some tumors. For example, scalene or retroperitoneal node biopsy is sometimes performed in patients with testicular cancer. *Sentinel node biopsy* with the use of radionuclide markers for nodal identification is being applied in malignant melanoma and breast cancer as an alternative to standard node dissections. This approach involves performing intraoperative lymph node mapping to allow selective lymphadenectomy.

Laparotomy to detect intraabdominal disease that will affect choice of therapy is central to the staging of colon cancer, helpful in selected patients with Hodgkin's disease, and useful in ovarian cancer. *Mediastinoscopy* helps to determine operability for patients with lung cancer; the more invasive *Chamberlain procedure* is sometimes necessary. *Bone marrow biopsy* provides an efficient means of pathologic staging in cancers that frequently metastasize to bone marrow (e.g., lymphoma, small-cell carcinoma, prostate cancer).

PRINCIPLES AND PROCEDURES OF MONITORING DISEASE

Monitoring for disease recurrence is appropriate for asymptomatic patients who have undergone curative cancer therapy.

Monitoring usually adds little to the care of patients with incurable disease except when it is desired to document tumor response to palliative treatment objectively. Monitoring activities that can affect decision making and improve outcomes are the only ones that should be undertaken. All others just add expense and may even cause harm in the case of a false-positive result. The cost-effectiveness of many routine programs of monitoring has been called into question by some. Although a host of increasingly sophisticated tests are available, few have demonstrated an ability to affect outcomes. The history and physical examination supplemented by a few simple laboratory studies remain among the most cost-effective of measures.

Monitoring Techniques

Many of the techniques useful for staging are pertinent to monitoring. Checking for residual disease or a new primary is the objective when curative therapy is employed; monitoring for reduction in tumor burden is the goal when palliation is undertaken. The frequency and duration of monitoring depend on the rate of disease recurrence. Tumor type, response to therapy, stage of disease, and pattern of metastasis also influence the selection of monitoring activities. Test sensitivity and specificity are important considerations. As noted, the emphasis should be on monitoring activities that will affect decision making and outcomes. Aggressive routine follow-up is pointless when the findings will not influence management or improve results.

Tumor Markers have been sought with the hope of obtaining a means of tumor detection more sensitive than those provided by other clinical methods. Although initially developed to aid in early diagnosis, most markers have actually proved better suited for monitoring of disease recurrence or progression after curative or palliative therapy. Baseline and posttreatment levels are obtained and follow-up readings repeated at regular intervals.

Carcinoembryonic Antigen is present in both normal and malignant tissue; serum levels in excess of 2.5 ng/mL are suggestive of tumor, but the test is too nonspecific for screening. Its most useful application is in early the detection of recurrence, especially for cancers of the colon and rectum, breast, and lung. The consensus is that serial determinations of carcinoembryonic antigen are the best currently available noninvasive means for identifying recurrent colorectal cancer after surgery.

a-Fetoprotein has been found in high serum concentrations in association with hepatomas, testicular carcinomas, and extragonadal germ cell tumors. Although lacking sufficient specificity for diagnostic purposes, repeated determinations of the a-fetoprotein level can be used to monitor for disease recurrence and assess adequacy of treatment.

b-Human Chorionic Gonadotropin Subunit is another useful tumor marker for germ cell tumors of the testes and ovaries. Monitoring of the b-human chorionic gonadotropin subunit provides information similar to that obtained from the a-fetoprotein level.

Prostate-specific Antigen is unique to prostate tissue and is found in both malignant and normal cells. A concentration in excess of 10 ng/mL is strongly suggestive of cancer and is found in fewer than 2% of patients with benign prostatic hypertrophy. Levels increase with the tumor burden and rise briefly after needle biopsy or with prostatitis, but not after a prostate examination. False-negatives occur with the use of finasteride.

Levels of CA-125, produced by 80% of epithelial ovarian cancers, correlate with the clinical course and are useful for monitoring. The specificity is high. This marker is the first of what promises to be a host of tumor-specific markers detected by monoclonal antibody methods.

Many other markers are under development (e.g., CA19-9) and are being applied experimentally in monitoring such cancers as those of the breast and pancreas.

Monitoring Local or Regional Disease. Patients with local or regional disease subjected to curative therapy may be monitored by history and physical examination supplemented by more detailed study of the disease site at routine intervals or as clinically indicated. The periodic evaluation of patients with regional disease who have undergone curative primary therapy should be directed less at detecting the presence of asymptomatic metastases and more at *finding new primary tumors* in

the involved organ. *Endoscopy* for colorectal cancer and *mammography* for breast cancer are prime examples of this approach.

In the absence of symptoms or signs of recurrence, monitoring is conducted at 3-month intervals for the first year following operation, and at 4-month intervals for the second year. Thereafter, follow-up may be accomplished at 6-month intervals for a minimum of 5 years. In general, most tumors recur at a maximum rate during the first 2 years following the initial operation—if in fact they are destined to recur. Three malignancies are notorious for late recurrence: breast carcinoma, melanoma, and renal cell carcinoma. In some patients with these tumors, the lag period before the development of detectable metastases may extend beyond 10 years after initial diagnosis.

Monitoring Metastatic Disease. Follow-up examinations for patients with metastatic disease who receive systemic therapy should be performed at intervals determined by the time expected for an objective clinical response. For hormonal therapy of breast cancer, clinical evidence of response may take as long as 3 months to appear. The effects of cytotoxic chemotherapy may be seen rapidly—for example, within two courses of treatment or 4 to 6 weeks. This is particularly true for exquisitely responsive tumors such as breast, testicular, ovarian, and oat cell carcinomas.

Patients with metastatic disease receiving palliative systemic therapy should be examined for evidence of new disease. Unnecessary chemotherapy-induced morbidity can be avoided if ineffective palliative systemic therapy is discontinued at the first signs of new disease. Response to therapy may be objectively demonstrated after a predictable interval, but new growth or spread may be noted on earlier examination.

An important corollary to the monitoring of patients with metastatic disease on systemic therapeutic regimens is to define the most objective site of disease to be followed and to avoid additional staging procedures if they do not alter the therapeutic plan. For example, a patient with hepatic metastases from a primary breast cancer need not undergo a bone scan unless bone pain or a fracture occurs. The tumor is already established as being incurable, and therapy is determined by the presence of liver metastases. Alternatively, the patient with bony metastases that are difficult to monitor may undergo selective staging to identify a more measurable marker of metastatic disease, such as plasma carcinoembryonic antigen. Identification of asymptomatic metastases by radionuclide scanning is of little use because the early detection and treatment of asymptomatic metastatic disease does not necessarily improve survival.

CHAPTER 87 COMPREHENSIVE CARE OF THE CANCER PATIENT

The treatment of cancer is multifaceted, involving the interdigitation of physician support and treatment with surgery, radiation, cytotoxic agents, and, most recently, biologic response modifiers. Comprehensive care requires a team approach, in which the primary physician plays a central role in coordinating the effort. To succeed in this role, the primary physician needs to understand the major issues of cancer management and be capable of interacting effectively with cancer specialists. The patient and family are likely to request the opinion of the primary physician, so that an ability to explain and assess management recommendations is necessary. Most cancer patients can remain at home with their families and receive optimal therapy on an outpatient basis when a primary physician is able to work closely with a cancer center or a local specialist in cancer management.

Curative treatment that focuses on the primary tumor site has traditionally been the province of surgery, with radiation and chemotherapy relegated to palliative roles. More recently, radiation and chemotherapy have been employed as adjuvants in the treatment of local disease, enhancing the capability of surgery to cure. Advances in radiation therapy have effected cures of some cancers in early stages. Biologic response modifiers hold promise for achieving further improvements in outcome.

Effective care of the cancer patient begins with communicating the diagnosis and strengthening the relationship between patient and physician. It also requires the establishment of a close working partnership with the cancer specialist, whose job will be to design and implement the treatment program. The primary physician can and should maintain a central role in the care of the cancer patient, but to do so requires a thorough understanding of the natural history of the tumor, its staging and monitoring (see Chapter 86), and its responsiveness to treatment. In addition, the patient will call on the primary physician for relief from symptoms related to the tumor or its treatment. This necessitates a thorough knowledge of measures to control pain (see Chapter 90), emesis (see Chapter 91), and related side effects of cancer therapy (see Chapter 88 and Chapter 89).

SUPPORTING THE PATIENT AND FAMILY THROUGH DIAGNOSIS AND TREATMENT

For most patients, the diagnosis of cancer evokes images of pain, suffering, mutilation, and certain death. These basic fears are so intertwined with the word "cancer" that confirmation of the diagnosis places extreme emotional stress on both patient and family. It is in managing this anguish that the primary physician plays a most important role as the person to whom the patient and family can turn. One must be not only the source of scientific and medical expertise but also the provider of emotional support and understanding.

Giving Bad News

It is always difficult to give bad news. Physicians sometimes avoid telling the patient the diagnosis in accurate and specific terms at the outset, resorting to such euphemisms as "lump," "mass," and "lesion." Further inhibiting communication may be the ill-advised, although well-intentioned, insistence of family members that the diagnosis be kept from the patient out of fear of precipitating a severe depression. Such concerns are usually ill-conceived. It is rare that ignorance of the diagnosis or prognosis is helpful for the patient or family. Quite the contrary. Patients and their families deal better with cancer when they are well informed.

The *goal* in communicating the diagnosis and prognosis is to be accurate without destroying all hope. First and foremost, the words "cancer" and "malignant tumor" should be used at the outset of the interview and not avoided, although constant repetition of the terms is usually unnecessary. The term "fatal" ought to be omitted in discussions of the prognosis because it implies little hope of control. When informed of an incurable malignancy, the patient and family want to know, "How much time is left?" A rough estimate may be necessary when patients must arrange their affairs, but if possible, the physician should avoid indicating a specific period of time because it is apt to be inaccurate. Preferably, the physician should direct the patient toward realistic therapeutic approaches and reinforce the role of living instead of dying.

The *candor* expressed by telling the diagnosis "as it is" facilitates the development of trust among patient, family, and medical staff and breaks down the barrier that often isolates cancer patients from their families. Being well informed also helps alleviate the sense of hopelessness and loss of control that can be one of the most frightening aspects of living with a malignant disease. Families are especially grateful for full and frequent reports of the patient's status and prognosis.

The *consequences* of not fully informing the patient and family can be considerable. The patient who is unaware of the diagnosis and prognosis may fail to put affairs in order and continue to have unrealistic plans or uncomfortable relationships with other members of the family, which might otherwise be resolved if all were to understand the prognosis. Similarly, the uninformed family is unable to grieve gradually over time, and death may appear to be sudden. The resulting unresolved grief may profoundly affect the surviving family members (see Chapter 227). Both patient and family may need to grieve and resolve their own fears and anxieties. By virtue of having a long-standing relationship with the patient and family, the primary physician is in an ideal position to provide effective support and guidance.

The Patient's Response

Cancer patients have been observed to pass through a series of emotional states. These include periods of denial, hostility, anger, hope, depression, and finally acceptance. The physician can help alleviate the more dysfunctional reactions and facilitate the patient's coping. The reactions of patients at the time of presentation of the diagnosis depend on preconceived ideas about cancer and what the specter of cancer suggests to them. Common misconceptions include the certainty of death, intractable pain, and erosive, disfiguring disease. To avoid needless worry, it is essential at the outset to address these common concerns directly, even if the patient does not express them. Nonetheless, a good number of patients will respond with denial, hostility, rejection of loved ones, regression, or even withdrawal. It is important to recognize such reactions as psychological defense mechanisms and respond to them in an understanding and patient manner.

Denial of the diagnosis is generally a transient reaction. When denial is mild, physicians may need only to reinforce their remarks with a repeated presentation of the facts or a provision of objective and tangible evidence. However, in some patients, denial is extreme and functions as a crude psychological defense mechanism, necessary for sustaining the psyche. A constant onslaught of evidence and reinforcement of the diagnosis or prognosis may be counterproductive and is not justified.

Hostility is occasionally an early reaction to the diagnosis. Anger may be directed against the medical team for the delayed diagnosis or for inadequate attention, and also toward family members, who may be viewed as not particularly upset and happy to finally "get their way." This phase is generally transient, receding as the patient comes to recognize the reality of the situation and the need for family and physician. Hostility is difficult for both patient and doctor and may be intense enough to lead the physician and family to reject the patient emotionally. If recognized, this reaction should be allowed to run a natural course without withdrawal of support.

Regression is an accentuated response commonly occurring in the patient with a dependent personality who may have appeared overly independent before illness. If it is more than transient, the regression may turn infantile and must be mitigated by providing a parental figure who will be, on the one hand, supportive and, on the other hand, stern and demanding. Infantile regression places an inordinate burden on the family, who are called on to provide extraordinary amounts of support.

Withdrawal is an extreme form of regression, often tinged with elements of hostility. Direct confrontation is essential for the patient who withdraws; constant encouragement and the setting up of goals to be achieved (e.g., ambulation, planning trips, visiting friends) are critical.

Family Reactions to the Diagnosis

Reactions of the family are critical to the patient's well-being and to aiding the health care team in providing maximum support. Thus, the physician must be concerned with the family's responses to the patient and the diagnosis. The physician is frequently obliged to deal with many members of the family, often with differing levels of need for information and support. Not uncommonly, complete families—wives, husbands, and children—may be alienated by the patient, who disallows them the opportunity to resolve their confusion. Such alienation, which may approach pathologic proportions, can be understood with the help of the physician. A frequent family reaction is to provide smothering protection in compensation for guilt over previous misunderstandings with the patient and the need to resolve such

differences. Again, the physician can help alleviate such pathologic reactions.

Psychological Reactions to Cancer Treatment

The patient who enters treatment for cancer is subjected to a reinforcement of the diagnosis and a rekindling of the fears regarding threats to self-esteem and self-image. The latter may be particularly demoralizing if the cancer treatment involves bodily disfigurement or a physical limitation that is either cosmetically mutilating or functionally disabling. Thus, the patient who requires a mastectomy, jaw resection, amputation, or colostomy faces a significant and frightening change in self-image. The distortions that are incorporated into the patient's unconscious, perhaps as a result of real or imagined experiences with friends, are potentially devastating. Often, these distortions are unrealistic and unsubstantiated, but more importantly, they may not be expressed. The physician must inquire into the patient's concerns and offer a realistic appraisal to minimize unnecessary anguish (see Chapter 1).

Patient education is a most important component of the approach to dealing with the stress of therapy. It additionally serves to cushion the stress by allowing the patient to intellectualize about the disease and its treatment. In this "demythologizing process," patient fears are identified and dealt with openly. Often, the result is a more acceptable view of one's illness and treatment. Educational materials available from the American Cancer Society and the National Cancer Institute can complement the educational effort by addressing common questions that patients have about cancer therapy. Detailed explanation of the therapy in terms of its effect on the tumor and its potential side effects allows the patient to approach treatment realistically. The use of support groups and meditation techniques can facilitate the patient's coping with the stresses of cancer therapy.

Such supportive efforts are designed to strengthen the patient psychologically and improve quality of life. Whether they affect survival or immune function is uncertain, but they certainly can help morale and coping with illness.

APPROACHES TO TREATMENT

The approach to treatment is determined by tumor type and stage (see Chapter 86). In the earliest stages of disease, the malignancy is localized and cure is possible through locally or regionally applied therapy. Regional spread reflects more advanced disease, and the chances of cure are lessened, but not eliminated. More systemic forms of therapy are added to local measures. With important exceptions (e.g., testicular cancer), distant metastasis indicates that cure is unlikely, and the goal is palliation through the use of systemic therapies.

Local Tumor Control: Surgery and Radiation

Surgery has traditionally played the dominant role in the management of localized cancer. The diagnosis is established and confirmed by surgical biopsy, and cure may be effected by operation. Nonetheless, the emphasis has shifted recently toward minimizing surgical procedures, particularly when the prognosis is determined by factors such as distant metastases and when salvage by secondary local modalities can be accomplished. For example, lymph node dissection for malignant melanoma, limb amputation for osteogenic sarcoma, ostomy and abdominoperineal resection for rectal cancer, and radical mastectomy for breast cancer have been scaled down in many cases to lesser procedures, so that morbidity is reduced without a compromise in survival. The surgical approach to these lesions may be modified by the addition of local therapy (e.g., radiation) or systemic therapy (e.g., cytotoxic agents).

Radiation Therapy has become more effective through the development of high-energy linear accelerators and technical improvements in delivery, which have lowered rates of morbidity and increased rates of survival and local control. For example, radiation has become the therapy of choice for early stages of Hodgkin's disease (see Chapter 84). Radiation in conjunction with surgery may be curative in some tumors when administered preoperatively or postoperatively. In other malignancies, the combined application of radiation and either surgery or chemotherapy may promote palliation and chances for long-term survival, although it rarely achieves cure (see Chapter 89).

Regional Cancer: Surgery Plus Adjuvant or Combined Therapy

Adjuvant therapy involves the addition of chemotherapy or radiation to surgical procedures. The rationale for adding radiation therapy is primarily to promote the local control of presumed residual microscopic tumor. In theory, chemotherapy functions as an adjuvant modality because of the possibility that tumor cells are released into the circulation at the time of surgery. In addition, adjuvant chemotherapy may be effective because it affects existing micrometastases at a time when they are rapidly proliferating and likely to be quite drug-sensitive.

Adjuvant therapy has been proposed or is part of ongoing trials of treatments for a number of regional cancers and is a proven and established therapy for others. For example, in breast cancer, premenopausal women with positive lymph nodes and pathologic stage II disease have benefited from the addition of chemotherapy. It has reduced the incidence of recurrence and prolonged disease-free survival. In patients with rectal cancer extending beyond the bowel wall (so-called Duke's stage B2 or C lesions), the use of radiation therapy has reduced local recurrence rates and possibly increased survival time. The role of preoperative radiation therapy in comparison with postoperative radiation therapy has not been definitely established.

With the vast majority of tumors, regional disease is incurable despite the use of adjuvant modalities, and some have a particularly poor prognosis. Long-term survival is seen in fewer than 5% of patients with lung, renal cell, or pancreatic cancers that are regionally advanced. Thus, multimodality therapy is generally not employed for patients with these tumors unless it is being used investigationally. Because of the high frequency of selection bias in many trials, it is critical to refer to results from randomized studies for a determination of efficacy. For some tumors (testicular cancer, osteogenic sarcoma, Hodgkin's disease), the role of ancillary modalities is important in extending survival time and limiting the morbidity of regional disease.

The advent of a host of advances in treatment (e.g., more effective cytotoxic drugs, *dose-intensifiec* therapy, *marrow transplantation, hematologic growth factors, biologic response modifiers*, local *radiation* for site sterilization; see Chapter 88 and Chapter 89) should improve approaches to local, regional, and even advanced cancers and become an increasing part of standard management. The optimal application of such forms of therapy will require reference to data from well-designed randomized trials.

Metastatic Cancer: Cytotoxic Drugs, Biologic Response Modifiers

The management of advanced disease is largely palliative and involves systemic therapy provided by cytotoxic drugs. Biologic response modifiers may begin to play an increasingly active role as research into their efficacy advances.

Chemotherapeutic Regimens have become increasingly sophisticated and complex, but they are also more effective because of the development of new agents and multiple-drug regimens (see Chapter 88). Decisions concerning the use and timing of cytotoxic therapy in advanced disease are difficult because of the potential morbidity associated with such therapy and the frequent lack of established benefit in promoting cure or even in prolonging survival. The decision to use chemotherapy in advanced disease is often a philosophical and psychological one, based on the feelings of patient, family, and physician.

Any decision to employ chemotherapy should involve an analysis of host tolerance in addition to potential tumor responsiveness. Most important, the use of chemotherapy must be preceded by informed consent of the patient, who should be aware of the side effects as well as the potential for response. A common misconception is that the drugs invariably create morbidity and prolong life only at the cost of agonizing discomfort. In fact, when effective, chemotherapy can improve the quality of life as well as prolong it, and when it is ineffective, it will not necessarily induce more than transient morbidity. Some of the newer chemotherapy regimens for this phase of illness utilize weekly administrations of drugs that are well tolerated at modest doses (e.g., paclitaxel, gemcitabine).

In addition to these considerations, the primary indications for the use of chemotherapy in advanced disease include the following:

1. A probability of tumor responsiveness to chemotherapy of more than 30% for a partial response and more than 5% for a complete response
2. Progressive tumor growth during a period of observation (e.g., pulmonary nodules doubling in fewer than 30 days)
3. Symptomatic metastatic disease (e.g., pleural effusion)

Within these guidelines, cytotoxic therapy can be administered with a reasonable risk–benefit balance.

The use of *experimental drug therapy* should be reserved for the following:

1. Patients who have failed with known effective drugs (i.e., drugs with a response rate >30% and an established ability to prolong survival)
2. Patients who wish to have or insist on a new form of treatment
3. Patients who have a measurable parameter that can be monitored to judge the effectiveness of therapy

Biologic Response Modifiers, such as the *interleukins* and *interferons*, are new forms of systemic treatment, designed to promote a generalized response that can affect tumors at any site. Although in most instances their use remains highly experimental, some have been approved for application in patients with cancer (e.g., interferon alfa for hairy cell leukemia and Kaposi's sarcoma; levamisole for Duke's stage C colon cancer). They offer considerable promise as an adjunct to cytotoxic chemotherapy. The literature should be followed closely (see also Chapter 89).

Management of the Preterminal Phase

(See also Chapter 90.)
"Terminal cancer" is an expression commonly employed by both patients and physicians, but with distinctly different definitions. Strictly defined, "terminal cancer" means that death will ensue within a 4-week period. The physician should avoid using the term "terminal" in talking with the patient or family. Not infrequently, patients may absorb the label and yet live for months or even years. The term imposes on both family and patient a tremendous stress that often results in withdrawal.

The physician's role in the terminal phase is a crucial one. It is essential to remain sensitive to all the patient's needs and, specifically, to the patient's need to know that the physician is always available. If the patient is at home, frequent home visits may be enormously appreciated. It may be helpful to allow the patient to come to the office once or twice a week, even though no specific medications are to be administered.

It is not incumbent on the physician to reinforce the inevitability of death to patients who have entered a preterminal or terminal state and are sustaining hope for a reversal of the tumor. More importantly, however, the family must be apprised precisely during this period to allow them to pass through the grieving process successfully.

The best approach to the management of the preterminal patient is to initiate *hospice care*, a comprehensive program of physical and psychological comfort measures delivered by skilled health care professionals either at home or in an inpatient facility. Hospital routines, laboratory studies, and life-sustaining therapies are omitted in favor of psychological and symptomatic support. Priorities include relief of pain (see Chapter 90) and psychological support of the patient and the family.

Psychotropic Drugs

Antidepressant therapy (e.g., use of an selective serotonin reuptake inhibitor, such as sertraline, at a dosage of 25 to 50 mg each morning) can help with the somatic symptoms of depression, such as marked fatigue and awakening in the early morning (see Chapter 227). Pain control may also be enhanced. Unless a contraindication is present, tricyclics should not be withheld on the basis of the common clinical misconception that "the patient is appropriately depressed, considering the diagnosis and prognosis." Checking for suicidal ideation is important because tricyclic overdose can be fatal. Asking about suicide does not suggest the act to the patient; rather, it conveys an understanding of how profoundly the patient is suffering. *Benzodiazepines* (e.g., 2 mg of diazepam daily at bedtime) given for short periods can facilitate coping with particularly stressful situations and the resultant difficulty in falling asleep. Patients with panic disorder may require more prolonged therapy with anxiolytics (see Chapter 226).

Nutrition and Pain Control

(See Chapter 90 and Chapter 91.)

Alternative or Complementary Approaches to Care

So-called "alternative" or "complementary" approaches to standard modern oncologic care are frequently sought by patients and their families, more as "natural" or "holistic" supplements to standard care than as substitutes. Subsumed under the rubric of "alternative medicine" are *meditation, relaxation* techniques, *mental imagery, massage, herbal remedies, megavitamins, chiropractic manipulation*, and *acupuncture*. To date, few data from randomized, controlled trials are available on which to base their use (although this is likely to change as U.S. government support for such trials emerges). Most claims of efficacy are based on anecdotal reports at best. Many patients view these measures as "natural" and therefore harmless and thus worth a try. Sociodemographic factors correlating with the use of alternative therapies include upper levels of income, younger age, and higher levels of education. Other triggers of use identified in cohort studies of cancer patients include depression, fear of recurrence of cancer, and psychosocial distress.

The primary care physician needs to be cognizant of the highly frequent use of alternative medicine among cancer patients and of the increased likelihood of underlying fear and psychosocial distress that may be driving the patient to seek such therapy. Eliciting and effectively addressing such fear and distress may be one of the most therapeutic responses one can make to the patient's use of or request for alternative medicine. Valuing informed medical opinions, patients hope their physicians will be knowledgeable about the safety and efficacy of such practices. The scientific literature should be followed closely and patients provided with the best of available information when it is desired. In this manner, patient safety and satisfaction can be maximized and unnecessary expense avoided.

APPROACH TO THE CARE OF CANCER SURVIVORS

Patients who survive cancer are increasing in number and are more commonly encountered than ever before in primary care practice. They present challenges in management that reflect both the psychological and physiologic consequences of the disease and its therapy. An expanding appreciation of their needs is essential to helping them return to full and productive lives.

Psychological Consequences. Although surviving cancer may be expected to be a cause for joy, studies show that considerable anxiety persists. Having had cancer appears to produce a heightened *sense of vulnerability* and fear of death and a decreased feeling of control and mastery over one's life. Fear of death wanes as the duration of survival increases, but *anxiety about recurrence* may persist and result in hypochondriasis or avoidance of follow-up health care. Contact with patients having active disease can be very stressful, rekindling feelings of fear and vulnerability. Conversely, some demonstrate marked anxiety over the loss of close contact with the health care team that characterized the active phase of their illness. Frank *separation anxiety* has been reported. Others begin to express feelings of *anger* over perceived shortcomings in diagnosis and care.

Physical disabilities resulting from cancer or its treatment can have a profound psychological impact, with *depression* being the most common and important. If not appreciated, it may present as fatigue or other physical complaints that generate concern in both patient and physician. Preoccupation with bodily sensations is another common manifestation of depression (see Chapter 227) that might be encountered in the surviving cancer patient. When not appreciated, symptoms of depression can be mistaken for more serious disease.

Interpersonal and Social Consequences. The psychosocial effects of having had cancer are equally important to keep in mind in helping the patient to adjust to survivorship. Some will miss the privileges that the *sick role* provided and may have difficulty in returning to the responsibilities of normal life. Family members and work colleagues may find it awkward to relate, not knowing whether to treat the survivor as still partially incapacitated or back to normal. A return to sexual activity may be a source of concern for the patient. Most patients with a close supportive marital relationship and no permanent loss of sexual capacity appear to do reasonably well, but preexisting marital problems or the absence of a close relationship can lead to considerable *sexual dysfunction*. Such dysfunction may result in depression. Sexual dysfunction may also be a symptom of an underlying depression unrelated to sexual issues. Of course, patients who have sustained gonadal injury or bodily mutilation are prime candidates for sexual dysfunction and its interpersonal consequences. Overall, psychological distress appears to be highest in patients lacking a close, supportive relationship. Single patients are most vulnerable.

Elements of *interpersonal isolation* have been reported, especially among those who are single and reluctant to share information about their cancerous past with a potential mate. Feelings of isolation may also be triggered by difficulty in discussing the cancer experience with friends, family, or co-workers. *Work difficulties* are often encountered. Survivors have fears, real or imagined, of losing their job. Prolonged absence and a perceived inability to perform may compromise their previous position and lead to long-term job insecurity. With job insecurity comes concern about maintaining adequate and affordable *health insurance*, especially in light of a past history of major illness and the tendency of insurance companies to "cherry pick" those whom it will insure. It is hoped that insurance reform with community rating will alleviate this major worry of surviving cancer patients.

Physiologic Consequences. (See Chapter 88 and Chapter 89 and the chapters on specific cancers for a detailed discussion of physiologic consequences.)

Supportive Therapy and Preparing the Patient. An understanding of the difficulties that cancer survivors may encounter helps the physician prepare the patient for life after cancer therapy. Counseling the patient and family about the challenges and potential difficulties likely to be experienced can go a long way toward ensuring an effective return to daily life. The counseling is carried out in the same honest, open, and supportive manner that characterized discussions in earlier phases of the illness. The issues can be every bit as difficult for the patient and require that physician support continue unabated. Regularly scheduled office visits for a check of symptoms, physical findings, and progress in returning to normal life are greatly appreciated and extremely therapeutic. Studies suggest that it takes as long as 3 years after the time of successful treatment for survivors to regain the confidence and social functioning that was lost as a result of having had cancer. Many survivors also exhibit a wisdom and sense of value and proportion that comes from having faced death, an appreciation of life that benefits all whom they encounter.

CHAPTER 88 PRINCIPLES OF CANCER DRUG THERAPY

Chemotherapy and, more recently, biologic agents represent important components of cancer management. However, such agents are potent and can be relatively unselective, with adverse effects that can offset their beneficial antitumor qualities. A well-constructed program attempts to strike an effective balance between beneficial and adverse effects and requires the expertise of the oncologist. The primary care physician has an important supportive role, which is increasing as more cancer chemotherapy is conducted on an outpatient basis and away from cancer centers. While maintaining a close working relationship with the oncologist, the primary physician may be called on to monitor the effects of therapy closely and provide initial care for the wide range of medical and emotional problems that may arise (see Chapter 87). These responsibilities necessitate a knowledge of the general indications for chemotherapy and biologic agents, and an awareness of the major toxic and adverse side effects of commonly employed agents. The primary care physician must also know how to evaluate the response to treatment and alleviate side effects.

PRINCIPLES OF THERAPY

Types of Regimens and Their Indications

Chemotherapy may be given as preoperative (neoadjuvant) therapy, as postoperative (adjuvant) therapy, or as palliative (occasionally curative) therapy for advanced disease.

Neoadjuvant Chemotherapy is used for the preoperative treatment of *locally invasive tumors* that are moderately sensitive and responsive to drugs (e.g., stage III non–small-cell *lung* cancer and stage III *breast* cancer; see Chapter 53 and Chapter 122, respectively). The goal is to decrease tumor bulk and make possible a more conservative surgical approach, and also to reduce the risk for systemic disease via micrometastasis. For patientswith locally invasive disease, an early consultation with the medical oncologist may be helpful and even precede the surgical referral.

Postoperative Adjuvant Therapy has now been established as a standard form of treatment for several cancers, including stages I and II *breast* cancer (see Chapter 122) and Duke's stage C *colon* cancer (see Chapter 76). The rationale behind giving chemotherapy to patients who have undergone what appears to be curative surgery is the frequency of distant micrometastases and local recurrences. Chemotherapy applied just after surgery has been more successful in prolonging survival than therapy delayed until clinical evidence arises of recurrence or spread.

Chemotherapy of Advanced Disease has evolved from a strictly palliative modality to a *curative* one in some instances (e.g., *lymphoma* and *testicular cancer*; see Chapter 84 and Chapter 143, respectively). This change has resulted from the discovery of increasingly effective chemotherapeutic agents and the development of *multiple-drug regimens* that have increased not only response rates but also the duration of response and the rates of complete clinical remission and cure. Nonetheless, much of chemotherapy in advanced disease remains *palliative*, designed to reduce morbidity and prolong survival without placing too heavy a burden on the patient. This is not always possible, and it takes good judgment to decide what and when to offer and when to withhold palliative therapy. When patients fail to demonstrate a clinically meaningful response, their chemotherapy regimen should be stopped or at least changed to an alternative program.

Basic Chemotherapy Strategies

Designing combination programs and applying dose-intensified therapy through the use of marrow transplantation and marrow growth factors are important chemotherapy strategies that maximize outcomes while helping to minimize risk.

Combination Chemotherapy. The use of regimens comprising agents with different modes of cellular action increases the effectiveness of therapy without greatly increasing toxicity. The best choices are drugs with nonadditive side effects. Synergistic effects are achieved while adverse effects are minimized. A meaningful response to cytotoxic chemotherapy is usually expected within two courses of treatment.

Dose Intensification. Using the highest possible doses is essential to ensuring effectiveness of therapy, especially when treating with curative intent. The use of too small a dose produces inferior outcomes. When cure is being attempted, it is best to try to maintain maximal doses and treat drug side effects by means other than dose reduction. Reductions in dose are among the most common causes of drug failure. Dose intensity and consequent long-term survival can be increased substantially by complementing chemotherapy with marrow-supportive efforts that include bone marrow transplantation and the use of hematopoietic growth factors.

Bone Marrow Transplantation. Efficacy is best established for its use in the treatment of lymphomas, myelomas, and leukemias. The role of bone marrow transplantation in breast cancer remains controversial and requires additional study. For the leukemias, the *allogeneic transplantation* of HLA-matched donor marrow cells has produced the best outcomes once cancerous marrow cells are eliminated by dose-intensified chemotherapy. In some instances, *autologous transplantation* and the use of *peripheral stem cells* has also produced meaningful results, especially in patients with solid tumors, extending the use of high-dose chemotherapy and reducing the costs and risks of marrow reconstitution. Risks are substantial; the most serious of these are life-threatening infection and acute graft-versus-host reactions in the short term, lymphomas and hematopoietic disorders within the first several years (a consequence of compromised immune function and Epstein-Barr virus infection), and solid tumors later in life (especially in patients also receiving radiation). Chronic graft-versus-host disease may also compromise outcomes. Such risks underscore the importance of careful patient selection, follow-up, and attending to cancer risk factors such as smoking. Although risk–reward ratios often favor proceeding to transplantation, the decision to proceed should be informed by data from well-designed randomized, controlled trials with long-term follow-up.

Growth Factors. *Granulocyte colony-stimulating factor* (G-CSF), *granulocyte–macrophage colony-stimulating factor* (GM-CSF), and *interleukin-1* (IL-1) can provide support to specific marrow cell lines and lessen the risks for infection that can result from intensive chemotherapy. These agents are expensive but are cost-effective when used prophylactically in situations in which febrile neutropenia is highly likely. They are not used routinely to treat episodes of neutropenia, but they do have a role in supporting allogeneic and autologous marrow transplantation and the use of peripheral stem cells. Recombinant *IL-11*, a cytokine that stimulates marrow, has been approved by the Food and Drug Administration to treat severe thrombocytopenia resulting from chemotherapy for nonmyeloid cancers. Under study is the use of *erythropoietin* and *thombopoietin*. For the former, the principal issue is cost-effectiveness; for the latter, the principal concerns involve long-term safety (i.e., risks for thrombosis, myelofibrosis, and stimulation of abnormal cells).

Follow-up. Only rarely does continued treatment in the absence of initial response result in an increased response; usually, more therapy is unwarranted. Follow-up assessment for response and determination of further chemotherapy is usually conducted within 2 months of initiation of the treatment program.

Cytotoxic Chemotherapeutic Agents

Cytotoxic drugs have been grouped into categories based on their mechanism of action or the chemical derivation of the drug (Table 88.1).

Table 88.1. Cytotoxic Chemotherapeutic Agents

Alkylating Agents. In general, the alkylating agents have a broad spectrum of antitumor activity, chemically interacting directly with DNA. As just noted, secondary malignancy is a concern associated with their use. The most commonly used drugs in this class are *cyclophosphamide* and *nitrogen mustard. Ifosfamide* is a newer alkylating agent that has shown promise in treating cancers of the testicle, lung, and cervix.

Antimetabolites. These drugs interfere with the synthesis of DNA by blocking the action of important metabolic precursors and cofactors. Their greatest effect is on rapidly growing cells. The most commonly used agents in this class are *fluorouracil* and *methotrexate.* The antimetabolites are rapidly metabolized and excreted in the urine. Methotrexate is distributed throughout total body water, so that pleural effusions and ascitic fluid are potential reservoirs of the drug. Newer antimetabolites include *gemcitabine* (for pancreatic, bladder and lung cancers) and *fludarabine, DCF*, and *2-CDA* (for chronic lymphocytic leukemia and hairy cell leukemia, respectively).

Topoisomerase Inhibitors. *Etoposide* and the anthracycline antibiotics (*doxorubicin* and *bleomycin*) impair the action of the reversible nucleases that create nicks in the DNA strands needed for DNA replication. The spectrum of activity of doxorubicin is comparable to that of the alkylating drugs. In combination with the alkylating drugs, doxorubicin appears to have a synergistic antitumor effect.

Mitotic Spindle Inhibitors. These agents inhibit mitosis. *Paclitaxel, vincristine*, and *vinblastine* are the best-known examples. Paclitaxel has the unique property of interfering with microtubular function. Much excitement accompanied the demonstration of its efficacy in the treatment of advanced ovarian cancer.

Miscellaneous or Mixed-mechanism Agents include two important drugs: the *nitrosoureas* and *cisplatin.* The *nitrosoureas* are alkylating drugs that cross the blood–brain barrier. *Cisplatin* is effective in the treatment of testicular and ovarian cancers.

Adverse Effects of Chemotherapeutic Agents

The principal factor limiting the usefulness of chemotherapeutic agents is their relative *lack of selectivity* for the tumor cell ([Table 88.2](#)). Cytotoxic drugs adversely affect normal cells, especially those populations with a rapid turnover (bone marrow, hair follicles, gastrointestinal mucosa). This leads to the development of *bone marrow suppression, alopecia*, and *gastroenteritis* shortly after the initiation of chemotherapy.

Table 88.2. Side Effects of Some Commonly Used and Important New Chemotherapeutic Agents

Typically, *acute marrow suppression* begins 7 to 10 days after the administration of chemotherapy and may last about 1 week. Continuous cytotoxic therapy may cause a more lasting *cumulative suppression of the bone marrow*. However, most forms of adjuvant chemotherapy are usually not associated with persistent marrow suppression, although a transient fall in cellular constituents may occur.

The most serious risks of chemotherapy are *leukopenia*, leading to overwhelming sepsis, and *thrombocytopenia*, resulting in hemorrhage. In most instances, leukopenia and thrombocytopenia are dose-related and may be prevented or lessened by dose adjustment in patients with marginal marrow reserve because of marrow invasion, advanced age, or prior therapy. Nonetheless, the goal of most chemotherapeutic regimens is to induce some degree of leukopenia, which can serve as a measure of the cytotoxic effect and a guideline to dosage.

The *gastrointestinal toxicity* of chemotherapy can be debilitating. It includes nausea, vomiting, mucosal injury (stomatitis), and diarrhea. Although not as life-threatening as leukopenia and thrombocytopenia, gastrointestinal side effects can significantly compromise quality of life, morale, and willingness to undergo further chemotherapy.

Alopecia is a consequence of most forms of chemotherapy. It is usually partial, but with doxorubicin the hair loss is generally total. It begins approximately 2 weeks after the initiation of treatment and becomes complete by 4 to 6 weeks. Hair loss is almost always transient, and often some hair grows during the course of treatment; however, total restitution does not take place until chemotherapy is stopped. When hair growth returns, darker, finer, more curly hair is usually produced, but with time, the normal texture and color return.

Of concern for younger patients, especially those undergoing curative-intent therapy for leukemia or a lymphoma, is the significant risk for a *secondary malignancy*. Acute leukemia may arise a decade or two after treatment for lymphoma; lymphoma is seen in some leukemic patients years after chemotherapy, especially when alkylating agents have been used. Although the evidence for risk is compelling, the benefits of treatment continue to outweigh the risks.

New Cytotoxic Therapies: The Biologic Agents

Interleukins. Naturally occurring cytokines such as the interleukins are produced by activated T cells and demonstrate immunostimulatory and antineoplastic effects. IL-2 triggers peripheral mononuclear cells to release a host of biologically active cytokines that in turn modulate the activity of natural killer cells, B cells, and suppressor cells, with eventual lysis of cancer cells. The best antitumor effects have been observed in patients with metastatic renal cell carcinoma, for which IL-2 treatment is approved by the Food and Drug Administration. Adverse effects are caused by the release of tumor necrosis factor and IL-1 and include fever, chills, lethargy, diarrhea, thrombocytopenia, liver dysfunction, and myocarditis. Vascular leakage is a major side effect. Adverse effects are dose-related and rapidly reversible.

Interferons are biologic response modifiers—proteins with antiproliferative and immunomodulatory properties. *Interferon alfa*, an interferon with antitumor activity, is produced by leukocytes, often in response to viral infection. It induces lymphocyte activation and has demonstrated antitumor effects clinically, most notably in chronic myelogenous leukemia, hairy cell leukemia, and, to a lesser extent, Kaposi's sarcoma. Interferon alfa is also moderately useful as adjuvant therapy in melanoma, renal cell carcinoma, and multiple myeloma. Although interferon alfa can exert antitumor effects when used as monotherapy, it often produces better outcomes in combination with chemotherapeutic agents (e.g., with cytarabine in chronic myelogenous leukemia). Adverse effects are dose-dependent and can be troublesome, frequently causing therapy to be stopped. The most common is a flulike syndrome of fevers, sweats, fatigue, and myalgias, experienced by most patients during the first several weeks of therapy. The flulike symptoms are often transient and likely to resolve unless the dose is increased, but a host of even more disabling symptoms may follow. These include marked anorexia, depression, anxiety, emotional lability, hair loss, tinnitus, reversible hearing loss, and thyroid dysfunction. An increased susceptibility to bacterial infection and cardiotoxicity may also develop.

Monoclonal Antibodies. Although treatment with monoclonal antibodies is still experimental for cancer, the efficacy of these agents in the treatment of Crohn's disease and rheumatoid arthritis has already been demonstrated. The use of antibodies is also being intensively studied as a means of enhancing the specificity of chemotherapeutic agents. The promise of these approaches is considerable and likely to result in major advances. The reader is urged to follow the literature closely for data on efficacy, safety, and indications for use.

PRACTICAL ISSUES

Administration of Chemotherapy. Sometimes, the administration of chemotherapy is assigned to the primary physician, particularly when the services of the oncologist are not locally available. Under such circumstances, it is particularly important to be aware of the potential hazard of *extravasation* associated with certain IV agents [e.g., doxorubicin, vincristine, vinblastine, dacarbazine (DTIC), carmustine (BCNU), nitrogen mustard]. The best treatment is prevention, with proper venous access being the most important element. When extravasation does occur, it results in tissue irritation and secondary inflammation that leads to ulceration and necrosis. Surgical grafting and debridement are sometimes necessary. In the event of extravasation, the infusions should be stopped immediately and *ice* applied. Any accumulation of drug should be removed by aspiration. The actual inflammation and necrosis may not occur for 3 to 10 days following injection, although pain is generally present early on. Corticosteroids have been used, but definitive evidence of efficacy has not been demonstrated.

Even without extravasation, the repeated use of irritating IV chemotherapy drugs can lead to sclerosis and endothelial deterioration, particularly when small-caliber veins are used for infusion. Large-diameter veins in the antecubital fossa or higher are preferred. Devices for venous access facilitate administration.

Suppression of Nausea and Vomiting. The drugs most likely to induce severe nausea and vomiting include cisplatin, dacarbazine, doxorubicin, nitrogen mustard, and high doses of cyclophosphamide. Some agents cause vomiting that begins approximately 30 to 45 minutes following injection; with others, particularly cyclophosphamide and doxorubicin, the vomiting begins 4 to 5 hours after injection. Recent advances in understanding the mechanisms of chemotherapy-induced nausea and vomiting have led to the development of effective multifaceted programs (see Chapter 91).

Management of Bone Marrow Suppression. Generalized marrow suppression is common. The pattern of suppression is a function of the type of drug, dose, and schedule of administration (Table 88.3). Standard approaches to this problem include adjustments in dose and timing of chemotherapy. Dose adjustments for subsequent courses of therapy are based on the nadir levels observed. In monitoring patients on chemotherapeuticregimens, the anticipated nadir days for blood counts are the most crucial times to obtain follow-up complete blood cell counts. For patients in whom leukopenia develops, the observation period should be intensified, depending on the level of the count and the presence of associated fever or sepsis. Emerging data suggest that *prophylactic oral antibiotics* (e.g., 500 mg of levofloxacin daily) reduce the number of hospitalizations in patients whose absolute neutrophil count falls below 1,000/mm[3]. The advent of marrow growth factors (see above) has enhanced our ability to administer the optimal doses of chemotherapy, which ordinarily might be limited by the onset of marrow suppression. Growth factors work best when given prophylactically, rather than after marrow suppression has set in. They are expensive but can prevent hospitalizations and limit complications.

AGENT	NADIR DAY	OPERATION

Table 88.3. Chronologic Patterns of Marrow Suppression Secondary to Chemotherapy

EVALUATION OF RESPONSE TO THERAPY

Patients on chemotherapeutic regimens are monitored for adverse effects at the same time that the effectiveness of treatment is evaluated (see also Chapter 87). Objective tumor measurements are often difficult to define, but generally the oncologist depends on them to gauge the response to therapy (Table 88.4).

Survival
Measured from time of diagnosis, metastasis, or initiation of treatment in days, weeks, or months, to be compared by median (as opposed to mean) with a randomized control or historical control not receiving treatment or receiving alternative treatment. Survival as a measurement of time may also be supplemented by a time measurement of diagnosis to point of recurrence and is translated as disease-free survival.

Objective Reduction in Tumor
Partial Response
Equals a 50% reduction in the product of the maximum perpendicular diameters of the most easily measurable lesion without increase in other lesions and with a minimum duration of 4 weeks.

Complete Response
Equals a 100% reduction in all evidence of tumor for minimum of 4 weeks without appearance of new lesions.

Stable Disease
Equals a less than 25% decrease in measurable disease without development of other lesions.

No Response (Progressive Disease)
Equals a more than 25% increase in the size of the lesion or the development of new lesions.

Improvement
Equals a 25%–50% reduction in the product of maximum perpendicular diameters lasting at least 4 weeks.

Table 88.4. Criteria of Response to Therapy

The criteria of response are often difficult to evaluate because partial responses may be influenced by nontumor factors. In addition, some forms of metastatic disease simply cannot be measured, such as osseous metastases and, particularly, osteoblastic lesions. Criteria for some metastatic patterns have been established, such as hepatomegaly, in which the criterion for response is a 30% decrease in the sum of measurements made below the costal margin at the midclavicular and midxiphoid lines. Peritoneal masses, pleural effusions, and skin ulcerations are not considered amenable to evaluation. *Ultrasonography* and *computed tomography* have helped quantify lesions in the retroperitoneum.

Tumor markers (see Chapter 86) have facilitated gauging the response to therapy objectively. Serum levels of markers, monitored sequentially, correlate well with tumor mass and often predict recurrence before it becomes clinically evident. For example, measurement of levels of human chorionic gonadotropin has proved useful

in the management of testicular cancer, and determination of carcinoembryonic antigen in colorectal cancer. Markers derived from monoclonal antibody techniques are increasingly important, including CA19-9 for pancreatic cancer, prostate-specific antigen for prostate cancer, CA15-3 for breast cancer, and CA-125 for ovarian cancer. Other biochemical parameters, such as levels of alkaline phosphatase and the various hepatic enzymes, have proved uniformly inadequate in the evaluation of the effectiveness of treatment.

PATIENT EDUCATION

The ability to tolerate chemotherapy is enhanced by a strong and trusting patient–doctor relationship. Fully educating patients and families about diagnosis, prognosis, and the rationale and side effects of planned treatment can greatly facilitate the development of trust and confidence (see Chapter 88). Concerns about alopecia, sterility, gastrointestinal upset, and other side effects should be elicited and directly addressed. The probability of response also deserves review. A comprehensive educational effort appropriate for the patient's level of understanding allows the patient to participate meaningfully in decision making and encourages a sense of partnership in the undertaking, an attitude that can help sustain the patient through this often difficult time.

INDICATIONS FOR ADMISSION AND REFERRAL

The onset of febrile neutropenia (absolute neutrophil counts <1,000/mm^3) requires immediate hospitalization. The development of bleeding in the setting of thrombocytopenia is an indication for urgent hospitalization and consideration of platelet transfusion. The asymptomatic patient with severe thrombocytopenia (platelet count <20,000/mm^3) also deserves consideration for admission and platelet transfusion. Counts of 20,000 to 50,000 are an indication for close observation and warning the patient to avoid trauma.

Chemotherapy programs are in a constant state of revision as new combinations are tried and new agents developed. Each patient's treatment program must be designed in conjunction with an oncologist. When such expertise is not locally available, patients may have to travel to a regional center for therapy. Computer-based chemotherapy protocol advisory systems are now available to help provide expert input where it may not otherwise be obtainable.

CHAPTER 89 PRINCIPLES OF RADIATION THERAPY

THOMAS DELANEY

Modern radiation therapy represents an important means of achieving local and regional control of malignancy in addition to providing palliation. When given with the intent of controlling disease and attempting cure, it is termed *radical*; when given for symptomatic relief, it is designated *palliative*. Although the design and implementation of such therapy is the responsibility of the radiation oncologist, the primary physician shares in the decision to use the modality, monitors and supports the patient while it is being administered, and watches for and treats late complications. The primary care physician needs to be familiar with basic aspects of radiation therapy, its applications, and its side effects.

PRINCIPLES OF MANAGEMENT

Response to Irradiation

Determinants of Radiosensitivity. Exponential killing of both tumor and normal cells occurs after an initial, sublethal accumulation of radiation damage. The ability of cells to accumulate some radiation damage before cell death is manifested is believed to be linked to *repair capacity*. The general shapes of the radiation response curves of cells in culture are remarkably similar, with most of the difference in "*radiosensitivity*" a consequence of subtle differences in the ability of cells to accumulate and repair radiation damage. Cells in the S phase of the cell cycle (when DNA synthesis is taking place, but no mitosis) are the least sensitive to radiation, probably because of the enhanced capacity for repair in this phase. In response to radiation injury, normal cells initially stop proliferating because of "checkpoints" in the cell cycle designed to allow the cell to repair DNA damage before cell division is attempted. Malignant cells often have mutations in these critical cell cycle regulatory genes (such as *p53*) that perturb the checkpoint function, so that progress through the cell cycle is uninterrupted despite the presence of radiation-damaged DNA; as a consequence, cell death occurs during mitosis.

The response to irradiation is also affected by the *volume* of the tumor. Except for uniquely radiosensitive tumors (lymphomas and seminomas), larger tumors are more difficult to eradicate with any given dose of irradiation. This is in part related to the larger number of tumor cells that must be killed. Another part of the reason for this resistance, however, is *tissue hypoxia*. Oxygen facilitates the cytotoxic effect of x-rays, which is mediated in part by oxygen free radicals. Hypoxic cells are about three times more refractory to irradiation than are cells treated in the presence of oxygen. Interior areas of large tumors can become hypoxic and relatively refractory to radiation. However, as the tumor shrinks, the access of its hypoxic cells to oxygen increases, and they become more susceptible to radiation if doses are given in sequential fractionated fashion (see below). Nevertheless, the presence of anemia (hemoglobin levels <10 to 12.5 g/dL) has been shown to have a negative impact on radiotherapy treatment outcome in multiple anatomic sites, which has led to the clinical practice of administering red cell transfusions or erythropoietin to maintain hemoglobin levels during a course of radiotherapy.

Strategies to Improve Response. Effective approaches include the use of *particle beams*, concurrent *chemotherapy*, and compounds that *sensitize hypoxic tumor cells*. Particle beamssuch as neutrons are less dependent on oxygen for their cytotoxic action than are x-rays and represent another means of treating large, poorly vascularized tumors. Other particles, such as protons, have significantly better dose distribution properties than conventional x-rays do, so that the dose to the tumor can be increased substantially while adjacent normal tissue is spared. Many chemotherapy compounds, such as *cis*-platinum, 5-fluorouracil, and paclitaxel, enhance radiation cytotoxicity, which results in simultaneous improvement in local and distant control of tumor. Compounds that sensitize hypoxic tumor cells and improve their response to radiation therapy are under investigation.

The *dose* of irradiation that can be safely directed at a malignancy is limited by the tolerance of the organs surrounding it. Although the energy (i.e., voltage) of the radiation determines its ability to penetrate tissue, it is the amount of radiation actually absorbed that determines the biologic effects. *High-energy* megavoltage beams spare the skin, with better cosmetic results. Focusing beams on a tumor from multiple directions concentrates the dose in the tumor and avoids excessive irradiation of critical adjacent normal structures. Damage can be particularly injurious when radiation is absorbed by cells of the heart, liver, brain, intestines, bone marrow, kidneys, or lung (see below). These structures have defined radiation tolerances that are related to the volume irradiated and the dose received. Usually, trade-offs must be made between therapeutic benefits and adverse effects.

Minimizing Adverse Effects. The probability of radiation-induced complications depends on how narrow the difference is between the dose needed for control of the tumor and the dose that causes injury to normal tissue. (The ratio of the two doses is termed the *therapeutic ratio*.) The greater the difference in doses, the better the result. Dose fractionation, shielding of normal tissue, and use of imaging techniques to define tumor volume and location precisely have helped limit the adverse effects of radiation therapy.

Fractionating the dose helps to widen the margin of safety and improve the selective killing of tumor cells. Normal cells repair sublethal radiation damage more effectively than do tumor cells. Traditional fractionation programs provide about 200 centigray (cGy) or rads per treatment, applied five times per week. Newer fractionation schemes hyperfractionate radiation with two to three treatments per day to exploit differences in radiation repair capacity between tumor and normal tissue maximally and accelerate the treatment to overcome the repopulation of tumor cells that occurs during the conventional treatment of some tumors.

Shielding helps protect vital organs adjacent to the portal from radiation exposure. Often, custom-fabricated lead shields or analogous, automated blocking devices in the head of the treatment machine (multileaf collimators) are used to prevent the irradiation of normal tissue abutting the tumor.

Computed tomography (CT) and *magnetic resonance imaging* (MRI) have improved the delineation of tumor volume and the surrounding anatomic structures so that the target can be more precisely defined. *Simulation* reproduces the geometry of the actual radiation portal and helps to ensure that only the desired tissue is irradiated. CT-based simulation is increasingly used for this purpose; patients are scanned in the treatment position with markers on the skin or other structures to allow the tumor to be referenced to a reproducible, spatial coordinate system. The CT data set is transferred electronically to a three-dimensional treatment system that allows the tumor, normal tissues, and doses to be displayed in three dimensions. This technology permits the radiation dose to the tumor to be escalated, so that the tumor control rate is increased, while normal tissue is simultaneously protected; as a result, fewer side effects to normal tissue are produced. Specific applications of this technology include *stereotactic radiosurgery* for the treatment of intracranial tumors. In this technique, the patient is rigidly immobilized in a head frame for CT and radiation treatment. In addition, amifostine is the first compound to be shown to be a clinically useful and preferential protector of normal tissue from radiation damage.

Clinical Applications

Three basic *delivery modes* are currently used. External sources (teletherapy or external beam) are the most frequently applied. Brachytherapy, in which encapsulated sources are placed directly into the body at tumor sites, has selective advantages in the treatment of very localized disease. Improvements in imaging and radiation treatment planning have resulted in a resurgence of interest in brachytherapy at such sites as the prostate, where the therapeutic ratio for this technique is high. Systemic delivery via radionuclides is the third mode. Investigational forms entail IV administration of radionuclide-labeled monoclonal antibodies designed to attack a target cancer selectively. The theoretical attractiveness of the latter two methods is closer proximity to the tumor and the limited exposure of normal tissue to radiotherapy.

Radiation is applied for to achieve cure and control in addition to palliation. It may be the sole treatment or an alternative therapy, or it may be combined with other modalities ().

Table 89.1. Applications of Radiotherapy

As Sole or Alternative Therapy. Like surgery, radiation therapy is primarily a method of treating local or regional disease. The goal is to "sterilize" both the primary site and likely areas of local and regional spread. In some instances, such as stage I *Hodgkin's disease* or early low-grade *non-Hodgkin's lymphoma* (see Chapter 84), radiation therapy is the treatment of choice. When preservation of function and appearance can be achieved with comparable survival outcome, radiation may be preferred by some patients over surgery (as in localized *breast cancer*, localized *prostate cancer*, or early *head* and *neck cancers*). When surgery and radiation provide similar rates of cure and control, the choice depends largely on the impact of treatment on the patient.

As Combination Therapy. Several characteristics of radiation therapy make it a good complement to *surgery*. Surgery is the more effective of the two modalities in the management of bulky disease, whereas radiation appears to be more effective in the treatment of small-volume, locally invasive disease, which is the basis for the sequence of surgery for local disease followed by radiation as adjunctive therapy. Radiation can also reduce tumor bulk and destroy microscopic disease, thereby facilitating surgical removal and local control. By allowing the use of lower doses of radiation and less radical surgery, combination therapy minimizes side effects and has become the cornerstone of the organ-preservation treatments for cancer. Such combination therapy often also includes chemotherapy (see below).

With Surgery. Whether to administer radiation before, during, or after surgery depends on several practical and theoretical issues. Favoring *preoperative treatment* are the need to reduce tumor size for easier resection and the desirability of sterilizing tumor cells that might be spread during surgery. Moreover, *postoperative irradiation* may be less effective if the vascular bed is surgically reduced and oxygen delivery impaired. Factors favoring postoperative treatment include prompt performance of surgery, ability to determine the need for radiotherapy based on a pathologic review of the resected specimen, avoidance of radiation effects on wound healing, and destruction of any remaining microscopic disease. *Intraoperative treatment* allows one to displace normal abdominal organs (which are quite intolerant of the high radiation doses necessary to sterilize gross tumor) and target diseased tissue more precisely.

With Chemotherapy. The application of radiation in combination with chemotherapy to achieve cure is established for advanced stages of *Hodgkin's disease*, and the combination has been demonstrated in the last decade to result in improved outcome in locally advanced cancers of the *head* and *neck, lung, esophagus, rectum, anus*, and uterine *cervix* in comparison with radiotherapy alone. The rationale is to treat local disease with radiation and administer chemotherapeutic agents that both increase the efficacy of radiation against the primary tumor and target occult systemic metastases. Radiation can also be used to treat areas not readily accessible to chemotherapy, such as the brain in patients with small-cell lung cancer. Although improved survival has been demonstrated, acute and late toxicities can be additive. Marrow suppression can be the limiting problem. Other instances of additive adverse effects include the following: Cyclyphosphamde (Cytoxan) and radiation produce acute hemorrhagic cystitis; 5-fluorouracil and radiotherapy cause acute mucositis of the oral cavity and acute radiation enteritis; *cis*-platinum, etoposide, and taxanes combined with thoracic radiotherapy produce acute esophagitis, and combination chemotherapy with radiation increases the risk for leukemia. Some drugs enhance radiation reactions in normal tissues, even when given up to a year after radiotherapy. Adriamycin is the most prominent example of a drug producing this *"recall phenomenon."*

At present, the optimal strategies for the application of combined-modality therapy are continuing to evolve. The literature should be followed for the results of studies now ongoing.

As Palliative Therapy. Radiation serves an important function in providing symptomatic relief to some patients with incurable disease. For those tumors that respond to chemotherapy or hormonal therapy, radiation should be held in reserve. However, if localized tumor is not sensitive to other modalities, palliative radiation may be an effective means of providing symptomatic relief. In most instances, the treatment of asymptomatic lesions yields little benefit, although prophylactic brain irradiation appears useful in patients with small-cell lung cancer. One of the best examples of palliative therapy is for painful *bony metastases* from such tumors as those of breast and prostate. Within 2 to 3 weeks of the start of a relatively short course of radiotherapy (2 weeks), many patients experience relief from bone pain. Radiation to bony metastases has also been used to stabilize a weight-bearing bone, but if cortical involvement is present, then surgical stabilization of the bone may be necessary. Radiation plays an important role in the urgent treatment of certain oncologic emergencies, including *spinal cord compression* and *superior vena cava syndrome* (see Chapter 92).

Adverse Effects

As noted previously, many normal cells tolerate radiation better than do malignant cells. However, the degree of tolerance varies greatly (Table 89.2). Tissues with high rates of turnover and large stem cell populations are among the most vulnerable. Even organs with almost no proliferative capacity are at risk by virtue of the vulnerability of their vascular endothelium. Much radiation-induced injury is vascular in nature. Toxicity may be acute or chronic. Acute toxicity is noted in tissues with the highest rates of turnover (e.g., marrow, skin, gastrointestinal mucosa). *Acute radiation toxicity* is often defined as that appearing within 90 days after the start of radiotherapy. It usually resolves with supportive care in the majority of patients without significant late consequences. *Toxicity appearing later*, however, is usually more serious and clinically significant, as it may involve irreversible injury to the involved normal tissue.

TISSUE	ADVERSE EFFECT	DOSE LIMIT [cGy (rads); ≤5% TOXICITY]
Bone marrow	Marrow suppression	250
Kidney	Nephrosclerosis	2,000
Lungs	Pneumonitis	2,000
Liver	Hepatitis	3,000
Heart	Pericarditis	4,500
Spinal cord	Myelitis	4,500
Small intestine	Ulceration, fibrosis	4,500
Skin	Dermatitis, sclerosis	5,500
Brain	Necrosis	6,000

Modified from Chabner BA, Principles of cancer therapy. In: Wyngaarden JB, Smith LH, eds. Cecil's textbook of medicine, 16th ed. Philadelphia: WB Saunders, 1982:1034, with permission.

Table 89.2. Serious Adverse Effects of Radiotherapy

Tolerance to radiotherapy decreases as the dose is increased. The *dose limit* for a tissue can be expressed as the cumulative dose that produces a 5% incidence of toxicity when radiation is delivered in 200-cGy fractions for 5 days a week. Beyond the dose limit, the incidence of toxicity rises quickly.

Bone Marrow Suppression. The bone marrow is the most radiosensitive tissue, with marrow suppression developing when exposure exceeds 250 cGy. Suppression is usually transient and reversible, unless large marrow volumes are irradiated. Skin, gastrointestinal mucosa, and lung are of intermediate sensitivity.

Radiation Pneumonitis starts to appear when the dose to a large volume of the lung surpasses 2,000 cGy; the incidence reaches 100% at doses of 4,000 cGy. The

onset, usually within 6 to 12 weeks, is characterized by dyspnea, cough, low-grade fever, hypoxemia, and a "ground glass" appearance on chest x-ray films. CT may show straight lines that match the radiotherapy field. Restrictive defects and chronic hypoxemia follow if fibrosis sets in, which typically takes place during the ensuing 6 to 24 months. Treatment is mainly supportive. High-dose steroids (1 mg of prednisone per kilogram initially with gradual taper as tolerated) and oxygen can alleviate symptoms during the acute phase; once fibrosis occurs, no treatment is available. The best approach is prevention through careful limitation of the radiation portal.

Other Radiation-induced Organ Injury. *Nephrosclerosis* is the renal response to doses in excess of 2,000 cGy. *Hepatitis* is a consequence of doses to the liver above 3,000 cGy. Gastrointestinal *ulceration* followed by perforation or fibrosis are complications of bowel doses exceeding 4,500 cGy. *Pericarditis* and *spinal cord infarction* are risks of 4,500-cGy doses to the heart and spinal cord, respectively. With mediastinal irradiation, pericarditis can become constrictive, and valvular injury has also been noted.

Although acute reactions are common, the skin can tolerate as much as 5,500 cGy given over time; *dermatitis* becomes a problem at higher doses. The brain (except the brainstem) can withstand up to 6,000 cGy before the risk for *necrosis* begins to rise. Radiation can also induce cataracts and retinal damage and can lead to blindness. Gonadal radiation is likely to induce permanent *sterility*, and pelvic irradiation during the first trimester of pregnancy is teratogenic.

Risk for Secondary Malignancy. A genuine risk for secondary malignancy in the field of treatment exists; it is usually small, approximately 0.2% at 10 years, but in some instances can be considerably higher. In children with bilateral retinoblastoma and mutations of the tumor suppressor gene, this risk may approach 1% each year.

Minor and Temporary Side Effects can be quite disabling unless anticipated and dealt with. *Nausea* occurs with abdominal irradiation; onset can be as soon as 1 to 2 hours after treatment. Prior administration of prochlorperazine, ondansetron, or granisetron helps to lessen gastrointestinal upset. Small, frequent feedings are better tolerated than large ones. If nausea and vomiting become problems, the daily radiation dose can be scaled back or treatment temporarily halted. Head and neck irradiation may cause dryness in the mouth and *difficulty* with *mastication* and *swallowing*. Initiation of pilocarpine (Salagen)treatment with the start of radiotherapy can help to maintain salivary function. The use of blenderized meals or liquid dietary supplements can help to maintain adequate caloric intake. *Diarrhea* resulting from bowel radiation responds to diphenoxylate (Lomotil) and loperamide. *Skin care* can sometimes be overlooked. Although the use of megavoltage machines has reduced skin exposure to 30% of the total dose delivered, avoidance of heat and excessive sun exposure helps preserve the integrity of irradiated skin.

PATIENT EDUCATION

Patients undergoing radiation therapy need plenty of emotional support. The fears associated with cancer are compounded by the awesome machinery and concerns about exposure to radiation. Patients who are well informed tolerate therapy better than those who are not. Answering questions and addressing concerns about the rationale for radiation therapy, the side effects to be expected, and how they will be controlled are essential to the successful conduct of a radiation therapy program. Printed information about radiation treatment can be very useful for the patient. In particular, one needs to review the risk for sterility with patients of reproductive age and the chances of a second malignancy in patients considering curative radiotherapy. Such cost–benefit discussions are critical to helping the patient make an informed choice. Knowing that treatment can be adjusted to one's tolerance to therapy is also reassuring.

COORDINATION OF CARE

Conducting a radiotherapy program is the province of the radiation oncologist, carried out in the context of an overall treatment plan developed by the surgeon, medical oncologist, and radiation oncologist in consultation with the primary care physician. The primary physician can ensure that the therapeutic program is well suited to the patient's needs and carefully monitored. A multidisciplinary team approach works best when one member has been designated as the person to whom the patient can always turn for advice and help; in many instances, this important role can be best carried out by the primary care physician.

CHAPTER 90 MANAGEMENT OF CHRONIC CANCER PAIN AND PALLIATIVE CARE

Part 1: Management of Chronic Cancer Pain

LINDA A. KING AND J. ANDREW BILLINGS

Relief of pain is an essential objective in the treatment of the cancer patient at all phases of the illness. Unrelieved pain interferes with a patient's ability to work, enjoy life, and function maximally in family and society. Effective amelioration of pain can almost always be achieved with proper use of analgesics. Unfortunately, undertreatment of pain is frequent. Common barriers to effective pain management reflect problems with health care professionals, patients, and the health care system, and they need to be explored actively and addressed (Table 90.1).

Problems Related to Health Care Professionals
Inadequate knowledge of pain management
Poor assessment of pain
Concern about regulation of controlled substances
Fear of patient addiction
Concern about side effects of analgesics
Concern about patients becoming tolerant to analgesics
Problems Related to Patients
Reluctance to report pain
Concern about distracting physician from treatment of underlying disease
Fear that pain means disease is worse
Concern about not being a "good patient"
Reluctance to take pain medications
Fear of addiction or of being thought of as an addict
Worries about unmanageable side effects
Concern about becoming tolerant to pain medications
Problems Related to the Health Care System
Low priority given to cancer pain treatment
Inadequate reimbursement and prohibitive costs
Restrictive regulation of controlled substances
Problems of availability of treatment or access to it

From Jacox A, Carr DB, Payne R, et al. Management of cancer pain. Clinical practice guideline No.9. AHCPR Publication No. 94-0592, Rockville, MD: Agency for Health Care Policy and Research, U.S. Department of Health and Human Services, Public Health Service, March 1994.

Table 90.1. Barriers to Cancer Pain Management

Fear of unrelieved cancer pain is widespread. The primary care physician must know the appropriate treatments and their limitations, and must also be able to support the cancer patient and minimize the emotional suffering that is invariably intertwined with the perception of pain.

PATHOPHYSIOLOGY AND CLINICAL PRESENTATION

Pain in cancer patients may result from direct effects of the tumor (e.g., infiltration into bone, viscera, nerves), from treatments directed at the cancer (e.g., chemotherapy, radiation, surgery), or from causes unrelated to the cancer (e.g., arthritis, migraines). Three broad physiologic categories describe the underlying pathophysiology: somatic, visceral, and neuropathic. Multiple pain complaints caused by multiple mechanisms are the rule.

Somatic pain arises from the activation of nociceptors in cutaneous or deep musculoskeletal tissues. This pain is usually well localized and often described as dull or aching. Examples of somatic pain include that from bone metastases, surgical incision, and radiation burns.

Visceral pain results from infiltration, compression, or distention of thoracic or abdominal viscera. Visceral pain is usually poorly localized and often described as deep, squeezing, or as if caused by pressure. Referral of the pain to overlying or distant cutaneous sites is common. Causes of visceral pain include liver metastases that distend the capsule and obstruct the biliary tree, bowel, or urinary tract.

Neuropathic pain results from direct injury to peripheral or central nervous system structures. Pain from nerve injury may be described as constant, aching, or as if caused by a vise; paroxysms of sharp, burning, or shocklike pain are superimposed. The pain may follow a nerve distribution and can be associated with sensory or motor (including sphincter) disturbances. Causes of neuropathic pain include spinal nerve root compression, radiation-induced plexopathy, and chemotherapy-associated neuropathy.

Common Pain Syndromes

In cancer patients, a number of pain syndromes occur frequently; some involve a single mechanism, and others operate through multiple mechanisms.

Osseous Pain. Metastases to the bony skeleton may cause pathologic fractures; the development of pain in a bony site is invariably secondary to interruption of the cortex, which may or may not be observed radiographically. Common sites are vertebrae, long bones, pelvis, and skull. Another form of osseous metastasis involves the bone marrow or medullary cavity. Intramedullary tumor is characteristic of leukemia but may also be observed in some solid tumors. These produce a pain syndrome characterized by diffuse bone sensitivity in the presence of normal radiographic findings.

Thoracic Pain. Pain associated with thoracic disease is generally a consequence of local invasion of the intercostal nerves. Pleuritic pain may develop if the malignancy spreads to involve the pleura. Direct invasion of a contiguous bony structure may result in local or referred pain.

Abdominal Pain may develop as a consequence of intestinal obstruction; cramping pain is characteristic (see Chapter 58). Ascites can be uncomfortable as a consequence of abdominaldistention. Hepatic metastases may cause pain by distending the liver capsule or irritating the peritoneal surface secondary to tumor necrosis. The latter is often associated with a friction rub.

Nerve Root Compression. Pain originating in the back and radiating down an extremity is characteristic of root compression. When an associated neurologic deficit is present, it suggests the possibility of evolving cord compression. The tumor most commonly extends either from the retroperitoneal space or from a contiguous involved bony structure. Bone scans or radiographs often demonstrate lytic or blastic lesions. Compression syndromes may also occur as a consequence of vertebral body collapse secondary to tumor without direct tumor compression of the nerve.

Peripheral Nerve Compression. The relatively uncommon nerve compression syndromes result in pain in the shoulder or arm (brachial plexus), buttocks and perineum (sacral plexus), lumbar area (paraspinal nerves), and mouth or face (trigeminal nerve). All are secondary to nerve entrapment and, occasionally, to nerve invasion by tumor growth.

Special Pain Syndromes. The *phantom limb syndrome* characteristically develops following amputation in patients with osteogenic sarcoma, especially when the tumor has been present for a long period. Persistence of phantom limb pain may lead to narcotic dependence. It is only after a protracted period of time that the reverberating neural circuit is eventually exhausted.

Herpes zoster (shingles) occurs in patients with hematologic malignancies, particularly Hodgkin's disease, the non-Hodgkin's lymphomas, and chronic lymphocytic

leukemia. Post-herpetic pain may persist in the absence of typical skin lesions; herpes zoster should be suspected in patients who have pain in a dermatomal distribution (see Chapter 193).

Hypertrophic pulmonary osteoarthropathy produces a periarticular pain syndrome in patients with primary or metastatic tumors of the lung and with mesotheliomas. The mechanism of periarticular pain is unclear.

WORKUP

Prompt, careful assessment of the cancer patient's pain is essential to the timely design and implementation of a rational treatment plan. Assessment should be carried out at the time of the initial report of pain, at regular intervals thereafter, and with any treatment changes. As noted above, cancer patients commonly report multiple types of pain. Each complaint should be individually assessed and prioritized. Because pain is a subjective phenomenon, the patient's report of pain must be taken seriously. The focus of the workup includes an assessment of the underlying mechanism(s) of pain in addition to their impact on the patient's quality of life and ability to carry out the activities of daily living.

History. A careful pain history includes the intensity, duration, location, and quality of the pain, in addition to aggravating and alleviating factors and associated symptoms. It is worth noting whether the pain is well localized, which suggests a somatic mechanism; more diffuse, which is indicative of visceral pain; or in the distribution of a nerve, which points to a neuropathic cause. If the pain is somatic in quality, is there a history of bony metastases, surgical incisions, or radiation burns? If the pain is more diffuse and visceral in quality, one needs to consider capsular distention and also obstruction of a viscus, be it bowel, biliary tree, or urinary tract, depending on the location of the pain. If the pain appears neuropathic in distribution, one needs to ask about sensory and motor disturbances (including those involving sphincters).

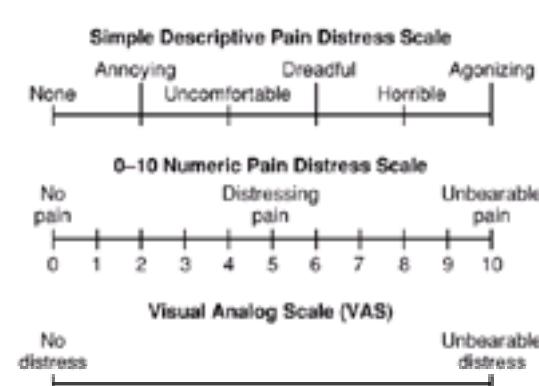
Another important component of the history is elucidating the impact of the pain on the patient's psychosocial state and on activities of daily living (sleeping, dressing, eating, moving around). A numeric rating scale (Fig. 90.1) helps to quantify pain intensity and follow it over time. Exploring the past use of analgesic therapies, their effectiveness, and their side effects helps in the design of the treatment program. Identifying how the patient interprets the meaning of the pain provides an opportunity to understand and ease the worry contributing to the pain.


FIG. 90.1. Pain Assessment Intensity Scales.

Physical Examination. A focused physical examination can provide essential corroborating evidence for the underlying mechanism(s) and site(s) of pain suggested by the history. For example, if the patient's story suggests neuropathic pain, then a careful neurologic examination confirming the neuronal distribution of the pain and examining for motor and sensory deficits and sphincter incompetence is critical. Similarly, somatic pain should be confirmed by the finding of focal tenderness. If the pain is poorly localized, then checking for an obstructed viscus or distended organ capsule is in order.

Laboratory Studies. Imaging studies and other laboratory means of confirming the cause of pain are especially important to management when a surgical, chemotherapeutic, or radiotherapeutic approach to pain control is being considered. Determining the specific cause of the pain (e.g., bone metastases, bowel obstruction, spinal cord compression) allows appropriate, disease-specific therapy to be instituted. Patients with advanced disease who are not candidates for such aggressive therapeutic measures need not undergo extensive testing unless the results will affect clinical decision making. In such patients, the decision to initiate or escalate an analgesic program may require little more than a good clinical assessment. While the workup is proceeding, troublesome pain should be treated empirically.

PRINCIPLES OF MANAGEMENT

After a thorough assessment has been completed and the cause of the pain identified, if possible, an appropriate treatment regimen can be instituted. Often, a multifaceted approach is necessary. Analgesics, psychological support, control of tumor, neurosurgical procedures, and behavioral methods are among the important modalities for the treatment of cancer-related pain.

Pharmacologic Measures

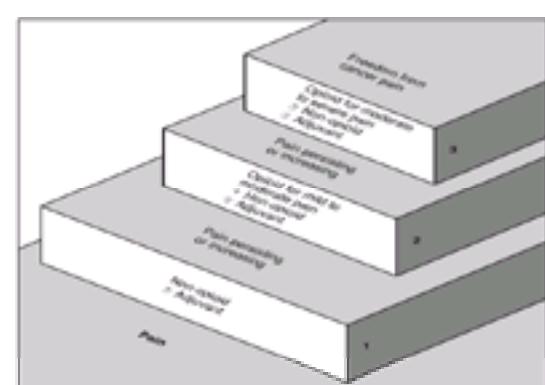
General Principles. Selection of the appropriate analgesic therapy must be individualized for each patient. The *World Health Organization analgesic ladder* (Fig. 90.2) provides a standard initial approach to drug selection for cancer pain based on pain severity and previous analgesic use. The ladder begins with the use of acetaminophen, aspirin, or NSAIDs for *mild to moderate pain*. When pain *persists* or *increases*, a weak opioid or a stronger opioid at a low dosage is added. Pain that is *moderate to severe* at presentation or more persistent should be treated with opioids at higher dosages or a stronger opioid preparation. The simplest route and dosage schedule and the least invasive pain management measures are preferred for initial use. *Chronic cancer pain* requires around-the-clock (*not as-needed*) dosing, supplemented by as-needed ("rescue") doses for breakthrough pain.


FIG. 90.2. The WHO three-step analgesic ladder.

Acetaminophen, Aspirin, and Nonsteroidal Antiinflammatory Drugs. These non-opioid drugs comprise the analgesics useful as initial therapy for mild pain (Table 90.2). Except for acetaminophen (which has no antiinflammatory effects), they have analgesic, antipyretic, and antiinflammatory effects. Adding aspirin or acetaminophen to an oral opioid regimen can boost the analgesic effect, which allows lower doses of opioids to be used and also limits side effects. Unlike opioids,

none of these drugs produces tolerance or physical dependence. There is a ceiling to their analgesic effects, beyond which no additional analgesia is achieved. Long-term use of oral NSAIDs for pain control in cancer has not been well studied, but availableevidence suggests reasonable efficacy, especially for bone pain or pain with an inflammatory component.

DRUG	USUAL ADULT DOSE
Acetaminophen	650 mg q4h
	975 mg q6h
Aspirin	650 mg q4h
	975 mg q6h
Choline magnesium	
trisalicylate (Trilisate)	750–1500 mg tid
Salsalate (Disalcid)	750–1500 mg tid
Ibuprofen (Motrin, Advil)	600 mg q6h
Naproxen (Naprosyn, Aleve)	250–500 mg bid
Ketorolac (Toradol)	10 PO mg q6h
	30 mg IM q6h (up to 5 days)
Celecoxib (Celebrex)	100–200 mg bid
Rofecoxib (Bioxx)	12.5–25 mg per day

Adapted from Jacox A, Carr DB, Payne R, et al. Management of cancer pain. Clinical practice guideline No. 9 AHCPR Publication No. 94-0592. Rockville, MD: Agency for Health Care Policy and Research, U.S. Department of Health and Human Services, Public Health Service, March 1994.

Table 90.2. Non-opioid Analgesics

The analgesia provided by NSAIDs is equivalent to that of aspirin, acetaminophen, and opioids at low dosages. NSAIDs are available in various oral formulations, including tablets, capsules, and liquids. Ketorolac, the only parenteral NSAID preparation, is recommended for short-term (<5 days) use only. Because responses to individual NSAIDs vary, titration of the dose and trials of different preparations are often necessary to achieve the best response. (For a discussion of adverse effects, see Chapter 68 and Chapter 156).

Cyclooxygenase-2 Inhibitors. The selective cyclooxygenase-2 (Cox-2) inhibitors (e.g., *celecoxib*) block both isoforms of cyclooxygenase to inhibit prostaglandin synthesis. The Cox-1 isoform is found in abundance in platelets, and its inhibition by NSAIDs is responsible for many of the side effects of these drugs. Cox-2 inhibitors are believed to cause fewer gastrointestinal and platelet side effects than do the traditional NSAIDs, but these drugs are expensive and may not have comparable analgesic efficacy.

Opioids are the preferred analgesics for the management of *moderate to severe* cancer pain. They are highly effective, easily titrated, and generally well tolerated.

Titration and Dosing. Opioid doses are *titrated* in each patient to maximize pain relief promptly and minimize side effects. Dosage requirements vary greatly among patients and with time, so that careful and ongoing titration is necessary to achieve and maintain adequate analgesia. The degree of analgesia that can be provided by increasing the dose of opioids is not limited, as it is with non-opioid analgesics. To provide optimal pain control, opioids should be prescribed on a *regularly scheduled* (around-the-clock) basis, rather than on an as-needed basis. This regimen actually minimizes the total daily amount of opioid required to control pain.

Dose titration is best accomplished by using a *short-acting preparation* and rapidly increasing the dose until pain resolves. At the end of every dosing interval, the dose is increased by at least 25% if pain persists; 50% increases are appropriate for severe pain. The goal is rapid implementation of effective pain control, accomplished by going "fast and high." Once the necessary daily opioid dose is established, a *long-acting oral preparation* that is taken twice daily can be substituted for the shorter-acting preparation. The shorter-acting oral opioids should be kept on hand for episodes of *breakthrough pain*. Breakthrough doses should be approximately 10% to 20% of the total 24-hour dose of the long-acting preparation and should be used every 2 to 4 hours as needed.

Routes of Administration. The *oral* route of opioid administration (Table 90.3) is ideal for patient convenience, but other routes (Table 90.4) are available for patients who cannot take their medication by mouth. The *IV* route allows for continuous administration of opioids, in addition to intermittent boluses as needed, although at a greater cost than that of other routes. *IM* dosing should be avoided because of the discomfort associated with injection and the availability of other equally effective routes of delivery. Equi-analgesic dosage guidelines and the duration of action must be understood when opioids or routes of administration are switched. In general, the same opioid dosages are required for oral, sublingual, buccal, and rectal administration. Likewise, roughly the same dosages are required for IM, IV, and SQ administration.

DRUG	OPIOID DOSE (mg)
Morphine	
MSIR tablets or capsules	15, 30
MSIR "soluble" tablets	10, 15, 30
Roxanol (elixir)	10/5 mL, 20/5 mL, 100/5 mL
MS Contin	15, 30, 60, 100, 200
Oramorph SR	15, 30, 60, 100
Hydromorphone	
Dilaudid, generic	2, 4, 8
Codeine	
Codeine sulfate tablets	15, 30, 60
Codeine with acetaminophen	
Tylenol No. 2, No. 3, No. 4	15, 30, 60, respectively
Codeine with aspirin	
Empirin No. 3, No. 4	30, 60, respectively
Hydrocodone with acetaminophen	
Lortab	2.5, 5, 7.5, 10
Lorcet	5, 7.5, 10
Vicodin	5, 7.5
Oxycodone	
Roxicodone	5
OxyContin	10, 20, 40, 80
Oxycodone with acetaminophen	
Percocet, Roxicet, Tylox, generic	5
Oxycodone with aspirin	
Percodan	5
Levorphanol	
Levo-Dromoran, generic	2
Methadone	
Dolophine, generic	5, 10

Table 90.3. Oral Opioid Preparations

ORAL DOSE (mg)	USUAL ORAL DOSING INTERVAL	ANALGESIC	PARENTERAL DOSE (mg)	USUAL PARENTERAL DOSING INTERVAL
200	q3-4h	Codeine	130	q3-4h
30	q3-4h	Hydrocodone (Vicodin, Zydone)		
20–30		Oxycodone (Percodan, Percocet, Tylox, Roxicet, Roxicodone, Roxiprin)		
30	q8h	Morphine	10	q3-4h
20	q6-8h	Methadone (Dolophine)	10	q6-8h
7.5	q3-4h	Hydromorphone (Dilaudid)	1.5	q3-4h
4	q6-8h	Levorphanol (Levo-Dromoran)	2	q6-8h

Table 90.4. Approximate Equianalgesic Doses of Short Acting Opioids for Chronic Pain [a,b]

Side Effects. The most common side effects of opioids include *constipation* and *sedation*; less commonly, these agents produce *nausea* and *vomiting, pruritus, myoclonus, dry mouth*, and *urinary retention*. Significant *respiratory depression*, a dreaded side effect in the treatment of acute pain, is extremely rare and not a concern in carefully conducted management ofchronic pain. One monitors for side effects and treats constipation prophylactically. Tolerance to many of the side effects, including nausea, sedation, and respiratory depression, occurs quickly. Constipation persists and should be managed with regularly scheduled laxative regimens (see Chapter 91).

Tolerance. Opioid tolerance is defined as the need for an increasing amount of drug to achieve the same analgesic effect. Tolerance develops with regular opioid use

and is manifested by a *shortened duration of pain control* and an overall increase in perception of pain. *Concurrent use* of a *non-opioid analgesic* (see above) or an *adjuvant drug* (see below) can delay the onset of tolerance by allowing the use of lower opioid doses and less frequent dosing. The simplest means of overcoming tolerance is to increase the dose or dose frequency. *Cross-tolerance* is common but not complete after prolonged opioid administration, so that it is possible to boost analgesia by *switching* to another opioid, starting at as low as one tenth and usually at about one half of the equi-analgesic dose.

Dependence. *Physiologic dependence* presents as the development of opioid *withdrawal* symptoms if opioids are abruptly discontinued or if opioid antagonists are administered. A withdrawal syndrome, although usually mild in patients with cancer pain, can be easily avoided by tapering the opioid dose by roughly 25% to 50% a day within a few days to a week. *Psychological dependence* (addiction) is an abnormal behavior pattern in which a person becomes overwhelmingly involved in the acquisition and use of a drug. Addiction remains very uncommon in cancer patients who take opioids for pain relief. Patients and their families should be counseled about the rarity of addiction when opioids are prescribed for cancer pain, as misconceptions often result in avoidance of pain medications or underreporting of pain. Similarly, health care professionals often inappropriately withhold opioids from patients who could benefit from these analgesics.

Pseudo-addiction describes the development of behaviors resembling psychological dependence. This state arises as a result of inadequate and inappropriate pain regimens, such as "only-as-needed" dosing for continuous pain, dosing intervals exceeding the duration of action of the medication, or inadequate doses. The "drug-seeking" behaviors observed are eliminated if an appropriate analgesic regimen is prescribed.

Choice of Opioid Agent. Choice should coincide with the patient's needs. For patients with mild to moderate pain that is becoming persistent, a low-potency opioid such as *codeine* is a reasonable choice. It is the least potent opioid; starting doses (15 to 30 mg) provide pain control comparable to that achieved with full analgesic doses of aspirin, acetaminophen, or an NSAID. Codeine in combination with acetaminophen provides effective analgesia at low cost for patients with mild to moderate pain. The related compounds *oxycodone* and *hydrocodone* are eight times more potent than codeine and are similar in potency to morphine. These opioids are also available in combination with aspirin and acetaminophen. The toxicities of the non-opioids in these formulations limit the overall dose of opioid that can be administered daily. Oxycodone is available in a long-acting, slow-release formulation (OxyContin) with an effect lasting up to 12 hours.

Morphine is the prototype opioid analgesic for severe cancer pain. It is effective both orally and parenterally and has a duration of action of approximately 3 to 4 hours. The use of sustained-release preparations (e.g., MS Contin, Oramorph SR) provides prolonged analgesia (8 to 12 hours) with less frequent dosing, but the cost can be substantial. These long-acting formulations cannot be crushed or chewed.

Hydromorphone (Dilaudid) is more potent than morphine and also more costly. Its duration of action and strength are reduced considerably when it is given orally rather than parenterally. Because hydromorphone is more potent and more soluble than morphine, a smaller injected volume can be used in patients requiring parenteral opioid infusions.

Methadone and *levorphanol* also have proved useful because of their longer duration of action. The cost of methadone is low, which makes it an attractive alternative to long-acting morphine preparations. With repeated dosing, excessive sedation and central nervous system depression can result because of the sustained half-life of these agents. Careful dose titration is required for proper use.

Although *meperidine* (Demerol) is commonly prescribed and available for both oral and parenteral use, it is not recommended for chronic cancer pain because of the rapid inactivation of an oral dose and overall short duration of action. In addition, its metabolite, normeperidine, causes dysphoria, tremors, and irritability, especially in patients with impaired renal function. In patients taking monoamine oxidase (MAO) inhibitors, meperidine can cause serious and sometimes lethal side effects.

Fentanyl, a potent opioid, is available as a transdermal preparation that provides 3 days of continuous analgesia. The fentanyl patch is generally more expensive than oral opioids and requires careful titration to avoid excessive sedation. The starting dose should be based on the patient's previous morphine requirement or determined empirically by starting with the patch of the lowest strength, which provides 25 µmg of fentanyl per hour (the equivalent of about 90 mg of oral morphine per day or 30 mg of parenteral morphine per day).

Some synthetic opioids have antagonist in addition to agonist activity. *Pentazocine* (Talwin) and *butorphanol tartrate* (Stadol) are opioid agonists–antagonists available orally and as a nasal spray, respectively. The opioid antagonist qualities of these drugs can precipitate withdrawal in a patient already taking an opioid agonist; therefore, they are not optimal drugs for cancer patients with long-standing opioid requirements.

Adjuvant Agents. Various agents can be used to enhance the effectiveness of the analgesics discussed above (Table 90.5). The *tricyclic antidepressants* (see Chapter 227) are effective for neuropathic pain, concurrent depression, and sleep disturbance related to ongoing pain. The analgesic effects may occur at lower doses and may develop more quickly than the antidepressant effects. Starting doses of desipramine (Norpramin) or amitriptyline (Elavil) as low as 10 to 25 mg at bedtime can reduce pain, with upward dose adjustment as necessary. Anticholinergic side effects and sedation may limit titration, especially in the elderly.

DRUG	USUAL ADULT DOSE RANGE
Antidepressants	
Amitriptyline (Elavil)	10–150 mg qhs
Nortriptyline (Pamelor)	10–150 mg qhs
Anticonvulsants	
Gabapentin (Neurontin)	100–400 mg tid
Carbamazepine (Tegretol)	100–800 mg bid
Phenytoin (Dilantin)	300–500 mg qd
Psychostimulants	
Dextroamphetamine (Dexedrine)	5–10 mg qd–bid
Methylphenidate (Ritalin)	2.5–15 mg qd–bid
Glucocorticoids	
Dexamethasone (Decadron)	4–96 mg bid–qid
Prednisone	10–100 mg qd–bid

Table 90.5. Adjuvant Analgesics

Anticonvulsants including *gabapentin* (Neurontin), *carbamazepine* (Tegretol), and *phenytoin* (Dilantin) are also helpful in relieving neuropathic pain. Again, doses should be started low and titrated to effect. Local anesthetics such as IV *lidocaine* and oral *mexiletine* have also been used effectively for neuropathic pain.

Stimulants, such as *dextroamphetamine* (Dexedrine) and *methylphenidate* (Ritalin), are sometimes used to counter the somnolence associated with opioid use. They can also have the beneficial effects of increasing energy and appetite. *Glucocorticoids* may lessen the pain associated with tumor-associated inflammation or infiltration while providing a stimulant effect in addition to an improved appetite and sense of well-being. The anticipated side effects of ongoing corticosteroid use (hyperglycemia, edema, infection, gastrointestinal bleeding) may limit their long-term use. *Benzodiazepines* are helpful on an intermittent basis if a patient reports situational stress or anxiety or increased pain with resultant difficulty in falling asleep. However, agitation caused by depression should be treated with an antidepressant and not a benzodiazepine.

Patients with pain caused by bone metastases may benefit from therapy with *bisphosphonates* or *calcitonin*, which both inhibit osteoclast activity and reduce bone pain. Monthly pamidronate therapy has been shown to reduce bone pain and the incidence of pathologic fractures in certain cancers.

Nonpharmacologic Measures: Physical and Psychological Modalities

These interventions represent an important component of a multifaceted approach to pain management. Such interventions should be used with, not instead of, appropriate analgesic regimens.

Physical Modalities. *Cutaneous stimulation* by the application of *cold* or *hot* packs or by the use of *massage, vibration, transcutaneous electrical stimulation* (TENS), or *acupuncture* helps to manage pain when employed in conjunction with appropriate analgesics. These modalities are easy to use and relatively inexpensive, and

they cause minimal morbidity.

Psychosocial Interventions. *Relaxation* techniques (focused-breathing exercises, meditation, music therapy), *guided imagery, biofeedback*, and *hypnosis* can be very helpful, especially for episodic pain and pain related to specific activities. These easily learned techniques enable patients to gain a sense of control over the pain. Belief in the validity of the underlying method strongly correlates with a positive outcome.

Psychological Support. The importance of psychological support from both physician and family cannot be overemphasized. The active involvement of the primary physician is vital to the successful control of pain. The understanding and concern expressed, with attention to the patient's worry in addition to the pain itself, are as central to effective pain relief as are tumor control and proper use of analgesics (see Chapter 87).

Nonpharmacologic Measures: Invasive Modalities

Anesthetic Procedures. Patients in whom adequate pain control is not achieved with application of all the above measures or who experience intolerable side effects may be candidates for invasive anesthetic or neurosurgical procedures. Before such an invasive measure is utilized, a multidisciplinary team including oncologists, pain specialists, and neurosurgeons should review the situation to ensure appropriate patient selection. It is important to characterize the pain as precisely as possible to target the planned interventions appropriately. A number of approaches are available.

Epidural or *intrathecal injection* of opioids and local anesthetics can be used for either short-term or long-term control of intractable pain in the lower part of the body. Operator expertise is essential to ensure proper catheter placement and manage potential complications, including respiratory depression, hypotension, and infection.

Nerve blocks utilize the application of a local anesthetic, corticosteroid, or neurolytic to control intractable pain related to an identifiable nerve structure. Application of a short-acting local anesthetic provides useful diagnostic and management information by confirming the specific source of pain and predicting likely side effects. Once an appropriate site has been identified by diagnostic block, a neurolytic agent such as ethanol or phenol is injected to destroy the involved nerve and provide long-term pain relief. Neurolytic blocks can relieve pain related to tumor infiltration of the upper abdominal organs (celiac block), pelvic organs (hypogastric block), head and neck (stellate ganglion block), and legs (lumbar sympathetic block). Precise technique is required for the successful implementation of a nerve block and to prevent damage to surrounding tissue and other nerves.

Neurosurgical Procedures for pain control are now used less frequently because of the development of more advanced, radiologically guided techniques for anesthetic blocks. Pituitary ablation (hypophysectomy) has been used successfully in rare patients with refractory disseminated pain.

INDICATIONS FOR REFERRAL AND ADMISSION

Successful management of cancer pain requires a team approach. The primary physician plays a major role in the design and implementation of an effective analgesic program and in monitoring the patient for painful complications of the malignancy. When such complications arise, prompt consultation with the oncologist, radiation therapist, or surgeon is often indicated because of the potential need for further systemic treatment or additional local measures. Patients with *refractory pain* in the absence of evident, focally approachable disease may benefit from consultation with a specialist in the treatment of chronic pain. The patient with new onset of pain suggestive of *spinal cord compression* or *pathologic fracture* requires prompt consultation and hospital admission.

PATIENT AND FAMILY EDUCATION

Patients endure their condition much better when they know that maximum pain relief is available. The educational effort should take into account any cultural or language barriers that might contribute to undertreatment, a phenomenon noted with increased frequency among minority patients with cancer. To avoid underdosing, all family and health care team members need to be informed of the patient's analgesic needs and the low risk for true addiction. The issues of drug tolerance and physiologic dependence should be reviewed and their significance discussed. Few patients should have to endure disabling pain, given the array of effective treatment modalities available. Many patients do best when they maintain an active role in their care. Enlisting their help in the design, implementation, and monitoring of the pain management program can be of considerable psychological benefit. Effective pain control is central to sustaining a reasonable quality of life and is one of the most basic requests of cancer patients.

RECOMMENDATIONS

- Carefully assess each complaint of pain. Patients may have multiple pains with multiple origins and mechanisms.
- Attempt to diagnose each underlying cause because specific causes respond best to specific treatments. In particular, be alert for bone pain, neuropathic pain, and cord compression.
- Treat the worry in addition to the discomfort. Psychological support contributes greatly to effective pain control.
- Utilize the stepped approach for analgesic use as outlined by the World Health Organization analgesic ladder, while recognizing that analgesic therapy must be individualized for each patient.
  - For *mild to moderate* pain, begin with acetaminophen, aspirin, or NSAIDs.
  - When pain *persists* or *increases*, add a weak opioid or a stronger opioid at a low dosage.
  - For pain that is *moderate to severe*, treat with higher dosages of opioids or a stronger opioid preparation.
  - Treat *chronic cancer pain* with around-the-clock (*not as-needed*) dosing, supplemented by as-needed ("rescue") doses for breakthrough pain.
- Initiate opioid therapy by quickly establishing the necessary opioid dose. Do this by titrating with a short-acting preparation, increasing each dose by 25% to 50% until satisfactory pain control is achieved. Once the effective dose is established, switch to a long-acting preparation (e.g., MS Contin, OxyContin, Oramorph SR, Duragesic patch). Use as high a dose of opioid as is necessary to achieve effective pain relief.
- Treat *"breakthrough"* pain with doses of a short-acting opioid equal to 10% to 20% of the total 24-hour opioid dose and give every 2 to 4 hours as needed.
- Use the simplest route of administration, the most convenient dosage schedule, and the least invasive pain management measures. Oral therapy is preferred.
- Address common misunderstandings about addiction to minimize underdosing.
- Consider adding simple nonpharmacologic modalities, such as application of heat or cold, massage, relaxation techniques, and guided imagery, which can complement appropriate analgesic regimens.
- If *tolerance* to one opioid seems to be developing, consider switching to another opioid. Use equi-analgesic doses when switching between different opioids and routes.
- To help control severe *neuropathic* or *bone pain*, consider an adjuvant agent (e.g., tricyclic antidepressant or anticonvulsant for neuropathic pain, bisphosphonate for bone pain).
- Minimize adverse effects of opioid use by periodically retitrating and prescribing such measures as laxatives to prevent severe constipation.
- For *pain caused by severe localized disease*, consider tumor-specific therapy (e.g., radiation, surgery, chemotherapy).
- For *poorly controlled pain* or problematic side effects, consider referral for nerve block or placement of an epidural catheter.
- Reassess frequently and at regular intervals, especially when pain worsens and after medication changes have been made.
- When pain is not responding well to treatment, reevaluate the role of psychosocial factors, consider whether pain is neuropathic, and seek help from pain specialists.

Part 2: Palliative Care

ERIC L. KRAKAUER

Palliative care is comprehensive care focused on alleviating suffering and promoting the quality of life of patients living with a life-threatening or terminal illness. Major concerns are pain and symptom management, information sharing and advance care planning, psychosocial and spiritual support of both patient and family, and coordination of care, including arranging for services in the community. The orchestration and provision of palliative care is part of the purview of any primary physician who cares for a dying patient. It may be provided in an acute care hospital, a skilled nursing facility, an inpatient hospice, or the home. Community hospice organizations and visiting nurse associations can assist in arranging palliative care outside the hospital.

PRINCIPLES OF PALLIATIVE CARE

Transition to Palliative Care. Although attention to palliation and comfort should be part of the care plan for all patients, including those receiving curative or life-sustaining treatments, many patients reach a point at which they want the primary focus of care to shift to comfort and achievement of the best possible quality of life. Helping patients and surrogates to determine the timing of this shift requires (1) an assessment of their understanding of the diagnosis and prognosis, (2) the communication of information about the illness—what is wrong, the likely outcomes, the potential benefits and burdens of each treatment option, (including no treatment); and (3) an understanding of patients' goals and values. Previously executed advance directives such as a living will or health care proxy form can be useful in these discussions. Factors that may impede a patient's ability to make treatment decisions, such as delirium, dementia, or denial, should be taken into account. When the patient's capacity to understand medical information is questionable, a psychiatric consultation may be useful. Efforts should be made to discern and respect cultural and familial factors that may inform a patient's decisions.

Non-abandonment. As the goal of care shifts from cure or life support to comfort, it is important to reassure patients, surrogates, and families through words and deeds that they will not be ignored or abandoned and that attentive palliative care will be provided. A decision to forego "aggressive" interventions, or to request a "Do Not Resuscitate" or "Comfort Care Only" order, should never lead to a diminution of attention to the patient's well-being. Phoning to "check in" or a home visit can be very comforting.

Proportionality. When deliberating with patients or surrogates about specific treatments, it is important to weigh the potential benefits against the potential or certain burdens. If a treatment seems likely to be more burdensome than beneficial, the physician should suggest that it not be used.

Withholding and Withdrawing Treatments. It sometimes can be emotionally more difficult for surrogates and families to withdraw life-sustaining treatments that have been initiated than to withhold them. However, no medically, ethically, or legally relevant distinction can be made between withdrawing and withholding such treatments if the patient would not want them or if their burdens to the patient would outweigh the benefits. When discussing with surrogates or families the withdrawing or withholding of artificial nutrition and artificial hydration, it may be helpful to allay the common misconception that lack of nutrition or dehydration is inevitably uncomfortable and thus inhumane (see sections below on the management of anorexia and dry mouth).

Comprehensive Care. Palliative care is best provided by a team, directed by the physician, that may include nurses, a social worker, a chaplain, hospice workers, health aides, and specialists in oncology, radiation therapy, psychiatry, or palliative care. Regular case review with team members is necessary to ensure coordinated, high-quality care. Although the patient is the focus of care, the family's emotional, social, and spiritual needs also require attention, both for their own well-being and for the patient's. After the patient's death, grieving families may benefit from bereavement care.

Maximizing Dignity and a Sense of Control. Patients may fear the loss of dignity and control as much as any physical symptom. The care plan should be developed so as to maximize the patient's personal sense of dignity and to give the patient as great a sense of control as possible.

Double Effect. It is important to make clear to patients, surrogates, families, and clinicians that palliative care or a shift of focus to comfort is not euthanasia or physician-assisted suicide. Rather, palliative care is standard, appropriate medical care when curative or life-sustaining treatment is no longer beneficial or desired. It is particularly important to make this clear when control of the patient's symptoms may require the administration of opioids, benzodiazepines, or other medications in doses high enough to cause serious side effects. In this situation, the principle of double effect, a centuries-old tenet of the Catholic Church, is critical to the physician.

The principle of double effect states that "an action with two possible effects, one good and one bad, is morally permitted if the action (a) is not in itself immoral; (b) is undertaken only with the *intention* of achieving the possible good effect, without *intending* the possible bad effect even though it may be *foreseen*; (c) does not bring about the possible good effect by means of the possible bad effect; and (d) is undertaken for a proportionately grave reason." For example, a patient with advanced metastatic lung cancer and intractable pain may be given opioids even at the risk of side effects including sedation, hypotension, respiratory depression, respiratory arrest, and death as long as the action (giving opioids to relieve pain) (a) is not in itself immoral (giving opioids for pain is not); (b) is intended only to relieve pain and suffering and to ensure comfort; (c) does not intend to achieve relief and comfort by means of the possible side effect (death); and (d) is undertaken for the purpose of relieving the pain and suffering of a gravely ill patient.

Patients who wish to be made comfortable, their families, and other caregivers should be assured that the intention of treatment is to use the minimum doses of medications necessary for comfort, no more but also no less. When it is anticipated that adequate symptom control may unintentionally hasten the patient's death, the patient or surrogate should be advised of this and reassured that this is medically appropriate and ethically legitimate as well as compassionate.

PALLIATIVE CARE ASSESSMENT

A thorough palliative care assessment includes a comprehensive history and physical examination. It should address not just the medical issues of the patient but also

the psychosocial and spiritual issues, and the needs of the family and significant others. Certain aspects of the palliative care assessment require particular attention.

Review of Symptoms. The palliative care assessment replaces the standard review of systems with a review of *symptoms* that is designed to explore typical causes of suffering at the end of life. It generally should cover pain, shortness of breath, nausea, vomiting, constipation, anorexia, dry mouth, odynophagia, insomnia, anxiety, and depression. Further review of symptoms should be tailored to the patient's illness.

Functional Status. The patient's performance status currently and during the past 2 weeks should be assessed. Categories might include the following: fully active, restricted strenuous activities, ambulatory/not able to work, limited self-care, confined to bed or chair/no self-care.

Awareness of Illness and Preferences for Care. The patient's and family's understanding of the diagnosis and prognosis should be explored. Patients should be asked whether they would like to receive all diagnostic and prognostic information and make all necessary decisions. Some patients may prefer instead that a surrogate receive this information and make these decisions, or that decisions be made by the physician. The existence of any advance directive such as a living will or health care proxy form (durable power of attorney) should be established. The physician particularly needs to know whom the patient wishes to serve as surrogate in case of decisional incapacity. The patient's hopes and goals for care should be explored and discussed. Helpful questions include the following: "Are there important tasks that would require your immediate attention if you were unable to function well in the future?" "If time were limited, what would be your priorities?" "Are there any upcoming events, such as births, weddings, or graduations, that are especially meaningful to you?" The patient's preferred location of care—home or hospital—should be explored. If possible without upsetting the patient, the preferred location of death also should be explored. Finally, any wishes to forego specific life-sustaining treatments, such as cardiopulmonary resuscitation, endotracheal intubation and mechanical ventilation, artificial nutrition, and artificial hydration, should be explored if the patient is ready to do so.

Social History. The social history should probe for sources of social suffering and identify psychosocial supports for both the patient and family. It should include the patient's living situation, names of all immediate and close family members and friends, work history, religion and degree of participation in organized religion, major sources of joy, major losses and disappointments, including deaths in the family, and the patient's and family's history of coping with these losses.

Medications. When the focus of care is shifted to palliation, the medication list should be reviewed and irrelevant medications such as cholesterol-lowering drugs discontinued.

Physical Examination should focus on evaluating current symptoms and anticipating future symptoms. Care should be taken to minimize the discomfort of the examination itself.

Laboratory and Imaging Studies. Diagnostic tests not needed for comfort care should not be performed. Occasionally, additional studies are indicated to help determine the prognosis, plan optimal palliative care, or maximize the patient's quality of life.

Impression. This should include a determination of prognosis and a list of actual and potential causes of discomfort. A differential diagnosis of an uncomfortable symptom should be performed whenever the cause is not obvious.

Plan. The treatment plan should be organized primarily by *symptom* rather than by organ system or disease. The list of symptoms should be exhaustive and should include anticipated symptoms. For example, three actual or potential symptoms—chest pain, hemoptysis, and acute respiratory distress—may be caused by the same underlying disease, but each symptom requires separate management. The preferred location of care should be identified and contingency plans made for major changes in the patient's condition. Psychosocial and spiritual supports (family, friends, social worker, clergy, visiting nurses, home health aides, hospice volunteers) should be identified. If relevant, financial or insurance problems should be addressed. Plans should be made to facilitate communication between the physician and the primary caregiver, nurses, and other physicians involved in the patient's care. If the patient wishes to forego resuscitation in the event of cardiac arrest or respiratory failure, a plan should be made to protect the patient from unwanted resuscitation in the event 911 is called. Many states have established protocols for this purpose.

MANAGEMENT OF MAJOR SYMPTOMS IN PALLIATIVE CARE

Dyspnea is a common symptom among terminally ill patients with primary or secondary lung neoplasms, pneumonias, cardiogenic or noncardiogenic pulmonary edema, chronic obstructive pulmonary disease, pulmonary embolism, and other conditions frequently seen at the end of life. The cause (or causes) of dyspnea should be identified and treated as aggressively as is compatible with the overall goal of comfort. Chest radiography, computed tomography, antibiotics for pneumonia, or thoracentesis, chest tubes, and pleurodesis for large pleural effusions may or may not be appropriate, depending on the patient's wishes and the plan of care. Occasional patients are maintained at home on positive inotropic agents for end-stage congestive heart failure. The workup for pulmonary embolism is rarely indicated for a patient whose care is focused on comfort.

When air hunger persists despite maximal appropriate treatment of the underlying condition, palliative treatment with *morphine* is indicated. Mild symptoms can be treated with 5 to 10 mg PO every 4 hours as needed (or around the clock if the symptoms are constant), and the dose can be titrated upward (e.g., to 15, 20, 30 mg) to achieve the desired effect. The regimen for patients who persistently require frequent doses should be changed to a long-acting opioid (e.g., MS Contin) at the equi-analgesic dose, with a short-acting dose available as needed for breakthrough dyspnea (see Part 1 of this chapter). For sudden, severe, or rapidly progressing dyspnea that is typical of massive pulmonary embolism, septic shock, or intrapulmonary lymphangitic spread of tumor, SQ or IV morphine often is necessary. Even at home, a constant SQ or IV infusion can be administered by means of a small infusion device and titrated to comfort. The starting dose will depend on the previous dose of opioids and the severity of symptoms. When a change is made from oral to parenteral morphine, the total daily parenteral dose should equal one third of the total daily oral dose. An opioid-naive patient can be started on an infusion of 1 to 2 mg/h. Bolus doses of 2 to 10 mg can be given for worsening symptoms and when the infusion rate is titrated upward. In the setting of severe respiratory distress, opioid doses necessary to achieve comfort may have the unintended but foreseeable side effect of hastening death (see preceding discussion of the principle of double effect).

Dyspnea frequently is associated with anxiety. *Benzodiazepines* can be helpful adjuncts to opioids when anxiety is prominent. Troublesome respiratory secretions causing choking, coughing, or respiratory distress can be treated with *sco-polamine* transdermal patches (most patients need at least 1 mg/d) or glycopyrrolate via a nebulizer (0.8 mg every 6 hours), orally (1 to 2 mg three times daily), or parenterally (0.1 to 0.2 mg IV or SQ every 6 hours). Secretions are often reduced or absent in patients whose artificial nutrition and artificial hydration is discontinued before the terminal phase. Oxygen sometimes relieves dyspnea even in patients who are not hypoxic, as does a cool breeze from a fan.

Anorexia can be the consequence of any of the causes of chronic nausea. It also can be caused by factors elaborated by tumors (e.g., tumor necrosis factor), a massive tumor burden, chronic infection (e.g., viral hepatitis, AIDS), an increased basal metabolic rate (as in cancer, AIDS, end-stage congestive heart failure), gastroparesis, bowel surgery (e.g., short-bowel syndrome, dumping syndrome), and depression. Treatable underlying causes should be addressed. Medications that enhance the appetite for some patients include *megestrol acetate* (Megace; 160 to 800 mg PO daily), low doses of a cortico-steroid (2 to 4 mg of *dexamethasone* PO twice daily), or *dronabinol* (Marinol; 2.5 to 5 mg PO twice daily before meals). Artificial nutrition by means of nasogastric, gastrostomy, or jejunostomy tubes or parenteral nutrition often is not appropriate in patients for whom the goal of care is comfort; these interventions may be more burdensome than beneficial by prolonging the dying process and worsening terminal respiratory distress.

Dry Mouth. Xerostomia, a very common symptom among dying patients, may be caused by dehydration, mouth breathing, or opioids and other medications with anticholinergic side effects, or it may follow head and neck surgery or radiation. Patients may take sips or ice chips if they wish. In severe cases, or when patients are unable to sip fluids, a saliva substitute (several commercial brands) should be applied every 4 hours around the clock and as needed. Petroleum jelly may be applied to the lips three times a day. Patients and families worried about discontinuing artificial hydration for fear of discomfort from dehydration may be assured that dry mouth is usually the only uncomfortable symptom of dehydration and that careful oral care is effective in preventing it.

Thrush. Candidal infection of the oropharynx and esophagus is common in patients who are immunosuppressed because of cancer, cancer therapy, AIDS, or the use of immunosuppressive medications such as corticosteroids. Mild cases may be treated with *nystatin* (5-mL Swish and Swallow four times daily) or *clotrimazole* (10-mg troche five times daily for 14 days). More severe cases require *fluconazole* (200 mg PO or IV on the first day, followed by 100 mg PO or IV for 2 weeks or until symptoms are resolved). Suppressive therapy with *fluconazole* is 100 mg PO weekly.

Constipation. This very common symptom can cause serious distress in terminally ill patients, who are typically immobile, somewhat dehydrated, and taking

constipating medications such as opioids. Opioid regimens should virtually always be accompanied by a bowel regimen. Patients should be advised to make sure they move their bowels at least every 2 to 3 days. A typical starting regimen is senna (Senokot, 1 to 2 tablets PO twice daily; hold as needed in case of loose stools) and lactulose (30 mL PO at bedtime as needed if no bowel movement in 1 to 2 days) (see also Chapter 65).

Bowel Obstruction causing abdominal pain or vomiting, even when proximal, can sometimes be managed medically with a combination of IV morphine, scopolamine, and haloperidol. *Octreotide* IV or SQ often is useful to reduce gastrointestinal secretions and vomiting. *Dexamethasone* may help reduce the obstruction from complete to partial. When vomiting is refractory, *decompression* is required with a nasogastric tube. If the obstruction persists and the patient's prognosis is longer than a few days, permanent decompression with a gastrostomy tube may be considered.

Delirium and Agitation. The myriad possible causes of delirium and agitation in dying patients include side effects of medications, metabolic derangements (e.g., electrolyte abnormalities, uremia, liver failure), pain, infection, and central nervous system lesions. Underlying causes should be addressed if this can be done with minimum discomfort. Among medications, common offenders are opioids and the very drugs used to treat agitation, such as benzodiazepines and neuroleptics. When an opioid is felt to be the offending agent, an alternate opioid can tried. Because of incomplete cross-tolerance to opioids, pain relief is often adequate with no more than one half of the equi-analgesic dose of the alternate agent. Because of the risk for delirium and paradoxical agitation, *benzodiazepines* such as *lorazepam* (Ativan) and neuroleptics such as *haloperidol* should be used cautiously in elderly or debilitated patients. Often, haloperidol (0.5 mg PO at bedtime or two or three times daily) is all that is needed to induce sleep or relieve agitation.

Depression. For rapid treatment of depression in a patient with a short prognosis, psychostimulants such as *dextroamphetamine* (Dexedrine) or *methylphenidate* (Ritalin) are the treatments of choice. The dosage for either is 2.5 to 5 mg PO each morning, titrated upward to 5 to 10 mg PO twice daily, at 8 a.m. and noon (see also Chapter 227.)

Sedation is a common side effect of opioids and other medications used frequently in palliative care. It can be treated with dextroamphetamine or methylphenidate (see also Chapter 226).

Myoclonus is a common side effect of opioid analgesics, particularly when given in high doses. Its appearance is idiosyncratic and may resolve with a switch to an alternate opioid. Again, adequate analgesia often can be maintained with less than the equi-analgesic dose of the alternate agent because of incomplete cross-tolerance. Mild myoclonus may cause no discomfort. If myoclonus is severe or clearly uncomfortable and not controlled by switching to an alternate opioid, lorazepam (Ativan; started at 0.5 to 1 mg PO or IV every 6 hours) or diazepam (Valium; started at 2 to 5 mg PO or IV every 8 hours) may be effective.

Hemorrhage. Sudden massive hemorrhage can be very distressing to the patient and family members. However, some highly motivated patients and families may remain at home during hemorrhage if they are properly prepared by the primary care physician and if adequate home nursing is available to ensure comfort. If massive hemorrhage is a likely scenario, the physician should explore the patient's desire to remain at home and the family's willingness to do whatever is necessary to keep the patient at home. The physician should reconfirm that the goal of care is comfort, that no resuscitation is to be performed, and that no blood products are to be given. The physician also should ascertain that a hospice or visiting nurse is available around the clock and able to get to the home in less than 1 hour. The physician should discuss the possibility of massive hemorrhage with the primary nurse and review the management plan. The physician then should explain to the patient and family what might happen, what the patient might feel, and exactly what measures would be taken to ensure comfort.

When hemorrhaging occurs, several simple steps are appropriate. First, the patient and family should be calmed and reassured that the situation can be handled. The nurse or other clinician on the scene should cover the blood or melena and remove it frequently. Morphine or a benzodiazepine such as lorazepam should be given IV or SQ to calm the patient. A constant IV or SQ infusion of morphine should be started and titrated to comfort. As the patient exsanguinates, additional symptoms may arise, such as shortness of breath, chest pain from ischemia, light-headedness, and anxiety. Additional morphine (and sometimesalso benzodiazepine) in IV or SQ bolus doses should be given to control these symptoms quickly.

Pain. (See Part 1 of this chapter.)

Ascites. (See Chapter 71, Chapter 91, and Chapter 92.)

Hiccups. (See Chapter 221.)

Nausea and Vomiting. (See Chapter 59 and Chapter 91.)

Dysphagia, Odynophagia. (See Chapter 60.)

Insomnia. (See Chapter 232.)

Seizure. (See Chapter 170.)

Pressure Ulcers. (See Chapter 197.)

Pruritus. (See Chapter 178.)

Terminal Distress. (See section above on dyspnea.)

OTHER ISSUES AND INDICATIONS FOR ADMISSION

Hospice and Home Services. Hospice services are available in inpatient hospices, in some nursing homes, and at home through home hospice organizations or visiting nurse associations. The primary care physician may choose to remain in charge of the patient's care in all settings. Most hospices accept patients only when the patient and family are aware of the terminal diagnosis and prognosis and accept care focused purely on comfort.

Psychosocial and Spiritual Support. Emotional and spiritual support and counseling can be extremely important for dying patients and their loved ones. All accredited hospice organizations have a social worker, chaplain, and volunteers available. They can assist with the search for meaning in the dying process, religious and spiritual issues, anticipatory grieving, life review, preparation of a legacy, and financial issues.

Bereavement. Hospices also make available some form of support for bereaved family members and loved ones. A note of condolence from the physician with an offer to be available by phone to answer any lingering questions can be very comforting. The physician also might call the family to provide support, answer questions, and assess the need for a referral for formal bereavement counseling.

Indications for Admission. In some situations, it is necessary to admit a patient to the hospital to protect the patient from end-of-life suffering. For example, a patient with severe or refractory pain, dyspnea, or seizures may require treatments not available at home. In other cases, adequate home nursing care may not be available or the family may be overwhelmed. Patients who are near death may be admitted for terminal care. Others are admitted just long enough to control symptoms and arrange appropriate end-of-life care in a skilled nursing facility, inpatient hospice, or the home.

CONCLUSIONS AND RECOMMENDATIONS

- Patients with chronic life-threatening illnesses and their families need reassurance that attentive comfort care can be provided if desired in lieu of aggressive, life-sustaining treatment.
- The benefits and burdens of all diagnostic and therapeutic measures should be weighed and the physician should suggest that more burdensome measures not be used.
- No medical, ethical, or legal distinction is made between withdrawing and withholding a treatment that is more burdensome than beneficial or not desired by the patient.

- Artificial nutrition and hydration are medical treatments that may be provided or not provided, like any other intervention, depending on the benefit-to-burden ratio and the patient's or surrogate's wishes.
- Treatments intended only to relieve serious refractory symptoms in a terminally ill patient often may be provided even at the risk of unintended but foreseeable side effects, including a hastening of death.
- Sources of physical and social suffering should be thoroughly explored, along with the patient's awareness of the diagnosis and prognosis and preferences for end-of-life care.
- A differential diagnosis of uncomfortable symptoms should be performed and the underlying cause treated to the fullest extent consistent with the goal of comfort.
- Anticipate sources of terminal distress and make treatment plans in advance.
- Treat dyspnea with morphine administered orally, sublingually, or rectally. If the dyspnea is severe, morphine can be administered IV or SQ.
- Troublesome respiratory secretions can be treated with anticholinergics such as scopolamine or glycopyrrolate.
- Treat xerostomia with a saliva substitute around the clock, particularly in dehydrated patients.
- Inpatient and outpatient hospice services are available to help manage symptoms and psychosocial problems under the direction of the physician. Hospice teams include nurses, social workers, chaplains, health aides, and volunteers.
- Dying patients sometimes must be admitted to the hospital to control refractory symptoms.

CHAPTER 91 MANAGING THE GASTROINTESTINAL COMPLICATIONS OF CANCER AND CANCER TREATMENT

The gastrointestinal symptoms that accompany cancer and cancer therapy are among the most difficult for the patient to bear, often compromising nutritional status and quality of life. Problems may arise from primary disease, metastases, side effects of therapy, or metabolic disturbances. Successful primary care of the cancer patient necessitates attending to the anorexia, nausea, vomiting, weight loss, abdominal pain, ascites, and related gastrointestinal problems that often worsen their lives.

NAUSEA AND VOMITING

Cancer therapies are far and away the leading cause of nausea and vomiting in patients with malignancy. Treatments often have to be stopped or limited by the onset of emesis. This makes the control of nausea and vomiting important, not only for restoring patient comfort but also for ensuring completion of a full course of treatment. The presentation of emesis may precede, acutely follow, or follow after a short delay the application of cancer therapy; it may also become persistent.

Pathophysiology and Clinical Presentation

Current models postulate both peripheral and central components of therapy-induced nausea and vomiting. The peripheral pathway involves acute injury to the rapidly dividing cells of the gastric mucosa. The resultant cellular damage and accompanying inflammation cause the release of serotonin from gastric enterochromaffin cells into the gastric lumen, with subsequent activation of *serotonin S_3-receptors* in the gut wall and centrally in the brainstem vomiting center. Central stimulation of the vomiting center is also believed to occur when chemotherapy drugs directly stimulate the chemoreceptor trigger zone. A number of central receptors effecting emesis have been identified, including those responsive to *dopamine, endorphin, serotonin*, and *substance P*.

Most treatments produce *acute*, self-limited emesis that lasts only a few hours; however, the experience can be very uncomfortable, exhausting, and demoralizing. A milder, *delayed* emesis that can occur 1 to 5 days after therapy is most commonly seen with cisplatin therapy and is believed to be related to the development of gastritis and the persistence of active drug metabolites. Although less severe, it is discouraging and can impede nutrition. *Anticipatory* vomiting is a psychogenic behavioral phenomenon, derived from the association of severe emesis with the administration of cancer treatment. Nausea and vomiting can be brought on just by the anticipation of chemotherapy. *Refractory emesis* suggests a metabolic or anatomic complication of cancer or cancer therapy (see below).

Antiemetic Agents

Serotonin S_3-receptor Blockers (Ondansetron, Granisetron, Dolasetron) have proved effective in the prevention of both acute and delayed chemotherapy-induced nausea and vomiting. When the drugs are used alone, complete prevention of acute nausea and vomiting is achieved in about 40% to 50% of patients; more than 70% have no vomiting, but some nausea. When they are combined with a program of acute glucocorticoid therapy (e.g., *dexamethasone*), their prophylactic efficacy rises to 90% for prevention of emesis and to 70% for prevention of both nausea and vomiting. All three available serotonin blockers are similar in regard to efficacy and side effects, which include mild headache, mild dizziness, and a transient, clinically insignificant prolongation of electrocardiographic intervals. These drugs can be administered IV or orally. Ondansetron is the least expensive of the oral preparations (two 8-mg doses are administered orally); dolasetron is the least expensive IV agent.

Glucocorticoids have proved effective, especially in the prevention of delayed nausea and vomiting (perhaps because of their antiinflammatory effects). In controlled trials, they have outperformed phenothiazines in the prevention of acute emesis and have provided protection similar to that afforded by the serotonin-receptor blockers. They are superior to the latter in preventing delayed nausea and vomiting (50% rates of complete prevention vs. 30%) and provide enhanced control when used in combination with them. A typical program is a 4-mg oral dose of dexamethasone given just before chemotherapy, followed by three more doses given every 6 hours.

Metoclopramide blocks both dopaminergic and serotonin receptors, which accounts for its antiemetic action and its side effects. Given parenterally in high doses just before chemotherapy, it too can suppress emesis, but to a considerably lesser degree than the serotonin-receptor blockers (42% complete suppression vs. 75%). It is frequently used in combination with other agents, especially to prevent delayed emesis. Its dopaminergic blocking effect promotes gastric emptying and gastroesophageal sphincter closure but also leads to dystonia in young patients and mental confusion in older patients. It too is administered IV in a loading dose (1 to 3 mg/kg) 30 minutes before chemotherapy. It can be continued as a slow IV infusion, given as another dose 90 minutes after the first dose, or continued orally.

Substance P Blockade (Neurokinin-1-receptor Antagonists). The identification of substance P receptors in the central sites triggering emesis has led to the investigation of agents that block such receptors and inhibit substance P–mediated effects. Although such therapy is still investigational, initial trials of substance P blockers in combination with granisetron and dexamethasone show significant additional benefit, especially in the prevention of delayed emesis. More data on efficacy and safety should be forthcoming. If initial results are confirmed, then improved prevention of delayed emesis may soon be available.

Benzodiazepines potentiate the activities of the central inhibitory neurotransmitter g-aminobutyric acid (GABA) and can enhance the antiemetic effects of other agents. They also cause a desirable degree of mild amnesia. A short-acting preparation such as *lorazepam* is commonly given before chemotherapy. It too is best used as part of a combination program. Some prescribe an *antihistamine* (e.g., diphenhydramine) in place of a benzodiazepine. *Psychogenic vomiting* that occurs in anticipation of chemotherapy responds to IV lorazepam or oral alprazolam in conjunction with behavioral *desensitization* therapy; however, the best treatment is prevention of emesis at the outset of chemotherapy.

Phenothiazines, such as *prochlorperazine* (Compazine), are well established as a treatment for mild nausea and vomiting associated with other conditions, but they are less effective in chemotherapy if used alone. However, when combined with other antiemetic agents, they may help provide additional prophylaxis. Phenothiazines act centrally, blocking serotonin and dopamine receptors in the chemoreceptor trigger zone. Sedation accompanies their use and is often desired, but extrapyramidal symptoms may also ensue. They are available in oral, suppository, and parenteral forms. The route of administration has little influence on effectiveness. On the day of treatment, a prochlorperazine capsule or suppository is given 4 to 8 hours before the administration of chemotherapy and again on a regularly scheduled basis for the next 24 hours. The main drawback to phenothiazine therapy is the precipitation of extrapyramidal symptoms, which are most likely to occur when daily doses exceed 50 mg. Their onset necessitates discontinuation of therapy. Under such circumstances, the mild antiemetic *trimethobenzamide* (Tigan) is worth a try, although it is less effective than prochlorperazine. *Haloperidol*, a major tranquilizer that is not a phenothiazine, is similar to prochlorperazine in antiemetic and extrapyramidal effects. It blocks dopaminergic receptors. Side effects are similar to those of metoclopramide.

Cannabinoids and Marijuana were transiently popular, but they were found to be little better than phenothiazines and have been supplanted by more effective regimens with fewer side effects. Evidence suggests some antinausea and appetite-stimulant effects with the use of purified tetrahydrocannabinol, but no evidence that smoking crude marijuana is required to achieve these effects has been found.

Design of a Comprehensive Prophylactic Program

The optimal goal of antiemetic therapy is to prevent the nausea and vomiting associated with cancer therapy. This eliminates the dread of undergoing therapy and prevents any behaviorally triggered emesis. To design an effective prophylactic program, the physician must be familiar with the propensity of various agents to cause

emesis (Table 91.1) and the mechanisms and synergistic effects of available antiemetic drugs (Table 91.2).

Table 91.1. Chemotherapeutic Agents and Their Emetic Potential

Table 91.2. Combination Approach to Prophylaxis of Chemotherapy-Induced Emesis

A combination strategy takes advantage of the mechanistic synergistic effects afforded by administering effective drugs with different modes of action. More complete and extended prophylaxis, the use of lower doses of individual agents, and therefore a reduction in side effects become possible. For example, to treat a patient with anticipatory, acute, and delayed forms of emesis, an effective program might include a benzodiazepine(lorazepam), a serotonin-receptor blocker (e.g., ondansetron), and a corticosteroid (dexamethasone). Normal food intake before chemotherapy is encouraged because it minimizes retching on an empty stomach, which produces muscle cramps and pain. The chemotherapy schedule should comprise no more than two to three applications per month.

Refractory Emesis. A few treatable causes need to be considered when a patient presents with refractory emesis. Persistent vomiting can be a manifestation of *bowel obstruction* or severe *ileus*, which respond to decompression by *nasogastric suctioning. Hypercalcemia* and *hypokalemia* may be causes as well as consequences of vomiting; monitoring of electrolytes and correction of any imbalances can help lessen the anorexia, nausea, and vomiting that sometimes accompany them.

ANOREXIA AND WEIGHT LOSS

The cachexia of cancer is one of its hallmark manifestations, characterized by anorexia, early satiety, profound weight loss, and inanition. Maintaining adequate nutrition becomes very difficult in this situation.

Pathophysiology

Although multifactorial, *cachexia* has been strongly linked to elaboration of the macrophage-derived protein *cachectin* (also referred to as *tumor necrosis factor*), which is capable of inducing a wasting syndrome in animals and mediating adverse metabolic changes in human malignancy. Increased gluconeogenesis, excessive catabolism of body protein (especially muscle), abnormal fat metabolism, and abnormal substrate use have all been observed. In addition to cachectin, tumor-induced tissue breakdown, caloric wasting, and sequestration of protein-rich ascitic fluid in the abdomen may also contribute. Further aggravating the situation are disorders of digestion and absorption that are associated with malnutrition, obstructive lesions, and surgical therapies such as gastrectomy or intestinal bypass procedures. Abnormal caloric utilization is a consequence of tumor-related changes of metabolism, with food intake and lean body mass being channeled to support the caloric demands of the tumor.

The mechanisms behind *anorexia* remains incompletely understood. A paraneoplastic syndrome has been postulated, linked to a tumor-induced polypeptide that can affect the satiety center in the brain. Additionally, radiation and chemotherapeutic agents may contribute by distorting taste, causing stomatitis, and injuring the gastrointestinal mucosa and liver.

Management

The single most effective means of overcoming anorexia and cachexia is to achieve control of the underlying malignancy. In the interim, patients need practical suggestions that can be put to immediate use.

Dietary Measures. *Small, frequent feedings* (about six per day) of foods high in protein and calories should be advised. *Liquid dietary supplements* in the form of milk shakes and commercial preparations are excellent if tolerated. If nausea is prominent, the patient should be advised to try foods that are *salty*, beverages that are *cool* and *clear*, and desserts such as *gelatin* and *popsicles.* Dry foods such as *toast* and *crackers* also help. Dietitians recommend that the food be served in a *relaxed* family or group setting, *attractively prepared* and readily available. When *altered taste* makes food unpalatable, meat shouldbe avoided and dairy products substituted as the main source of protein. *Acidic foods* may stimulate the appetite when taste acuity seems to wane, as may *extra seasoning* and spicy foods. The use of *zinc* to treat dysgeusia has been reported, but results are not very impressive. Foods best to *avoid* when nausea is prominent include those that are overly *sweet, greasy*, or *high in fat.*

Medications. *Tricyclic antidepressants* (e.g., amitriptyline) have a nonspecific appetite-stimulating effect that is sometimes helpful and often independent of the antidepressant effect. *Corticosteroids* have sometimes been used to stimulate appetite, but their effect is transient and not worth the major side effects associated with the high doses and prolonged administration needed to achieve a sustained increase in appetite. *Megasterol* has been administered as an anabolic steroid with some success.

Treatment of Stomatitis. Stomatitis is an often overlooked cause of poor intake and weight loss. The management of chemotherapy-induced stomatitis includes avoidance of smoking, alcohol, and foods that are very hot, cold, spicy, or salty. A mixture of *Benadryl elixir* and *Kaopectate* used as a mouth wash is often helpful and well tolerated. *Chlorhexidine gluconate* is an antimicrobial oral rinse that can be used as a preventative, but a non–alcohol-based mouthwash is better once sores occur. *Viscous Xylocaine* preparations are not very helpful because they wash away quickly and thus provide only very transient relief; paste preparations last considerably longer. Unfortunately, taste can be distorted as a consequence of the topical anesthetic effect.

When radiation therapy to the head and neck results in *xerostomia* and *mucositis*, the dryness and thick secretions can be lessened by chewing gum or sucking on hard candy, which helps stimulate salivation. The use of gravies and avoidance of dry foods helps deglutition in patients whose salivary glands are damaged by

radiation. In refractory situations, artificial saliva preparations can be used.

MALNUTRITION

One of the most serious consequences of nausea, vomiting, and cachexia is malnutrition. A self-perpetuating and debilitating cycle of food rejection and malnutrition weakens host immune defenses and permits further tumor growth. Moreover, host tolerance to radiation and chemotherapy is compromised, so that the ability to tolerate therapeutic doses of either form of treatment is restricted. The goals and methods of nutritional therapy vary according to the patient's clinical situation. In most instances in which gastrointestinal function remains intact, minor dietary alterations and oral dietary supplements are sufficient. More elaborate means of nutritional support are sometimes necessary and appropriate on a temporary basis to tide the patient over a difficult period. Such therapy is rarely indicated in the very late stages of cancer.

Detection. Recognition of mild to moderate malnutrition is important. Manifestations include a 10% weight loss, serum albumin level below 3.5 g/dL, total lymphocyte count of less than 1,500/mm^3, and serum creatinine level that is low for the patient's size. More severe malnutrition is characterized by further weight loss, a serum albumin level below 3.0 g/dL, and a lymphocyte count of less than 1,000/mm^3.

Use of Supplements. For patients who have upper alimentary discomfort but can still swallow liquids, a *nutritionally complete liquid preparation* may offer a more comfortable and palatable means of keeping well nourished. These preparations are available commercially and are reasonably well tolerated. Most contain all the necessary vitamins and minerals. Lactose-free formulations are available for those who may have acquired lactose intolerance. Blenderized meals are another alternative.

Hyperalimentation. More intensive temporary nutritional support is worth considering during difficult phases of cancer therapy, although evidence of cost-effectiveness is often wanting and indiscriminate use can be counterproductive and increase morbidity. Most controlled studies of hyperalimentation and other nutritional therapies have failed to demonstrate any significant improvement in response to chemotherapy or radiation, lessening of side effects of these treatment modalities, prolongation of survival, or improved tolerance to higher doses or longer periods of treatment. However, the selective use of hyperalimentation may be of benefit in some instances.

Enteral hyperalimentation is utilized for the nutritional support of malnourished patients with an obstructed or injured upper alimentary tract, provided the remainder of the gastrointestinal tract is intact. Such hyperalimentation is particularly well suited to patients recovering from radiation or surgery in the upper alimentary tract. A feeding tube is either passed or surgically placed beyond the point of obstruction or injury. An enteral hyperalimentation program can then commence. The use of long (43-in), flexible silicon nasal feeding tubes makes it possible to administer feedings directly into the distal duodenum or proximal jejunum, so that the risks for aspiration and reflux that occur with gastrostomy feedings are avoided. When a feeding tube cannot be passed nasally, feedings can be administered through a jejunostomy.

Enteral hyperalimentation utilizes milk-based and soy-based formulas, in addition to less viscous formulations, although sometimes a pump is needed. The formulas are quite hypertonic and must be started at less than full strength (usually at half-strength) and increased during several days, as tolerated. Cramps, symptoms of dumping syndrome (flushing, tachycardia, sweating), and diarrhea are the major manifestations of intolerance. The goal is a daily intake of 2,000 to 3,000 calories.

Total parenteral nutrition is an alternative form of nutritional support reserved for short-term use in persons whose oral or enteral intake is likely to be inadequate for more than 10 to 14 days. The best evidence for its efficacy is in severely malnourished cancer patients about to undergo surgery; morbidity and mortality are reduced with preoperative administration of total parenteral nutrition. It can be carried out *at home* so long as the patient and family are capable of mastering the procedures necessary to ensure the sterility of the line and integrity of the infusion apparatus. Visits by a hyperalimentation nurse are also helpful. The access site can be maintained as a heparin lock, which allows the patient to disconnect easily from the infusion. About 12 to 14 hours are needed for infusions daily, which areadministered as solutions containing 4.2% or 5.2% amino acids and 20% to 25% glucose. The infusion schedule provides the patient with 10 to 12 hours of independence each day and an opportunity to ambulate. Careful monitoring of metabolic parameters, including glucose, calcium, phosphate, magnesium, blood urea nitrogen, and creatinine levels, is essential, as is close coordination with a hyperalimentation consultant.

DIARRHEA AND CONSTIPATION

Diarrhea is another gastrointestinal nemesis familiar to cancer patients. When it ensues from radiation- or chemotherapy-induced enteritis, the problem is usually self-limited, resolving within the 1 to 2 weeks needed for the mucosal surface to reconstitute itself. If it is persistent or troublesome, low doses of *diphenoxylate* (Lomotil) or nonprescription *loperamide* (Imodium) can be prescribed for symptomatic relief (see Chapter 64). *Steatorrhea* is experienced by patients who have undergone pancreatectomy or who have pancreatic insufficiency; intake of several *pancreatic enzyme* tablets with each meal (see Chapter 72) usually alleviates the problem. The postgastrectomy patient is at risk for the symptoms of the *dumping syndrome*. Avoidance of *sweets* and large *fluid volumes* (especially those rich in sugar) helps prevent attacks, as does lying down after a meal (see Chapter 64).

Constipation can be a very troublesome and often unavoidable consequence of *narcotic use* for pain control. However, prophylactic institution of some simple measures can help prevent disabling symptoms and fecal impaction. These include a *high-fiber diet*, good *fluid intake* (at least 2 L/d), use of *stool softeners* (e.g., dioctyl sodium sulfosuccinate), and, if necessary, administration of a gentle *laxative* before bed (e.g., 15 mL of milk of magnesia). Constipation may also be a sign of *obstruction* in the lower intestinal tract or ileus, conditions that need to be ruled out before laxative therapy is escalated. *Hypokalemia* and *hypercalcemia* are two other important causes that deserve attention.

MALIGNANT ASCITES

Ascites may occur as a complication of diffuse peritoneal implantation or the combination of portal venous hypertension and hypoalbuminemia. When it is caused by peritoneal implants and the primary is unknown, one should consider treatable malignancies such as ovarian cancer. Occasionally, the ascites will cause disabling symptoms such as marked abdominal distention and pain. Only in debilitating circumstances should it be treated. The most direct means is *therapeutic paracentesis*. Recent experience with large-volume paracentesis suggests that it can be performed with safety so long as care is taken to preserve intravascular volume. About 4 to 6 L of ascitic fluid is removed slowly during 60 to 90 minutes. (An infusion of albumin is administered simultaneously in severely hypoalbuminemic patients.)

Large-volume therapeutic paracentesis has reduced the need for *peritoneal venous shunting*, which is associated with a high rate of complications, including encephalopathy, disseminated intravascular coagulation, peritonitis, sepsis, and superior vena cava syndrome (see Chapter 71). Shunting should be considered only in the most refractory and disabling of cases. The use of surgical drainage for ascites is not as effective as it is for effusions of the pleural space. Similarly, intraabdominal instillation of chemotherapeutic agents and radioisotopes has been relatively ineffective. Sclerosing drugs and irritants to seal the peritoneal space are not recommended because an irritant effect on the bowel may result in necrosis, perforation, or secondary fibrosis and adhesions leading to obstruction.

PERITONEAL IMPLANTS, BOWEL OBSTRUCTION, AND FISTULAS

Peritoneal implants within the abdominal cavity may develop in a diffuse miliary pattern or coalesce into large mass lesions capable of causing obstruction. A surgical *bypass* procedure or regional surgical resection (*"debulking"*) is indicated under such circumstances for palliation when there is some hope of prolonging meaningful survival. For patients with an indolent malignancy, particularly those with a localized point of obstruction, an aggressive surgical approach is worthy of consideration. When implants are centered in the pelvic area, fistulas communicating with the bladder or skin may form; local *surgical excision* or *radiation therapy* can help control the problem.

OBSTRUCTIVE JAUNDICE

Surgery used to be the traditional treatment, but it is often not feasible in patients with extensive disease of the porta hepatis extending into the liver. More recently, endoscopic or percutaneous *placement of a stent* has provided a less invasive alternative. The procedure should be attempted only by persons skilled in placement of such stents. Major complications do occur, particularly recurrent cholangitis. The procedure can be uncomfortable, and the stents tend to become dislodged. However, if the procedure is successful, significant palliation and an improved quality of life can result for the patient willing to undergo stent placement.

Radiation therapy has also been used to treat obstructive jaundice caused by tumor in the porta hepatis. It is particularly useful in patients with radiosensitive neoplasms (e.g., breast cancer, lymphoma).

CHAPTER 92 COMPLICATIONS OF CANCER: ONCOLOGIC EMERGENCIES AND PARANEOPLASTIC SYNDROMES

The complications of cancer are great in number and variable in degree of urgency. They range from commonly experienced gastrointestinal difficulties and pain syndromes (see Chapter 90 and Chapter 91) to true emergencies, stubborn malignant effusions, and the uncommon, but important, paraneoplastic phenomena. Most oncologic emergencies and malignant effusions are consequences of anatomic spread. Paraneoplastic syndromes result from hormonal and immunologic disturbances. The primary care physician's important role in monitoring the cancer patient requires familiarity with the early presentations of these complications, many of which are amenable to intervention. In most instances, hospital admission for inpatient treatment will be necessary, so the emphasis is on early detection.

ONCOLOGIC EMERGENCIES AND URGENCIES

The anatomic spread of tumor is capable of causing emergent complications, including spinal cord compression, cardiac tamponade, and hypercoagulability with acute bleeding or clotting. Urgent adversities associated with malignancy ensue from a combination of tumor invasion and metabolic/immunologic effects (e.g., superior vena cava syndrome, hypercalcemia, fever, infection).

Spinal Cord Compression

Extradural or epidural cord compression occurs in approximately 5% of patients with cancer. It is a *true emergency*, with early diagnosis and treatment essential to preventing serious, permanent neurologic damage. The majority of cases of epidural compression result from bony metastases in the vertebral bodies extending into the epidural space. Less frequently, metastatic tumor reaches the epidural space hematogenously or by direct extension through the intervertebral foramina. Malignancies with a propensity to spread to bone (e.g., myeloma, lymphoma, melanoma, renal cell carcinoma, and tumors of lung, breast, and prostate) are associated with the greatest risk for cord compression. Lymphoma may metastasize directly to the epidural space and not produce any bony changes. In more than 90% of cases, the initial symptom is *back pain*, often radicular in nature. The course is progressive; weakness and sensory deficits in the extremities follow. Sphincter incontinence is a late development, unless the cauda equina is the initial site of compression.

Diagnosis. *Plain films* of the spine should be obtained in all cancer patients with back pain. If the radiographic findings are normal in the area of pain, the patient does not have lymphoma, and no neurologic deficits are present, no further workup need be carried out immediately, but the patient should be followed closely. If the radiographic findings are abnormal or if neurologic deficits are noted, then immediate hospital admission and prompt neurologic and oncologic consultations are needed.

Magnetic resonance imaging (MRI) is the diagnostic procedure of choice, being the most sensitive and least invasive of the imaging procedures, especially when gadolinium enhancement is used. It allows identification of all affected areas without theneed for injection of contrast into the spinal canal. If MRI is not available, imaging of the spinal cord can also be performed by standard *myelography* with iodinated contrast or by *computed tomography* (CT) with water-soluble contrast. The use of a nonresorbable iodinated dye for the myelogram allows follow-up films to be obtained conveniently without the need for repeated injections of dye, but the thick dye does not always pass an obstructing lesion, so that multiple procedures are sometimes necessary to assess different sites. Use of a water-soluble dye (metrizamide) plus CT may provide better definition of an obstructing lesion. If myelography is performed, a sample of cerebrospinal fluid should be obtained at the time of lumbar puncture and sent for cytology, cell count, and determination of protein and glucose levels.

Treatment. *High-dose corticosteroids* (e.g., 4 mg of dexamethasone every 6 hours) and *radiation therapy* are the mainstays of treatment, with *surgical decompression* indicated when neurologic function deteriorates rapidly. Patients with myeloma, lymphoma, or small-cell cancers respond well to irradiation. Chemotherapy is worth considering in those with multifocal obstructing disease. The prognosis depends on the extent of neurologic damage at the time of presentation. Patients who are ambulatory have a 60% to 80% chance of leaving the hospital able to walk; those with paraplegia have less than a 20% chance of regaining their ability to walk.

Meningeal Carcinomatosis. Diffuse seeding of the meninges with malignant cells is a serious complication of a number of solid tumors (lymphoma, melanoma, cancers of breast, lung, and stomach) and leukemias. Even if true cord compression is not present, the entire neuraxis may become involved, with the development of meningeal, cranial nerve, and root symptoms. The diagnosis is confirmed by lumbar puncture, which typically reveals malignant cells in the cerebrospinal fluid. Corticosteroids, irradiation, and intrathecal administration of cytotoxic agents are the treatment modalities of choice.

Cardiac Tamponade

Life-threatening tamponade may arise as a complication of malignancy, either indolently or rapidly, depending on the progression of the underlying tumor. Compression may be caused by tumorous encasement, malignant effusion, or scarring from radiation-induced pericarditis. Cancers associated with tamponade include tumors of the breast and lung, lymphoma, leukemia, and melanoma. In some instances, symptoms and signs of pericarditis (see Chapter 20) precede those of tamponade. The presence of *pulsus paradoxus* strongly suggests significant tamponade. Unexplained elevation of neck veins, narrowed pulse pressure, inspiratory distention of neck veins, and a pericardial friction rub should raise suspicion. Unfortunately, a pericardial friction rub is often absent in cases of tamponade caused by a malignant pericardial effusion. The usual accompanying symptoms (dyspnea, weakness, chest discomfort, cough) are nonspecific. More definitive diagnosis is best made by *cardiac ultrasonography*, the most sensitive and specific noninvasive test for documenting the problem and its physiologic significance.

A strong clinical suspicion of tamponade necessitates urgent hospitalization for prompt sonography and cardiac consultation. Sometimes a right-sided heart catheterization is performed when the degree of tamponade is unclear or the diagnosis is still questionable. *Pericardiocentesis* is the treatment of choice for urgent tamponade and may also yield positive cytology.

Hypercoagulability

A number of the natural inhibitors of clotting, many of which are endothelial in origin (protein C, protein S, tissue plasminogen factor, antithrombin III), are disrupted directly by tumor invasion or indirectly by substances elaborated by cancers. Patients with adenocarcinomas appear particularly susceptible to recurrent or migratory *thrombophlebitis* or even thrombotic arterial occlusions. A more disseminated consumption coagulopathy (*disseminated intravascular coagulation*, or DIC) sometimes develops and can present acutely as a generalized bleeding diathesis. Acute DIC is a true medical emergency. Suggestive laboratory findings include prolongations in the prothrombin time, partial thromboplastin time, and thrombin time, a low platelet count, and elevated concentrations of fibrin split products. The peripheral smear shows a microangiopathic picture (schistocytes). Chronic DIC is more subtle in presentation, with thrombotic end-organ damage and thrombosis being the principal manifestations. Acute DIC requires immediate hospitalization to stop the bleeding. Platelet and plasma transfusions are given to replace those blood elements that have been consumed. More definitive therapy requires treatment of the underlying malignancy.

Superior Vena Cava Syndrome

Obstruction of the superior vena cava is usually caused by extrinsic compression. The majority of cases are associated with bronchogenic carcinoma (especially small-cell carcinoma), lymphoma, and metastatic disease. The earliest manifestation is asymptomatic, unexplained *distention of the neck veins*. Late signs include swelling of the face, neck, and upper extremities, plethora, shortness of breath, and persistent headache. Although the condition is rarely fatal, increased intracranial pressure and thrombosis leading to neurologic deficits may ensue. The clinical diagnosis is reinforced by the finding of a mass on chest radiography in the right superior mediastinum or hilar area. Venography and other flow studies are unnecessary in most instances.

At one time, it was considered essential to treat the mass immediately with emergency *radiotherapy*. Now, the view is one of *urgency* rather than emergency. The first task is to consider whether a *tissue diagnosis* should be obtained before radiotherapy is instituted (see Chapter 44), as a host of tumors with different degrees of radiosensitivity may be responsible for the condition. Although many malignancies respond within 1 week to radiation, some may respond better to chemotherapy, and

occasionally a nonmalignant process that would not benefit from radiation is the cause (e.g., tuberculous adenopathy, substernal goiter). When a tissue diagnosis will alter therapy, invasive study to obtain tissue should proceed. If a small-cell carcinomaor lymphoma is found, *chemotherapy* might be placed ahead of radiation as the treatment of choice (see Chapter 53 and Chapter 84).

Optimal therapy depends on the underlying diagnosis, prior treatment, and overall clinical status of the patient. Diuretics and corticosteroids can occasionally diminish local symptoms, but the effect is transient, and these agents are no substitute for more definitive therapy. The use of heparin provides no benefit. The occurrence of superior vena cava syndrome does not worsen the prognosis (if adjusted for stage of disease), particularly in cases of small-cell lung cancer.

Hypercalcemia

Hypercalcemia is a accompaniment of advanced carcinomas with extensive *lytic bony involvement* (breast cancer, myeloma, hematologic malignancies) and also a complication of epidermoid cancers (renal cell, ovarian, bladder, head and neck, and epidermoid and squamous cell lung cancers) with little or no bony metastasis. In the latter case, hypercalcemia has been linked to tumor elaboration of a protein with some parathyroid hormone–like activity (*parathyroid hormone–related protein*, or PTHRP). Cancers that invade bone and trigger a blastic response (e.g., prostate, oat cell cancers) are rarely associated with hypercalcemia.

Monitoring the serum calcium level provides the simplest means of early detection. Initially, the patient is asymptomatic. Later, such nonspecific symptoms as weakness, fatigue, lethargy, nausea, and constipation ensue. If the hypercalcemia progresses, it leads to an osmotic diuresis manifested by thirst and polyuria. The electrocardiogram may undergo change, with prolongation of the PR interval, shortening of the QT interval, and widening of the T wave. Dysrhythmias become a risk at very high calcium levels. Calcium potentiates the effects of digitalis and can trigger digitalis toxicity.

Hospitalization is needed if one decides to treat the hypercalcemia. (When it occurs in the setting of terminal illness, therapy may not be indicated.) One begins vigorous rehydration with *IV saline solution*, followed by *furosemide* to accelerate saline diuresis. *Calcitonin* also rapidly reduces serum calcium levels, but daily injections are required, and tachyphylaxis may be induced. *Corticosteroids* are useful for acute–subacute management, especially in cases of myeloma, lymphoma, and metastatic breast cancer. Long-term control can be achieved with the use of *bisphosphonates*; second-generation agents (e.g., *pamidronate*) are more effective than first-generation drugs (e.g., etidronate). Treatment of the underlying tumor remains the most definitive measure. Even with control of hypercalcemia and relief of symptoms, prognosis is poor and life expectancy limited.

Fever in the Setting of Neutropenia

Infection ranks as the leading cause of death in patients with leukemia and the cause of death in half of those with lymphoma and solid tumors.

Malnutrition, immune dysfunction, mechanical compromise, and a lowered neutrophil count (mostly caused by cytotoxic therapy) all contribute to the high risk of mortality from infection. Neutropenia is defined in cancer patients as granulocyte counts of less than 500/mL, the minimum needed to counter infection. Prophylactic therapy with *granulocyte colony-stimulating factor* (G-CSF) is being used to prevent neutropenia and lower the attendant risk of infection, but G-CSF is not effective as a treatment for febrile neutropenia.

Patients in whom fever develops during periods of neutropenia should be considered infected until proven otherwise. The majority of neutropenic cancer patients with fever will have a bacterial infection (often caused by a gram-negative organism). The possibility of viral, fungal, or parasitic infection is increased in patients who have leukemia or who are on long-term steroid therapy or prolonged broad-spectrum antibiotic coverage.

Often, neutropenic patients lack the usual signs of inflammation, which makes it hard to determine the site of infection at the time of presentation. Bacteremia without an identifiable primary site and pneumonitis lead the list of presentations. Onset of fever in the neutropenic patient is an indication for *prompt hospitalization*, regardless of whether or not any additional signs of infection are present. The mortality in such patients ranges from 18% to 40% within the first 48 hours. Outpatient management is not appropriate.

Once the patient is admitted, cultures of urine, sputum, and blood samples will be needed, as will samples of material from any suspected site (e.g., cerebrospinal fluid). In the absence of an identified pathogen, broad-spectrum antibiotic therapy is initiated, often with a *third-generation cephalosporin* (e.g., *ceftazidime*) or a *semisynthetic penicillin* (e.g., *imipenem*); an *aminoglycoside* is added when *Pseudomonas* infection is a concern. The short-term prognosis for patients treated early and aggressively is good. With the aggressive use of antibiotics, 60% to 90% of neutropenic, febrile cancer patients will recover from their infection.

Malignant Effusions

Some malignant effusions can be life-threatening (e.g., those in the pericardium; see above). Others are an important source of discomfort and disability.

Malignant ascites can lead to marked abdominal distention and respiratory compromise; treatment is supportive in most instances because the finding is a sign of end-stage disease. No randomized trials have compared treatment options, which range from peritoneal–venous shunt to intermittent drainage to medical management. Also largely unknown is the benefit of intracavitary versus systemic antitumor therapy. A wide range of agents have been tried intraperitoneally, but results are modest at best. Although peritoneal–venous shunting was at first applied with enthusiasm, an increased recognition of its risks (infection, DIC, venous thrombosis) and disappointing performance (frequent shunt clogging and failure) have limited its application. Only a small subset of patients (life expectancy longer than 3 months; nonloculated, nonbloody, viscous ascitic fluid; uncomfortably rapid reaccumulation of fluid despite repeated paracentesis and medical therapy) should be considered for shunting (see Chapter 91).

Malignant pleural effusions resulting from pleural implants or lymphatic obstruction can impair respiration. Lung, breast, and ovarian cancers are important causes of pleural implants; lymphomas lead to lymphatic obstruction. The optimal therapy is systemic treatment of the underlying malignancy. Repeatedthoracentesis is ineffective and associated with considerable morbidity. Definitive local therapy requires placement of an indwelling chest tube for several days to allow thorough drainage and closure of the third space. Instillation of a sclerosing agent (e.g., tetracycline) after drainage promotes the scarring process and helps to limit reaccumulation of exudate.

Thrombocytopenia and Bleeding

(See Chapter 81.)

PARANEOPLASTIC SYNDROMES

Ectopic Hormone Syndromes

Small-cell (oat cell) carcinoma of the lung is the archetypal tumor capable of ectopic hormone production. A variety of other tumors may behave in similar fashion. One or more polypeptides may issue forth from the tumor and lead to such complications as Cushing's syndrome and inappropriate secretion of antidiuretic hormone (ADH).

Cushing's Syndrome develops in approximately 5% of patients with small-cell carcinoma of the lung because of the ectopic production of *adrenocorticotropic hormone* (ACTH), although some degree of ectopic ACTH synthesis may take place in as many as 80% of patients with the tumor. The clinical syndrome can be subtle and is usually not manifested by the typical cushingoid appearance; rather, it is characterized by *increased pigmentation* and metabolic and immunosuppressive effects, such as severe, recalcitrant *hypokalemia* and *impaired resistance* to infection. The hypokalemia requires extraordinary doses of supplemental potassium and the use of spironolactone. Serum and urinary ketosteroids are especially abundant, with some patients demonstrating virilization. Metabolic inhibitors of adrenal hormone synthesis (metyrapone, mitotane, amino-glutethimide) have been tried; success has been variable. The prognosis is very poor; median survival is less than 2 months.

Syndrome of Inappropriate Secretion of Antidiuretic Hormone is not unique to cancers, but small-cell carcinomas (about 10% of cases) and a host of other cancers are capable of elaborating a polypeptide with ADH activity. The earliest manifestations are *hyponatremia* and renal sodium wasting. *Urine osmolality is*

inappropriately elevated. If the serum sodium falls to very low levels, confusion and disorientation may ensue. Treatment includes the use of *lithium carbonate* or *demeclocycline*, two agents that counter the action of ADH. A *restricted intake of free water* also helps to restore the serum sodium level. Infusions of hypertonic saline solution are to be avoided because these patients, although not edematous, tend to be volume-overloaded. However, diuretics are contraindicated because of sodium depletion. Inappropriate secretion of ADH is rapidly reversible with effective *treatment of the underlying tumor.*

Hypercalcemia associated with epidermoid cancers is, as noted above, caused by the ectopic production of PTHRP, a protein with *parathyroid hormone–like activity.* Unlike the hypercalcemia of osteolytic disease, the hypercalcemia associated with epidermoid cancers is characterized by elevations in urinary cyclic adenosine monophosphate and serum PTHRP. Because symptoms may not develop until the serum calcium becomes markedly elevated, routine monitoring of the serum calcium is the best means of early detection and is worthwhile in patients with tumors that frequently lead to this complication (squamous cell cancers of the head, neck, and lung; ovarian cancer; bladder cancer; hypernephroma). The diagnosis requires a high index of suspicion and direct testing for PTHRP; the protein is too different structurally from parathyroid hormone (PTH) to be detected by standard assays for PTH. Symptomatic relief can be achieved acutely by lowering the serum calcium (see above and Chapter 96). Treatment of the underlying cancer is more definitive.

Hyperthyroidism and Acute Thyrotoxicosis have resulted from ectopic production of chorionic gonadotropin (which functions like thyroid-stimulating hormone). Choriocarcinomas are the main source of the overproduction. Patients can present with all the typical hypermetabolic manifestations of thyrotoxicosis. b-Blockers are only modestly effective; primary treatment must be directed at the tumor.

Others. The ectopic production of *human chorionic gonadotropin* by testicular and lung cancers is sometimes sufficient to cause *gynecomastia. Fasting hypoglycemia* is a classic manifestation of insulinoma and a rare complication of sarcoma.

Immunologically Mediated Paraneoplastic Syndromes

A series of syndromes, mostly neurologic in nature, have been linked to aberrations in immune function. The precise identification of the mediator or immune complex has not been possible in all instances; at times, the link to an immune mechanism is merely speculative.

Myasthenic (Eaton-Lambert) Syndrome occurs most commonly in patients with small-cell carcinoma of the lung and characteristically results in *proximal muscle weakness* of the limbs. Its electromyographic pattern is distinct from that of true myasthenia, being characterized by facilitation and an increasing evoked muscle potential. Clinical management includes the administration of *guanidine*; the anticholinesterases used to treat myasthenia do not work.

Subacute Cerebellar Degeneration is another remote neurologic syndrome, characterized by injury to the Purkinje cells of the cerebellum. Ataxia, dysarthria, dysphagia, and even dementia may comprise the clinical picture. It has been associated most commonly with small-cell carcinoma of the lung and with ovarian and breast cancers.

Peripheral Neuropathy is the most common form of neurologic deficit in cancer. The mechanism(s) are poorly defined but likely to be multifactorial. The most typical is a symmetric sensory neuropathy seen in patients with advanced malignant disease. Motor and mixed sensory and motor neuropathies have also been described.

Paraneoplastic Syndromes of Unknown Etiology

A host of other purportedly paraneoplastic syndromes have been described, linked to malignancy by the fact that symptoms recede with effective treatment of the underlying tumor. A tumor secretory product or other mechanism has not yet been identified.

Hypertrophic Pulmonary Osteoarthropathy presents with the findings of digital clubbing and tenderness along the distal long bones. Most commonly, the syndrome occurs in the setting of primary or metastatic lung tumors. Radiography of the long bones shows an elevated periosteum, and radionuclide scanning demonstrates a distinctive pattern of increased uptake along the cortical margins. The exquisite pain accompanying these changes is relieved by removal of the tumor. The mechanism of the syndrome remains unknown.

Hyperpyrexia and Tumor-related Fever have been observed in patients with hepatic metastases, typically from colon cancer, and also as a manifestation of the "B" syndrome associated with Hodgkin's disease. The release of pyrogens from tumor has been proposed as the cause of fever, but other possibilities include the inability to detoxify endogenous endotoxin and an alteration in the metabolism of fever-producing steroids. The fever can be controlled with the administration of *NSAIDs*, which can also serve as a diagnostic test for the condition.

Nephrotic Syndrome. In some patients with Hodgkin's disease, massive edema with proteinuria and hypoalbuminemia develops. The renal lesion appears as an accumulation of immune complexes along the basement membrane. The nature of the antigen is unknown. The problem does not respond to steroid therapy but does regress with control of the malignancy.

Cachexia. (See Chapter 91.)

Cutaneous Paraneoplastic Syndromes

Cutaneous paraneoplastic syndromes are quite rare, but they are important to recognize as clues to the presence of internal malignancy. They may be a consequence of hormone secretion, such as the hyperpigmentation or *melanosis* associated with ACTH-producing tumors or the *necrotizing erythema* seen with glucagon-secreting malignancies of the pancreas. The proliferation of *seborrheic keratoses* can be a sign of internal malignancy; *acanthosis nigricans* or freckling and hyperpigmentation in the axillary folds suggest neurofibromatosis and intestinal cancer. *Acquired ichthyosis* is associated with lymphomas and several other tumors.

PART 7 ENDOCRINOLOGIC PROBLEMS

CHAPTER 93 SCREENING FOR DIABETES MELLITUS

Diabetes is, after obesity and thyroid disease, the most common metabolic disorder seen by the primary care physician. Patients' concerns about the possible need for insulin injections and about such well-known complications as blindness, kidney disease, premature vascular disease, and impotence make diabetes one of the most feared diagnoses. Detection campaigns and advertising have further heightened public awareness. Diabetes screening is commonly requested by patients, even in the absence of symptoms or risk factors. There is no question that treatment effectively reduces symptoms associated with the metabolic derangements induced by diabetes. Results of the Diabetes Control and Complications Trial (DCCT) have definitively answered long-standing questions about the reduction in complication rates that can be achieved with intensive efforts to control glucose level, at least for type 1 disease. Less definitive but consistent results are also available for type 2 disease from the U.K. Prospective Diabetes Study Group. Nevertheless, the benefits of treatment initiated in the asymptomatic phase have not been demonstrated. Furthermore, labeling a patient "diabetic" on the basis of results of a nonspecific screening test may be harmful. Although some advise screening for high-risk groups, uncertainty about the natural history of diabetes and its complications precludes making definitive recommendations.

EPIDEMIOLOGY AND RISK FACTORS

Diabetes mellitus is heterogeneous. The destruction of b-cells in the islets of Langerhans through a number of pathophysiologic mechanisms is responsible for the clinical syndrome of type 1 mellitus, previously referred to as *insulin-dependent diabetes* (IDDM). The etiology and pathogenesis of type 2 diabetes, previously called *non–insulin-dependent diabetes mellitus* (NIDDM), may be even more heterogeneous; multiple lesions include a blunted b-cell response to glucose, a defect at the insulin receptor, and a defect in hepatic uptake of glucose that contributes to glucose intolerance. Depending on the diagnostic criteria used, the prevalence of all types of diabetes in the United States is between 3% and 7%; type 2 diabetes is nearly 10 times more common than type 1 diabetes.

Type 1 Diabetes is generally manifested in childhood or early adulthood. Only 20% of patients with type 1 diabetes have a first-degree relative with diabetes. However, a predisposition to type 1 diabetes, apparently mediated through the immune system, is inherited. This pathologic predisposition to autoimmune destruction of the b-cells has been linked to the presence of certain HLA antigens, some of which are also associated with other autoimmune diseases, including Hashimoto's thyroiditis and Addison's disease. Conversely, other HLA antigens seem to be associated with protection against diabetes. Overall, the risk for eventual development of diabetes in a sibling of a patient with type 1 disease is between 3% and 6%. However, the risk for siblings can be defined by comparing HLA antigens with those of the index case. Although siblings who are HLA-identical to the diabetic patient face a risk for diabetes that is 25 times greater than that of the general population, the relative risk for those who share no antigens or are haplo-identical is only two or three times greater. The role of autoimmune destruction of b-cells in many patients with type 1 diabetes is attested to by the presence of islet cell antibodies in a large proportion of newly diagnosed cases. Islet cell antibodies can also be detected in nondiabetic relatives of patients with type 1 disease.

At least in some cases, islet cell destruction is the result of viral infection, which perhaps initiates the autoimmune response. coxsackieviruses, particularly coxsackievirus B4, have been most strongly implicated. Mumps virus, cytomegalovirus, Epstein-Barr virus, and hepatitis viruses have also been associated with type 1 diabetes. The role of viral infection has been linked to a seasonal variation in the incidence of type 1 disease and has raised questions about a relationship between socio-economic status and risk for type 1 diabetes, but the evidence is equivocal.

Type 2 Diabetes has a much stronger *genetic component* than does type 1 diabetes; concordance in identical twins is greater than 90%. The genetic link is not related to HLA antigens, and islet cell antigens are no more prevalent than in the general population.

The overwhelming risk factor for type 2 diabetes is overnutrition and resulting *obesity*. Eighty percent of diabeticadults are obese or have a history of obesity. Among adults who are at least 25% over their ideal body weight, one of every five has elevated fasting blood sugar levels, and three of every five have abnormal results on glucose tolerance tests. Obesity increases insulin levels and decreases the concentration of insulin receptors in tissue, including skeletal muscle and fat. The relationship between the concentration of insulin receptors and glucose tolerance is modified, however, by intracellular sequences following insulin binding that are poorly understood. Exercise increases the concentration of insulin receptors, and a *sedentary life-style* is associated with glucose intolerance. Regular exercise has been shown to be associated with a decreased incidence of type 2 diabetes after adjustments for body mass index.

Steroids reduce receptor affinity for insulin, as do uremia and hepatic failure. Other drugs can impair glucose tolerance by further diminishing the sluggish response of b-cells to glucose. These include *thiazide* diuretics, b-adrenergic blockers, a-adrenergic stimulants, and phenytoin. Prostaglandin inhibitors, including indomethacin and salicylate, may increase b-cell release of insulin.

Persons with *impaired glucose tolerance* are also at greater risk for frank type 2 diabetes (see below). Although long-term follow-up studies indicate that as many as half of those with impaired glucose tolerance will have normal glucose tolerance test results 5 to 10 years later, somewhere between 1% and 5% of these patients become diabetic each year.

In approximately 3% of previously euglycemic women, glucose intolerance develops during pregnancy. The fetal hyperglycemia and hyperinsulinemia that accompany maternal diabetes result in increased neonatal morbidity and mortality and the increased birth weight common in infants of diabetic mothers. *Gestational diabetes* in the mother resolves after delivery in 90% of cases, but type 2 diabetes eventually develops in more than half of these women.

NATURAL HISTORY OF DIABETES AND EFFECTIVENESS OF THERAPY

The natural history of diabetes mellitus has been difficult to define because the condition is so heterogeneous. This problem has historically been confounded by studies that have defined diabetes according to varying degrees of glucose intolerance.

The natural history of asymptomatic impaired glucose intolerance is variable; only 15% to 30% of these patients progress to frank diabetes during 10 to 15 years. Patients with impaired glucose tolerance are at increased risk for the development of the macrovascular complications that result from accelerated atherogenesis. However, unless glucose intolerance progresses to frank diabetes, characteristic diabetic microangiopathy does not develop in these patients.

The *asymptomatic detectable period* seems to be much shorter for type 1 diabetes than it is for type 2 diabetes. Despite some evidence for a longer asymptomatic period than was previously estimated, the markedly lower prevalence of asymptomatic type 1 diabetes, in comparison with type 2 disease, makes such patients a very small target for screening efforts.

The incidence of *vascular* and *neurologic complications* clearly tends to increase with the duration of clinical diabetes. However, some long-term studies of patients followed for as long as 40 years have indicated that clinical evidence of microvascular disease, atherosclerosis, or neuropathy may occur in only 20% to 40% of type 1 patients.

The increased risk for vascular and neurologic complications is reflected in the relative mortality rates of diabetics. The relative risk for death of diabetic patients, in comparison with that of age-matched nondiabetic persons, increases with the duration of known disease. In one study of patients followed for up to 25 years, the increase in mortality risk with increased duration was greater after age 40 and among women. *Coronary artery disease* is the most common cause of death among diabetics. Autopsy studies indicate that coronary disease is two to three times more common among diabetics than in nondiabetics. Peripheral vascular disease is also very common among diabetics; clinical studies have indicated a prevalence of about 60%. Diabetics in the Framingham study were shown to be four to five times

more likely to have *intermittent claudication* and two to three times more likely to suffer the morbid consequences of stroke than were nondiabetics. On the other hand, the presence of peripheral vascular disease in a nondiabetic person increases the risk for eventual development of NIDDM.

Retinopathy is the most common specific complication of diabetes. In general, the incidence of retinopathy increases with the duration of diabetes, regardless of age at onset. Prevalence ranges of 40% to 80% have been reported among patients with known diabetes lasting 20 to 30 years. In one study of patients whose diabetes began before age 30, nearly all had retinopathy 25 to 30 years later and about 50% had proliferative changes. Retinopathy was less prevalent among those whose diabetes began later in life and those not receiving insulin. Laser photocoagulation has been shown to decrease the progression of diabetic retinopathy. However, this does not provide a basis for recommending screening for diabetes; retinopathy that warrants treatment is very rare early in the course of disease. (Once diabetes is diagnosed, screening for retinopathy is indicated.)

Renal disease has been reported in 15% to 80% of diabetic patients at autopsy. Renal failure is the cause of death in 6% to 12% of diabetic patients. Prevalence estimates vary widely from study to study, but it is clear that the risk for glomerulosclerosis with clinically evident functional impairment increases dramatically with the duration of disease.

Although the *duration of glucose intolerance* and associated metabolic abnormalities can be related to many of the complications of diabetes, the variability of the natural history must be kept in mind. It has been argued that all complications, including specific microangiopathic changes, have been identified in patients without evident glucose intolerance. Whether or not the morbidity and mortality associated with the complications can be influenced by therapy is a matter of long-standing debate (see Chapter 102). The DCCT provided compelling evidence that rates of microvascular complications and other consequences of diabetes could be reduced with intensive efforts to control glucose levels among patients with type 1 diabetes. Intensive therapy was associated with an increased frequency of hypoglycemic episodes and considerable inconvenience and cost. Questions remain about whether these findings apply to patients with type 2 diabetes and about whether treatment during the asymptomatic period would improve outcomes.

Gestational diabetes is a special case. As noted, it occurs in 3% of pregnancies, although considerable variation is noted in different populations. It is associated with perinatal morbidity, including macrosomia and the associated increased risk for seriousbirth trauma and cesarean section. Evidence from observational studies and randomized trials supports the contention that identification of gestational diabetes, followed by management with diet, insulin, or both, can reduce the incidence of macrosomia and perhaps improve birth outcomes.

SCREENING AND DIAGNOSTIC TESTS

In 1979, the National Diabetes Data Group (NDDG) published criteria for the diagnosis of diabetes. In 1997, these criteria were updated by a committee of the American Diabetes Association. According to these revised criteria, at least one of the following conditions must be met to establish the diagnosis of diabetes in the nonpregnant adult:

1. Symptoms of diabetes plus a *casual glucose* concentration of 200 mg/dL (11.1 mmol/L) or more. Casual is defined as any time of day without regard to time since last meal. The classic symptoms of diabetes include polyuria, polydipsia, and unexplained weight loss.
2. A *fasting plasma glucose* concentration of 126 mg/dL (7.0 mmol/L) or more (fasting defined as no caloric intake for at least 8 hours).
3. A 2-hour postprandial level of 200 mg/dL or more during an oral glucose tolerance test, performed as described by the World Health Organization (glucose load equivalent to 75 g of anhydrous glucose dissolved in water).

To confirm a diagnosis of diabetes, any one of the criteria must also be met on a subsequent day. It is worth noting that capillary blood glucose levels are lower than plasma levels by approximately 10 mg/dL during fasting, but are equal to or higher than plasma levels after a glucose load.

In addition to defining these diagnostic criteria, which have since been widely accepted in the United States, the group suggested new designations for persons with glucose intolerance who do not meet the criteria for frank diabetes. The term impaired glucose tolerance is reserved for patients with a glucose tolerance between normal and that of frank diabetes (e.g., fasting plasma glucose from 110 to 125 mg/dL).

It should be remembered that any criteria for the diagnosis of diabetes based on glucose levels are, by necessity, arbitrary. The sensitivity and specificity of the tests will depend on the arbitrary levels chosen. At the time of their publication, the principal effect of the NDDG criteria, which require higher levels than were commonly used previously, was to increase the specificity of the criteria at the expense of sensitivity. This trade-off reflected the judgment that little benefit can be expected from aggressive identification and treatment of early or mild degrees of glucose intolerance, and that the label diabetes can engender substantial anxiety and morbidity. The recommendations made in 1997 increase sensitivity at the expense of specificity, reflecting an implicit judgment that more benefit than harm will result from identifying and labeling patients with less severe levels of glucose intolerance as diabetic.

Despite the widespread acceptance of these diagnostic tests, the indications for performing oral glucose tolerance tests and any blood glucose measurements to screen asymptomatic persons remain controversial. The American Diabetes Association advocates use of a fasting glucose level to screen for diabetes among people over age 45. They recommend earlier screening for those at higher risk for diabetes because of racial background, family history, obesity, or prior evidence of impaired glucose tolerance. However, no evidence from a prospective, randomized trial is available to support such recommendations. The U.S. Preventative Services Task Force has concluded that sufficient evidence for or against routine screening for diabetes in asymptomatic adults is lacking.

The detection of autoantibodies as predictors of type 1 diabetes among asymptomatic persons with a strong family history of type 1 disease has also received considerable attention. However, because no interventions have been proved to slow or prevent onset of disease, this approach is not recommended in the general population.

Screening for gestational diabetes is generally accomplished between 24 and 28 weeks of gestation by administering 50 g of glucose orally and measuring the glucose level 1 hour later. A level above 140 mg/dL would prompt further evaluation with an oral glucose tolerance test (see Chapter 102). This generally accepted policy is not supported by conclusive evidence from randomized trials; both the U.S. Preventative Services Task Force and the Canadian Task Force on the Periodic Health Examination have recommended neither for or against this practice. Recently, selective screening on the basis of age (over 35), body mass index, and race has been advocated.

Some have advocated the use of hemoglobin A_{1c} measurements to screen for and diagnose diabetes. However, in population-based studies, fasting glucose levels have been found to be more sensitive and more specific.

CONCLUSIONS AND RECOMMENDATIONS

- Diabetes mellitus is a common but heterogeneous condition. The most important risk factor for type 1 diabetes is a family history of diabetes in a twin, sibling, or parent. Family history is even more predictive for type 2 diabetes, but the most important risk factor is obesity. Persons with a history of gestational diabetes or with impaired glucose tolerance also are at risk for the development of frank diabetes.
- The natural history of diabetes and the incidence of complications is highly variable. The incidence of diabetic complications increases with duration of disease. Close control of glucose levels in patients with type 1 diabetes has been shown to reduce the incidence of microvascular diabetic complications, at the expense of increased rates of hypoglycemia and substantial inconvenience and cost. Consistent but less conclusive evidence exists for type 2 diabetes, but no effect on the macrovascular complications that confer much higher burdens of morbidity and mortality was noted. No evidence is available to indicate that therapy of asymptomatic, nonpregnant patients with diabetes or impaired glucose tolerance offers any benefit.
- Therefore, the routine measurement of blood glucose levels to screen asymptomatic, nonpregnant adults for diabetes is not recommended.

CHAPTER 94 SCREENING FOR THYROID CANCER

Cancer of the thyroid is a relatively rare disease with a low mortality rate. Approximately 14,000 cases are diagnosed each year in the United States; the number of deaths caused by the tumor is about 1,000 annually—only 0.2% of cancer deaths. Nevertheless, this disease is of major significance for the primary physician because of its iatrogenic relationship to childhood irradiation of the head and neck. A high prevalence of thyroid cancer, diagnosed after a long latent or asymptomatic period, has repeatedly been documented among patients exposed to such irradiation. The appropriate approach to the evaluation and management of radiation-exposed patients remains a subject of debate.

EPIDEMIOLOGY AND RISK FACTORS

Generally, the incidence of thyroid cancer increases with age. This is particularly true of tumors with an anaplastic or follicular histopathologic pattern and of the medullary carcinomas derived from the parafollicular cells. The most common tumors, with a papillary histopathologic pattern, have a bimodal, age-specific incidence, peaking in the thirties and late in life. Thyroid tumors occur more than twice as frequently in women. In the United States, African-Americans seem to be at lower risk than others. Wide variations in thyroid cancer prevalence at autopsy have been reported internationally, from 3% to more than 10% in nonirradiated thyroids, with the highest rates reported in Japan. Approximately 20% of the rare medullary carcinomas, which comprise fewer than 10% of thyroid cancers, are familial.

The major identifiable risk factor for the development of thyroid cancer is a history of *external irradiation of the head and neck*. External irradiation was used as early as 1907 to shrink an enlarged thymus in infancy. During the 1920s and subsequently until the 1950s, it was used extensively to treat enlarged tonsils and adenoids, cervical adenitis, mastoiditis, sinusitis, hemangiomas, tinea capitis, and acne. Concern about ill effects began to mount in 1950 when a history of neck irradiation was noted in 9 of 28 cases of childhood thyroid cancer with a latency period of 5 or more years. Further documentation followed, and radiation to the neck was discontinued. In 1973, attentionfocused on the issue again when 40% of a series of adults with thyroid cancer were found to have a history of irradiation. Clearly, the latent period between exposure and the diagnosis of cancer could be measured in decades. It was also clear that the exposed population at risk was substantial—estimates ranged from 1 million to 2 million persons—and largely unidentifiable.

Successive reports focused on the risk among exposed persons. Large studies indicated that more than 25% had detectable thyroid abnormalities; the prevalence of cancer was estimated at 7% to 9%. These figures must, however, be considered in the light of information available regarding the prevalence of thyroid abnormalities, including carcinoma, in the general population.

At least one investigation has questioned the value of thyroid screening in persons with a history of radiation exposure based on the legitimate questions that can be raised about the effects of sampling bias and observer bias on the results of most studies. In a small, retrospective cohort study comparing irradiated persons with siblings or patient-selected controls, the investigators found no difference in the prevalence of malignant and nonmalignant thyroid abnormalities. This study has in turn been challenged, however, because of its own potential biases and limited power.

Preliminary evidence suggests that some radiation-exposed persons may be at greater risk than others. Radiation during infancy may be most carcinogenic, with cancer risk decreasing as age at the time of radiation increases. Although the threshold dose for cancer risk appears to be low, risk may be greatly increased for persons who received multiple treatments.

NATURAL HISTORY OF THYROID CANCER AND EFFECTIVENESS OF THERAPY

The prevalence of occult carcinoma of the thyroid is not well defined. Autopsy studies have indicated that the prevalence ranges from 5% to 13%. An often-quoted study showing an overall prevalence of 5.7% found the highest age-specific rates in the fifth and sixth decades.

A high prevalence of asymptomatic thyroid cancer is not surprising considering the benign clinical course of most thyroid tumors after diagnosis. Follow-up studies have determined that the probability of survival depends on the tissue type and age of the patient. For localized papillary carcinoma, survival approximates that of age-matched controls; in one large study, no deaths occurred among patients younger than 40 years of age during 10 to 15 years of follow-up. The course of follicular cancer is only slightly more aggressive. Anaplastic tumors, on the other hand, run a rapid clinical course to death.

The relatively high prevalence of occult thyroid cancer presumed to be present in general raises a number of questions about the significance of tumors found during the evaluation of patients with radiation exposure. It is worth noting that in the largest study, conducted at Michael Reese Hospital in Chicago, 47% of the tumors were incidental findings identified after surgery was recommended because of palpable or scan abnormalities. That is, 29 of 60 cancers were not found in or near the benign nodule that prompted surgery. No evidence indicates that tumors found in patients with past radiation exposure are more likely to result in morbidity or mortality than are occult tumors found in the general population. However, they do have a high frequency of recurrence.

SCREENING AND DIAGNOSTIC TESTS

The sensitivity of *history taking* in identifying persons at risk is not known. Many who were irradiated during early childhood may be unaware of their exposure. *Physical examination* of the thyroid gland is often difficult, and the palpable nodule is a nonspecific finding that can be found in 4% to 7% of the adult population. *Thyroid scan* is more sensitive in detecting thyroid abnormalities, but because it fails to distinguish between benign and malignant disease, it is even less specific. A number of studies indicate that physical examination itself becomes more sensitive after scanning has been performed and the physician is aware of scan results.

Large studies utilizing both multiple examinations and technetium (^{99m}Tc) scanning indicate that 60% of thyroid abnormalities (identified by either or both modalities) will be identified by palpation alone. Scanning alone will be more than 95% sensitive. However, palpable abnormalities appear to be more specific for cancer. In one study of patients with palpable nodules who ultimately underwent thyroidectomy, the prevalence of cancer was 34%; it was 19% among patients who went to surgery on the basis of scan abnormalities alone. Physical examination was nearly 80% sensitive in identifying thyroid glands containing cancers. Cancers found in glands with scan abnormalities alone were often incidental, unrelated to the scan abnormality.

The availability of high-resolution *ultrasonography* has increased our capacity to identify small thyroid nodules. Ultrasonography has been shown to be better than physical examination, isotope scanning, magnetic resonance imaging, and computed tomography in detecting nodules. However, no specific sonographic criteria distinguish between benign and malignant nodules. In one study, 14% of cystic thyroid lesions were cancers, compared with 23% of solid lesions.

Attempts to use measurements of serum thyroglobulin as a screening test for thyroid cancer have not been successful. Despite poor specificity, thyroglobulin abnormalities are disappointingly insensitive.

When abnormalities are detected on examination or on scan, additional diagnostic steps are indicated. The refinement of *fine-needle aspiration biopsy* with *cytologic examination* has made this the first-line diagnostic test in many centers (see Chapter 95).

In cases of questionable physical examination or scan findings, some physicians have suppressed the thyroid for 3 to 6 months in an effort to shrink normal thyroid tissue and thereby increase the sensitivity of the examination for autonomous nodules. Although this remains a reasonable approach when cancer risk is low, it must be kept in mind that regression following thyroid hormone suppression is neither perfectly sensitive nor highly specific for thyroid cancer. Cases have been reported of confirmed carcinomas that apparently responded to suppression therapy; only a minority of nodules that do not respond prove to be malignant.

On the basis of animal experiments, long-term thyroid suppression as prophylaxis for thyroid cancer has also been advocated for all patients with a history of

exposure or, more selectively, those with questionable scan findings.

Patients with a familial risk for medullary thyroid cancer may be tested for an exaggerated increase in serum calcitonin levels in response to calcium or pentagastrin stimulation. Such a response is reasonably sensitive, but it is not specific for medullary thyroid cancer. High-resolution ultrasonography may play a role in the screening of these rather rare patients.

CONCLUSIONS AND RECOMMENDATIONS

- Childhood irradiation is an important risk factor for thyroid carcinoma, which may be diagnosed as long as 35 years after exposure.
- The prevalence of thyroid abnormalities among the estimated 1 to 2 million patients with a history of exposure is about 25%. The prevalence of thyroid cancer has been estimated to be 7% to 9%.
- The significance of occult thyroid cancer in exposed patients is not known. The prevalence of occult tumors in the general population appears to be a high.
- Identification of patients at risk is an important part of history taking.
- Patients at risk should be carefully examined yearly, or at least every 2 years.
- Needle biopsy may be preferred in cases in which a single nodule has been identified. Multiple examinations by experienced examiners may be necessary. Thyroid suppression may increase the sensitivity of thyroid palpation. The examination of patients with normal examination but abnormal scan findings should be repeated yearly.

CHAPTER 95 EVALUATION OF THYROID NODULES

Thyroid nodules are an extremely common phenomenon clinically, radiographically, and histologically. A palpable thyroid nodule can be detected in 4% to 7% of the adult population (10 to 20 million people in the United States alone). The pre-valence of nodules in autopsy series approaches 50%, a figure that is approximated by patients undergoing modern high-resolution, real-time ultrasonography of the thyroid. The incidence of thyroid nodules increases with age and neck irradiation; it is six to nine times more common in women than in men.

The principal objective in evaluating thyroid nodules is to differentiate malignant from benign lesions. About 70% of nodules subjected to fine-needle biopsy prove to be benign, and 4% malignant; in the remainder, the cytologic findings are either inadequate or indeterminate. Additional tasks are to determine the functional status of a nodule and assess any adverse effect on neighboring structures.

Because of the high frequency and potential importance of thyroid nodules, the primary care physician must be able to coordinate a cost-effective evaluation; to that end, familiarity with the indications for and utilities of scanning, ultrasonography, and fine-needle aspiration is necessary. In addition, an understanding of the respective roles of surgery, suppressive therapy, and watchful waiting facilitate the formulation of an appropriate program of symptomatic management.

PATHOPHYSIOLOGY AND CLINICAL PRESENTATION

Thyroid nodules may be single or multiple, with or without underlying disturbances of hormonal homeostasis. A solitary nodule is usually more worrisome because it may represent a malignancy, although on occasion a multinodular gland may harbor a cancer. Benign and malignant thyroid nodules are usually asymptomatic and discovered incidentally by the patient or examining physician. Large nodules may cause a cosmetic problem or compress an adjacent structure. The nodules are usually painless unless rapid growth, inflammation, or hemorrhage occurs and produces significant discomfort.

Solitary Nodule

Solitary thyroid nodules represent benign adenomas, carcinomas, or multinodular conditions in which only a single nodule is palpable.

Benign Adenomas account for most nonmalignant truly solitary nodules. The majority are designated as *follicular* and have a true capsule; the remainder are labeled *colloid* or *adenomatous nodules* and are not well encapsulated. Both behave similarly. Growth is typically slow, extending over many years. Follicular adenomas rarely become large enough to encroach on the trachea or esophagus. Thyroid-stimulating hormone (TSH) receptors are present in most, making them hormonally responsive. Most do not produce much thyroid hormone, and their limited radioiodine uptake on scan sometimes gives the appearance of a "cold" nodule. Benign adenomas that outgrow their blood supply may undergo necrosis, degenerate, become filled with fluid, and appear on ultrasonography as nodules with solid and cystic elements. Adenomas make up a significant proportion of such "cystic" lesions. A few follicular adenomas produce such large quantities of thyroid hormone that the patient presents with thyrotoxicosis (see Chapter 103). This is particularly true of so-called "*toxic*" *adenomas* exceeding 3 cm in diameter. They function autonomously, suppress TSH (which renders the rest of the gland atrophic), and appear as "*hot*" *nodules* on thyroid scan. Patients with a smaller hot nodule may remain euthyroid, although enough thyroid hormone is produced to suppress the rest of the gland and render it atrophic.

Thyroid Carcinomas are uncommon; the current incidence is 2.5/100,000 persons annually, although it is higher in areas with radiation exposure. They are more frequent in women than in men. A major risk factor is prior head or neck irradiation. On radioiodine scan, most thyroid carcinomas present as "*cold*" *nodules*, failing to take up iodine, although on technetium scan a rare malignant nodule will take up the radionuclide. On ultrasonography, most cancers are solid, although a mixed cystic–solid appearance is encountered in about 20%, and even a purely cystic-appearing lesion may occasionally be malignant.

Papillary and *mixed papillary–follicular* carcinomas are the most common and account for 60% to 70% of all thyroid malignancies. The lesions tend to be very slow-growing, spreading locally to adjacent lymph nodes but not metastasizing distantly until very late. Consequently, the prognosis is good even after local spread has occurred. Although most are solid, some may present as mixed cystic–solid lesions because of necrosis and liquefaction.

Follicular carcinomas, which make up another 15% to 20% of thyroid cancers, are also slow-growing. Local spread to regional nodes may occur without invasion of the thyroid capsule, but this does not alter the prognosis. Hematogenous spread can develop early, and the initial presentation is often a metastasis to lung or bone.

Anaplastic carcinomas comprise another 10% to 12% of cases; these are very invasive, usually inoperable, and fatal within 1 year.

Medullary carcinomas, derived from the parafollicular cells of the thyroid, represent 10% of thyroid cancers. Sporadic and familial forms of the disease are seen; among the latter are familial medullary cancers unaccompanied by other conditions and *multiple endocrine neoplasia* types II and III (which occur in conjunction with pheochromocytoma and hyperparathyroidism). The malignancy often presents as a nodule located in the upper half of the thyroid gland. It can be multicentric, especiallyin the familial forms. At least 50% of medullary carcinomas of the thyroid occur sporadically. *Calcitonin*, produced by the parafollicular or "C" cells, is a unique tumor marker for medullary carcinoma.

Lymphoma may sometimes develop as a primary lesion within the thyroid of a patient with chronic lymphocytic thyroiditis. Its clinical course is a function of tissue type and stage at time of presentation (see Chapter 84). Spread to local nodes is common and prominent.

Multiple Nodules

Hashimoto's Thyroiditis, an autoimmune condition, is the leading cause of multinodular goiter in the United States. Evidence of the condition can be found in about 4% of the general population and up to 15% of women over the age of 65. Women patients outnumber men by a ratio of 3:1. Pathologically, a chronic inflammatory cell infiltrate, formation of germinal centers, fibrosis, and Hürthle cell changes are seen to involve follicular epithelial cells. Although not unique to this condition, *antimicrosomal antibodies* are found in 70% to 95% of patients. About one third of patients manifest a multinodular goiter, although euthyroid goiter is actually the most common presentation. The immunologically mediated injury impairs thyroxine synthesis and increases leakage of hormone into the circulation. A third of patients experience progressive loss of glandular function and eventually become hypothyroid. Hyperthyroidism in uncommon but can occur in patients with a prominent lymphocytic infiltrate.

Multinodular Goiter is the second most common cause of a multinodular gland in adults. It represents an advanced stage of focal autonomous hyperplasia, which initially presents as a diffusely enlarged gland but then progresses to multinodularity as areas of focal hyperplasia undergo degenerative changes. Nodules may also develop when colloid accumulates in hyperplastic cells (*colloid cysts*). Uptake of radioiodine on scan is heterogeneous; some areas may not take up iodine and appear "cold." The thyroid gland feels less firm than it does in Hashimoto's disease. The TSH level may be slightly reduced, reflecting the autonomous nature of the thyroxine output of the gland, but free thyroxine levels are usually within normal limits.

Cancers may arise in a multinodular gland, although this is very uncommon. Thyroid cancer and lymphoma are the leading causes. Cervical adenopathy, hoarseness (resulting from recurrent laryngeal nerve compression), and the continued enlargement of a "cold" nodule on thyroid scan are distinguishing features of the clinical presentation. A history of neck irradiation or family history of thyroid cancer (suggestive of hereditary disease) are risk factors. The nodule may be tender if the tumor is rapidly growing (as with lymphoma), a finding atypical of other multinodular goiters.

Incidentalomas

This term is used to refer to nonpalpable thyroid lesions detected incidentally in the course of imaging of the neck area by ultrasonography or other sensitive diagnostic modalities. The risk for malignancy is low when the diameter of the lesion is less than 1.5 cm. Even if some incidentalomas represent early papillary cancers, the rate of growth is likely to be very slow for lesions smaller than 1.5 cm.

DIFFERENTIAL DIAGNOSIS

The vast majority of solitary nodules are benign, even those that fail to take up radionuclide on thyroid scan (see below). In the United States, Hashimoto's thyroiditis accounts for the majority of cases of multinodular goiter. Cancers account for about 10% to 20% of solitary thyroid nodules; the prevalence is lower in patients with multinodular glands (Table 95.1.)

Table 95.1. Differential Diagnosis of Thyroid Nodularity

WORKUP

As noted earlier, the main objective is to differentiate a carcinoma from benign causes of nodularity. Although a definitive assessment cannot be made by history and physical examination alone, these elements provide important information regarding risk and need for biopsy or excision. Other tasks include identification of autonomous function and compression of adjacent structures.

History

The history is reviewed not only for the clinical presentation of the nodule and associated symptoms but also for important cancer risk factors, such as a history of neck irradiation inchildhood, exposure to excessive environmental radiation, and a positive family history of thyroid cancer. Age and sex are also relevant. Patients younger than 40 years and male patients are at increased risk for a malignant thyroid nodule. Symptoms suggestive of local compression or invasion (e.g., *hoarseness, dysphagia*, and *tracheal wheezing*) should be noted, as should the new appearance of a nodule or rapid growth of an existing one. However, bleeding into a benign cyst or subacute thyroiditis may cause a similarly abrupt change and new onset of symptoms. Conversely, many thyroid cancers are slow-growing and may have been present for years; duration is not particularly useful for distinguishing benign from malignant disease. Such factors as residence in an iodine-deficient area, presence of goiter, or intake of goitrogens (e.g., lithium, turnips, beets) favor a benign thyroid lesion, as does a family history of goiter (as opposed to thyroid cancer). Symptoms of hypothyroidism or hyperthyroidism argue against malignancy.

Physical Examination

The physical examination focuses on the gland and adjacent lymph nodes. The gland is noted for its overall size, consistency, and number and size of nodules. A solitary hard nodule that is irregular and fixed (fails to move with swallowing) is suggestive of malignancy. However, finding a soft nodule does not rule out the diagnosis of cancer because a papillary carcinoma that has undergone cystic degeneration can be soft to the touch. Finding a single nodule increases the chances of cancer; few multinodular goiters harbor a cancer.

The adjacent lymph nodes, especially those on the same side as the nodule, require detailed examination. A thyroid nodule with associated cervical adenopathy should be viewed with marked suspicion. A single node may represent metastasis from the thyroid, whereas multiple nodes in a young person with a thyroid nodule raise the possibility of lymphoma. The vocal cords should be viewed in patients with hoarseness.

Laboratory Studies

Fine-needle Aspiration Biopsy has become the test of choice for the initial evaluation of most euthyroid patients with a thyroid nodule, having supplanted the radionuclide thyroid scan and ultrasonography in determining who needs surgical excision. The fine ("skinny") needle is inserted into the nodule and its contents are aspirated for cytologic examination. In skilled hands, the sensitivity of fine-needle biopsy exceeds 95%. Although radionuclide scanning and ultrasonography also provide high sensitivity, their specificity is poor. The specificity of fine-needle biopsy ranges from 70% when patients with "suspicious" readings are included in the group in need of surgery to more than 90% when they are not. In comparison with ultrasonography and radionuclide scan, fine-needle biopsy has reduced by half the number of patients who undergo operations needlessly, doubled the incidence of malignancy in surgically excised nodules, and reduced costs by more than 25%. The procedure is safe, inexpensive, and readily performed in the office setting. A skilled physician is needed to perform the procedure and an experienced pathologist to interpret the results so that errors in sampling and interpretation are minimized. Failure to drain a cystic lesion completely and obtain samples from the residual mass is an important source of false-negative results. With cytologic information provided by aspiration biopsy only, it can be difficult for even experienced pathologists to differentiate benign Hürthle cell and follicular adenomas from their malignant counterparts. Patients with lesions labeled "suspicious" or "indeterminate" usually must undergo surgical excision of the nodule, although sometimes malignancy can be ruled out by radionuclide scanning.

Radionuclide Scanning. As noted above, radionuclide scanning has been supplanted by fine-needle aspiration biopsy as the initial test of choice in patients with a euthyroid nodule. Although it is true that most malignant disease has the appearance of a "cold" nodule on scan, only 15% to 20% of all "cold" nodules are malignant. Moreover, uptake in a nodule ("warm" nodule) does not entirely rule out malignancy. Thus, radionuclide scanning is best relegated to a supplemental role, performed after fine-needle biopsy in patients with "suspicious" cytologic findings. A "hot" nodule on the scan of such patients indicates an autonomously hyperfunctioning nodule, which is associated with a very low risk for cancer. A "suspicious" nodule that is "warm" or "cold" on scan is more likely to be cancerous, so that surgical excision must be considered. A radionuclide scan can also be of help in detecting multinodularity, although thyroid ultrasonography is even more sensitive.

Thyroid Ultrasonography has an excellent sensitivity in the detection of nodules (down to 1 mm) and a unique ability to differentiate solid from cystic lesions, and it plays a role in helping to localize a lesion for biopsy. However, even with the development of new, high-resolution ultrasonographic technology to detect ever-smaller lesions, the test still lacks diagnostic specificity because no clearly defined architectural criteria are available for differentiating benign from malignant lesions. Recently compiled combined data show that 21% of solid lesions, 12% of mixed lesions, and 7% of purely cystic lesions are malignant. Now that "cystic" is no longer considered synonymous with "benign," the test has fallen into disuse as a means of determining risk for malignancy. It is excellent for determining multinodularity, but the meaning of such multinodularity is unclear because up to 40% of all patients with a solitary nodule clinically are found by modern ultrasonography to have multiple nodules.

Ancillary Laboratory Studies. Most are usually of little direct help in deciding who should undergo biopsy, but they occasionally provide supportive information. An abnormal *TSH level* is uncommon in malignant disease, as are high titers of *antimicrosomal antibodies* (useful in suspected cases of Hashimoto's and subacute lymphocytic thyroiditis). Routine use of plain films is not cost-effective. A very high *erythrocyte sedimentation rate* in the setting of an acutely tender gland is very suggestive of subacute granulomatous thyroiditis. A serum *calcitonin* determination is indicated when the patient has a strong family history of thyroid cancer. No other markers are known at present for thyroid cancers. *Thyroglobulin* elevations do occur with cancer, but also with benign nodular thyroid disease. The response to *TSH suppression* (by administration of thyroid hormone) is not reliable for differentiating cancer from benign disease because both may either shrink or not in

response to exogenous hormone. In rare instances, a plain film of the chest may incidentally reveal punctate calcifications characteristicof the psammoma bodies of papillary carcinoma or the shell-like calcification characteristic of a benign lesion, but routinely obtaining such films is of low diagnostic yield.

Testing Sequence. The most cost-effective testing sequence for the euthyroid patient with a single thyroid nodule on physical examination is to begin with *fine-needle aspiration biopsy.* If the cytology is "malignant," then surgery is indicated. If the reading is "benign," then observation for 1 year and *follow-up ultrasonography* are reasonable. If the reading is "suspicious," then *radionuclide scan* for determination of nodule uptake is indicated. A "hot" nodule indicates a very low risk for cancer and requires only clinical follow-up with or without treatment, depending on whether the patient is euthyroid or thyrotoxic. A "warm" or "cold" nodule in a patient with "suspicious" cytology raises the question of cancer and necessitates surgical excision.

If after 1 year of observation the follow-up thyroid ultrasonography indicates an increase in nodule size, then repeated biopsy is indicated. An enlarging nodule that continues to appear benign on repeated biopsy can be treated with levothyroxine suppressive therapy (see below) and restudied by ultrasonography in another year's time. If the nodule has stopped enlarging on suppressive therapy, then suppressive therapy can be continued and the patient reassessed annually. If size is increasing, then surgical removal is undertaken. Malignant or suspect pathologic findings are always an indication for surgery.

Patients with Multinodular Glands. Biopsy is usually not required unless the concern for cancer is increased because of neck irradiation, cervical adenopathy, rapid growth of a single nodule in an otherwise stable gland, or onset of recurrent laryngeal nerve palsy. Most cases represent Hashimoto's thyroiditis, and a diagnosis can be made by obtaining antithyroid antibody determinations. High titers of *antimicrosomal antibodies* correlate best with biopsy-proven disease. Antithyroglobulin titers are less useful. The risk for *lymphoma* of the thyroid is increased in patients with Hashimoto's disease, so that *needle biopsy* of the gland is mandated in the presence of an enlarging tender goiter, cervical adenopathy, or a goiter markedly enlarging on thyroid hormone suppressive therapy (which should cause the nodule size to decrease in Hashimoto's disease).

Further Evaluation of the Benign Adenoma. When a lesion is found to be a benign adenoma, the question arises of whether it is functioning autonomously and thus posing a risk for toxicity. Adenomas smaller than 2 cm rarely change much in size or function and can be followed. Those larger than 3 cm are at risk for progressing to toxicity within a few years. Autonomous function is determined by performing *serial radionuclide scans* and demonstrating little change in uptake in a comparison of scans taken before and after *stimulation by thyrotropin-releasing hormone* (TRH) or *suppression by thyroid hormone.* Observation rather than ablation is now preferred for the smaller, low-risk lesions. Annual determination of the nodular size and hormonal output usually suffices. Every 5 years, scanning can be repeated to see if suppression of extranodular tissue function is increasing, a sign of impending toxicity. Other signs include size greater than 3 cm, a rise in serum triiodothyronine (T_3) to the upper limits of normal, and decreasing responsiveness to stimulation or suppression.

Incidentalomas. A stance of watchful waiting is reasonable as long as the patient has no risk factors for thyroid cancer and the lesion is smaller than 1.5 cm in diameter. Biopsy is not necessary under such circumstances, but careful follow-up with repeated examination is essential. Patients with lesions larger than 1.5 cm, prior head or neck irradiation, a strongly positive family history of thyroid cancer, or ultrasonographic findings suggestive of malignancy do require biopsy at the outset.

SYMPTOMATIC THERAPY

Euthyroid Patients with a Benign Solitary Nodule. The best approach to management remains unclear because no definitive data from prospective, randomized studies are available. *Low-dose suppressive therapy* (sufficient to reduce the TSH level to low but not indetectable levels) with *levothyroxine* is advocated by some as a relatively safe means of reducing the risk for nodule growth and decreasing the nodule size. In approximately 10% to 30% of patients with a nontoxic solitary nodule, the nodule size will decrease when doses of levothyroxine sufficient to suppress TSH are given, although such treatment does not appear to work in patients with colloid nodules. The rationale for suppressive therapy is that reducing TSH stimulation should diminish the size of lesions that are TSH-responsive (e.g., follicular adenomas, Hashimoto's thyroiditis). The required dosage of levothyroxine is in the range of 0.1 to 0.15 mg daily, with small doses (e.g., 0.05 mg/d) given first and increased gradually until the TSH level declines to about 0.3 mU/L. Further suppression markedly increases the risk forthyroxine-induced osteoporosis (see Chapter 104). The therapy is relatively contraindicated in the elderly and those with underlying coronary disease (see Chapter 103). It is not known whether therapy prevents an increase in nodule size in patients in whom it fails to effect a decrease.

Others counter that the risk for nodule growth is small and the ability of suppressive therapy to reduce nodule size is modest at best. Moreover, even partially suppressive doses of levothyroxine are associated with a risk for osteoporosis, especially in postmenopausal women, who comprise the majority of patients. Pending better data, one suggested approach is to observe the nodule for a year after the initial biopsy, recheck its size by ultrasonography, perform another biopsy on any nodule that appears to be enlarging, and, if the nodule is benign, institute modest suppressive therapy in an attempt to halt enlargement and achieve some reduction in size. If the nodule continues to enlarge, then *surgical removal* is recommended; otherwise levothyroxine is continued and the nodule size is checked at regular intervals.

Nontoxic Multinodular Goiter. Such nodular glands often do not shrink much because they are composed of a great deal of fibrous tissue. Dominant nodules caused by bothersome *large cysts* may require *surgical removal*, but smaller ones can be *aspirated* as necessary, both to rule out malignancy (incidence about 1%) and to increase comfort and improve appearance. Hormone therapy has no effect on the recurrence of thyroid cysts after aspiration or on nodular disease because glandular function typically becomes increasingly autonomous with age. *Radioiodine* is sometimes used, but high doses are required, which increases the chances of precipitating Graves' disease (5%) and possibly late malignancy.

Toxic Nodules and Autonomously Functioning Solitary Adenomas. Patients with these lesions are at high risk for thyrotoxicosis, especially if the nodule is larger than 3 cm in diameter, the serum triiodothyronine level is at the upper limit of normal, and the nodule is increasingly unresponsive to thyroxine suppression. Such patients should be considered for *ablative therapy.* Ablation is mandatory for those with autonomous nodules that have already become toxic. One needs to choose between surgery and radioiodine. *Surgery* represents a definitive approach with low risk if performed by a skilled thyroid surgeon. Young patients are the best candidates. *Radioiodine* is simpler and usually the treatment of choice in the elderly. The theoretical risk of inducing cancer in the remaining thyroid tissue makes radioiodine a less attractive option for young people, although no increase in the incidence of malignancy has been reported. A palpable nodule often remains after irradiation; it is of no consequence except for the cosmetic effect. The patient needs to be monitored for the development of posttreatment hypothyroidism (see Chapter 103).

Incidentalomas. As noted earlier, a stance of watchful waiting is reasonable as long as the patient has no risk factors for thyroid cancer and the lesion is smaller than 1.5 cm. Careful follow-up is critical.

PATIENT EDUCATION

The primary care physician should counsel and closely follow patients who have undergone previous head or neck radiation (see Chapter 94). Regular follow-up is important for any patient with a nodule, and the patient should be instructed to call if a change in size, development of lymphadenopathy, pain, dysphagia, or hoarseness is noted.

The patient with an autonomous nodule or a multinodular goiter should be advised to avoid substances containing high concentrations of iodine (medications, kelp, radiographic contrast media) because they may precipitate thyrotoxicosis. If a contrast study is necessary, the patient should be started on a b-blocking agent 10 days before the study.

INDICATIONS FOR REFERRAL

Detection of a solitary thyroid nodule in a clinically euthyroid patient should prompt a referral to a consultant skilled in performing fine-needle biopsy of the thyroid. Finding a worrisome nodule (see above) in a patient with a multinodular gland represents another indication for consideration of biopsy. Patients with a toxic or large (>3 cm) autonomously functioning adenoma require consultation for discussion of ablative therapy. Those with goiters that are unresponsive to thyroid hormone and are causing obstruction or unpleasant cosmetic effects may be surgical candidates.

CHAPTER 96 APPROACH TO THE PATIENT WITH HYPERCALCEMIA

SAMUEL R. NUSSBAUM

The advent of automated laboratory screening has led to an increased recognition of asymptomatic persons with hypercalcemia, with the annual incidence rising from 7.8/100,000 to 51/100,000. In addition, outpatients with nonspecific complaints, such as fatigue, weakness, abdominal discomfort, or constipation, may have hypercalcemia discovered during biochemical testing. Mild hyperparathyroidism is usually the explanation for these often inadvertently recognized elevations in calcium levels. Hypercalcemia may also herald other important underlying diseases, such as malignancy or sarcoidosis. Asymptomatic hyperparathyroidism is not necessarily a benign condition. The effect of excessive levels of parathyroid hormone for prolonged periods on target organs, such as bone and kidney, may lead to skeletal loss and impaired renal function.

The primary physician must be able to interpret an abnormal calcium value and diagnose its cause. If hyperparathyroidism is present, one must decide between surgery and medical therapy. The treatment of hypercalcemia resulting from malignancy can improve the quality of life and deserves consideration.

PATHOPHYSIOLOGY AND CLINICAL PRESENTATION

The serum calcium concentration is maintained within narrow limits by parathyroid hormone. Precise calcium homeo-stasis is necessary because of the vital role of calcium in membrane function, hormonal secretion and action, and neuromuscular function. The free or ionized portion of serum calcium is responsible for its physiologic actions. Slightly less than 50% of serum calcium is in the form of free calcium ions; the remainder is bound to plasma proteins, mostly albumin. Globulins can also bind serum calcium. Calcium binding by serum proteins is pH-dependent. Increased binding at alkaline pH explains the common symptom of paresthesias that occur in conjunction with hyperventilation. The normal range for serum calcium is 8.5 to 10.4 mg/dL, or 2.12 to 2.59 mmol/L. The normal range for ionized serum calcium is 1.16 to 1.34 mmol/L. True hypercalcemia requires an increase in the ionized fraction of serum calcium. A convenient correction factor to apply to the total serum calcium is the subtraction or addition of 1 mg/dL to the calcium concentration for every 1.0 g/100 mL of serum albumin above or below 4.0 g/100 mL.

Hyperparathyroidism. The hypercalcemia of hyperparathyroidism is caused by an increase in osteoclastic bone resorption, mediated by the binding of excess parathyroid hormone (PTH) to receptors on osteoblasts, in addition to an increase in gut calcium absorption. PTH also increases renal tubular reabsorption of calcium, which results in phosphate wasting. Pathologically, approximately 80% of patients are found to have a single parathyroid adenoma, whereas 20% have four-gland hyperplasia. Parathyroid cancer accounts for approximately 1% of all cases of hypercalcemia attributed to excess parathyroid hormone secretion.

The incidence of hyperparathyroidism increases with age, peaking in the fourth through sixth decades of life, and hyperparathyroidism occurs more commonly in women than men, by approximately a 2:1 ratio. It is not certain whether the increased recognition of the disease relates to multiphasic biochemical screening or whether the number of cases of the disease has increased, possibly as a result of head and neck irradiation in infancy or other environmental factors that affect parathyroid cell proliferation.

The majority of patients with hyperparathyroidism do not have symptoms. The "classic" presentation of "stones, bones, abdominal groans, and psychic moans" has been replaced by a more subtle and nonspecific presentation. *Fatigue, weakness*, mild gastrointestinal symptoms (*constipation, abdominal pain*), changes in intellectual performance, and depression may all be manifestations of hypercalcemia or excessive PTH. Often, such nonspecific symptoms are recognized only after successful parathyroid surgery has been performed, when the patient describes an improved sense of well-being.

The resultant hypercalcemia of hyperparathyroidism can lead to a renal concentrating defect and *increased urination*. Hyperparathyroidism is also associated with an increase in *calcium oxalate stones*, particularly in patients with elevated levels of 1,25-dihydroxyvitamin D$_3$ and urinary calcium excretion in excess of 300 to 350 mg/24 h. Bone pain results from skeletal fracture and osteitis fibrosa cystica. A possible but somewhat controversial increase in peptic ulcer disease and pancreatitis has been noted, and a spectrum of psychiatric disease. In persons with mild disease, survival appears to be unaffected.

Hyperparathyroidism may be observed in familial settings, such as the autosomal dominant syndromes of *multiple endocrine neoplasia* (MEN) types 1 and 2. In MEN 1, parathyroid hyperplasia occurs in conjunction with adenomas of the pituitary and pancreas. In MEN 2, parathyroid hyperplasia may occur with medullary cancer of the thyroid and bilateral adrenal pheochromocytoma.

Patients with "*normocalcemic hyperparathyroidism*" often have serum calcium levels at the upper limit of normal, which on repeated determinations fluctuate into the frankly elevated range. *Thiazide diuretics* may transiently elevate serum calcium by reducing urinary calcium excretion. More sustained elevations suggest mild underlying hyperparathyroidism that is unmasked by thiazide therapy.

Familial Hypocalciuric Hypercalcemia may cause hypercalcemia as often as MEN type 1. This condition is associated with an abnormality of calcium sensing by the parathyroid, which leads to parathyroid gland hyperplasia. Serum PTH is not elevated. Urinary calcium excretion is often less than 100 mg/24 h.

Malignancy is the second most frequent cause of hypercalcemia and more common among hospitalized patients than outpatients. Cancers of the *breast, lung*, and *kidney* lead the list of malignant causes, accounting for 50% to 60% of such cases. The incidence of hypercalcemia during the course of breast cancer ranges from 18% to 42%, and in lung cancer, from 6% to 16%. Other malignancies associated with hypercalcemia include *multiple myeloma* (incidence of 30% to 100%), squamous cell carcinomas of the head and neck (2%), lymphoma and leukemia (1%), and genitourinary cancer (1%).

Several *mechanisms* for the hypercalcemia of malignancy have been identified, with a common theme being increased osteoclastic bone resorption. Such resorption and resultant hypercalcemia can occur with or without bony metastasis, and many tumors that commonly metastasize to bone do not cause hypercalcemia. Squamous cell cancers produce a parathyroid hormone–related protein (PTHRP), a *PTH-like peptide* with an amino terminal structure similar to that of PTH and a nearly identical effect on mineral ion homeostasis. Myeloma cells produce *interleukin-1b* and *interleukin-6*, which stimulate osteoclast-mediated bone resorption. In some patients with lymphoma and leukemia, an increase in *1,25-dihydroxyvitamin D$_3$* is implicated.

Hypercalcemia is rarely the sole presenting manifestation of an underlying malignancy. The presence of hypercalcemia in association with malignancy indicates a grim prognosis, as the median survival is approximately 2 months. Very high levels of serum calcium (>14 mg/dL) are most often associated with malignancy, but levels up to 20 mg/dL may be seen in acute primary hyperparathyroidism caused by large parathyroid adenomas.

Other Causes. In *sarcoidosis*, enhanced conversion of inactive vitamin D to its active 1,25-dihydroxy form by granulomatous tissue increases absorption of calcium from the gut and resorption of bone. *Vitamin D intoxication* and *milk–alkali syndrome* are being seen increasingly with the popularization of calcium and vitamin D supplements to avert osteoporosis. Hypercalcemia may occur when an excess of 50,000 U of vitamin D and an excess of 3 to 5 g of calcium are consumed daily.

The *thiazide diuretics* cause a transient, mild increase in serum calcium, generally within the normal range. As noted earlier, a sustained increase in serum calcium beyond 10 days implies underlying metabolic bone disease, usually hyperparathyroidism. Some investigators have used thiazides as a provocative test for hyperparathyroidism in patients with borderline hypercalcemia. *Theophylline* excess is another pharmacologic cause of hypercalcemia.

Hyperthyroidism is associated with mild elevations in serum calcium in approximately 20% of patients because of increased skeletal turnover. *Immobilization* in young persons who have not completed skeletal growth and in patients with Paget's disease may cause severe hypercalcemia. *Lithium* therapy for manic–depressive illness is sometimes associated with hypercalcemia. Persons taking lithium may have an altered calcium set point for PTH secretion. *Addison's disease* and severe *liver*

disease may cause hypercalcemia; mechanism(s) remain unknown.

DIFFERENTIAL DIAGNOSIS

Hyperparathyroidism is overwhelmingly the most likely cause of hypercalcemia in the medically well, asymptomatic patient. In a Swedish population survey that yielded 95 persons with hypercalcemia, hyperparathyroidism was suspected in 88 patients and confirmed surgically in 57 of the 59 who underwent neck exploration for cure of hyperparathyroidism. Primary hyperparathyroidism accounts for more than 60% of hypercalcemic patients and is extremely likely to be the explanation for hypercalcemia in patients with an elevation of serum calcium dating back several years. *Malignancy, granulomatous disease, hyperthyroidism, Addison's disease*, and *excess ingestion of vitamin D* and *calcium* are the causes of most other cases. Occasionally, an underlying *MEN syndrome* or *hypocalciuric hypercalcemia* is present.

WORKUP

Because a more extensive laboratory evaluation is undertaken, a *repeated calcium determination* is indicated to confirm the elevation. Measuring serum albumin and globulin levels helps to confirm that the calcium elevation is not an artifactual result of elevated protein binding of calcium. Hypercalcemia that appears ephemeral may be spurious, caused by prolonged application of the tourniquet at the time of blood drawing. Should hypercalcemia be confirmed, then evaluation can proceed.

History. In the "asymptomatic" patient, subtle manifestations of hyperparathyroidism, such as fatigue, weakness, lethargy, arthralgias, nonspecific gastrointestinal complaints, impairment of intellectual performance, and depression, should be specifically sought. Associated conditions such as hypertension, gout, pseudogout, and nephrolithiasis should be recognized. A history of increased urination may indicate calcium-related defects in urine-concentrating ability. Symptoms of underlying malignancy, particularly of breast, lung, and hematologic origin, should be pursued. Review of intake of antacids, food additives, and health food store preparations may uncover excessive ingestion of vitamin D or calcium. Symptoms of hyperthyroidism (see Chapter 103) also need to be considered.

Physical Examination in the totally asymptomatic patient is generally unrevealing. However, a careful search for signs of malignancy (breast mass, lymphadenopathy, bone tenderness) and sarcoidosis (lymph node enlargement, abnormalities on lung examination) should be undertaken. Signs of hyperparathyroidism are not readily apparent; band keratopathy is rarely visible without the slit lamp.

Laboratory Studies. After confirmation of hypercalcemia and in the absence of an obvious cause, one should obtain a *serum PTH* determination. Improvements in the sensitivity and specificity of immunoradiometric assays for the intact PTH molecule have proved to be a great advance in differentiating patients with hyperparathyroidism from those with other causes of hypercalcemia. In virtually all patients with hyperparathyroidism, PTH 1-84 is either frankly elevated, in 90%, or at the upper limit of the normal range (10 to 60 pg/mL), in 10%. In hypercalcemia associated with malignancy, PTH is either undetectable or below normal in most patients. Therefore, a single laboratory test confirms the diagnosis of hyperparathyroidism.

When hyperparathyroidism is under consideration, serum *electrolytes* and *phosphate* concentrations can provide indirect evidence of the diagnosis. Fasting hypophosphatemia, hyperchloremia, and mild metabolic acidosis suggests the diagnosis. This is because PTH induces renal phosphate and bicarbonate wasting. A normal serum phosphate level does not exclude the diagnosis of hyperparathyroidism, and hypophosphatemia can be observed in malignancy. Furthermore, phosphate must be measured in the fasting state, as intake of food causes phosphate to shift into cells as glucose is phosphorylated. *Alkaline phosphatase* elevation implies increased osteoblastic activity and can be seen in malignancy, hyperparathyroidism with PTH bone disease, and Paget's disease.

Although *anemia* and an *elevated erythrocyte sedimentation rate* can be seen in severe hyperparathyroidism with osteitis fibrosa cystica, these laboratory findings are more suggestive of multiple myeloma, the diagnosis of which requires a serum *immunoelectrophoresis* or, occasionally, a urine immuno-electrophoresis for light-chain excretion. *Chest radiographic findings* of hilar adenopathy or pulmonary parenchymal abnormalities, in conjunction with an elevated *angiotensin-converting enzyme*, is indicative of sarcoidosis. The hypercalcemia of sarcoidosis may be more severe following an interval of sun exposure, so that more sophisticated diagnostic studies may be required, including diffusing capacity, a hydrocortisone suppression study in which orally administered hydrocortisone (40 mg three times daily for 10 days) normalizes the hypercalcemia of sarcoidosis, and even bronchoscopy or mediastinoscopy with biopsy for histologic confirmation (see Chapter 48).

A *bone scan* will detect the skeletal metastases of breast cancer. *Skeletal radiography* may show lytic or metastatic lesions. Radiographic findings are frequently normal in hyperparathyroidism, but the finding of *subperiosteal bone resorption* is specific for and diagnostic of hyperparathyroidism. Cortical bone is lost preferentially in hyperparathyroidism. Therefore, it is important that noninvasive measurements of skeletal mass include cortical bone, which predominates at sites such as the wrist (in contrast to trabecular bone, which predominates in the spine and is lost earliest following the menopause).

Familial hypocalciuric hypercalcemia can be considered and excluded in patients without frankly elevated serum PTH by the finding of a 24-hour *urinary calcium excretion* of 80 to 100 mg. *Thyroid hormone* determinations (see Chapter 103), particularly total triiodothyronine by radioimmunoassay, and measurements of serum cortisol following administration of Cortrosyn should be performed if the patient has a history suggestive of hyperthyroidism or Addison's disease, respectively. A *1,25-dihydroxyvitamin D$_3$* assay will unequivocally allay concerns of excessive vitamin D intake.

Despite the occasional usefulness of such determinations to exclude the myriad causes of hypercalcemia, the most direct approach to the workup is to measure the PTH level with the sensitive, specific PTH immunoradiometric assay that is now available. In principle, an elevated PTH concentration or an inappropriately "normal" level in the setting of hypercalcemia should indicate hyperparathyroidism. Older carboxyl terminal and midregion radioimmunoassays for PTH recognized PTH-like factors present in the serum in some patients with hypercalcemia of malignancy. The elevation noted by such PTH assays was minimal for the degree of hypercalcemia present. These assays do not test for PTHRP.

MANAGEMENT OF HYPERPARATHYROIDISM

A basic decision in the management of hyperparathyroidism is whether to treat definitively with surgery or follow expectantly and consider medical modalities. The decision must take into account the degree of symptomatology and the natural history of the disease. Prospective studies have attempted to ascertain the natural history of disease in asymptomatic patients. Only in rare instances does recurrent nephrolithiasis, pancreatitis, or hypercalcemic crisis develop. The major consequence of untreated disease appears to be a decrease in skeletal mass, which may predispose to fracture. There is no way to predict who will suffer these effects; monitoring is required. Routine skeletal radiography and alkaline phosphatase measurements are insufficient for long-term follow-up of bone demineralization. *Bone densitometry* is required (see Chapter 164). Because cortical bone loss is most prominent, measurements are made in the proximal wrist. Marked elevation of *urinary calcium* may predict the development of nephrolithiasis.

Candidacy for Surgical Cure. Most authorities agree that the *symptomatic patient* with recurrent kidney stones or parathyroid bone disease or a serum calcium level higher than 12.5 to 13.0 mg/dL is a candidate for surgery. Less clear are the indications for surgery in *asymptomatic* or minimally or nonspecifically symptomatic patients with mild hypercalcemia. A 1990 National Institutes of Health consensus conference to establish guidelines for the management of hyperparathyroidism in asymptomatic persons formulated a set of criteria for surgical intervention (Table 96.1). Surgical cure is warranted for all persons younger than age 40, for those who have a cortical bone density that is two standard deviations below normal, and perhaps for patients with a urinary calcium excretion greater than 350 to 400 mg in 24 hours, which implies, on a restricted calcium intake, that a negative calcium balance is occurring. Cure rates for the initial neck exploration in experienced surgical centers are better than 90%.

Marked elevation of serum calcium, usually >12.5 mg/dL
History of an episode of life-threatening hypercalcemia
Reduced creatinine clearance
Presence of kidney stones detected by abdominal radiography
Markedly elevated 24-hour urine calcium excretion
Substantially reduced bone mass determined by direct measurement
Medical surveillance neither desirable nor suitable:
 Patient is young (<50 years old)
 Patient requests surgery
 Consistent follow-up is unlikely
 Coexistent illness complicates management

Adapted from Proceedings of the NIH Consensus Development Conference on Diagnosis and Management of Asymptomatic Primary Hyperparathyroidism. J Bone Miner Res 1991;6[Suppl 1–2]:S1.

Table 96.1. Indications for Surgical Treatment of Hyperparathyroidism

As just noted, curative surgical treatment should be a serious consideration for persons with asymptomatic hyperparathyroidism who are young or middle-aged because of the likelihood of progression of skeletal disease, particularly in women, who must anticipate the synergistic effects of menopausal bone loss. The cost of medical surveillance, which includes yearly or biannual assessment of renal function and skeletal mass, may surpass the cost of surgical cure after 5 to 10 years of follow-up studies. Some now recommend parathyroidectomy for nearly all patients. Long-term follow-up study finds that surgery results in normalization of biochemical abnormalities and an increase in bone density. However, three fourths of asymptomatic patients who do not undergo surgery experience no progression of their disease within 10 years, which suggests that for truly asymptomatic patients, an alternative to surgery is close follow-up. For such patients, biannual serum calcium determinations and annual measurements of urinary calcium excretion and bone mineral density allow timely recognition of the need for operative cure. Nonetheless, asymptomatic patients at high risk for disease progression, especially women as they enter menopause, should be advised about a surgical option.

Before surgery, localization of the parathyroid adenoma may be helpful, even to the skilled surgeon. Ultrasonography and technetium Tc 99m sestamibi scanning with computer programs that subtract thyroidal uptake of technetium have localized parathyroid adenomas in approximately 70% of patients preoperatively. Anatomic localization by selective angiography or, less commonly, by venous sampling is generally reserved for patients in whom neck exploration by an experienced parathyroid surgeon fails to cure the disease.

Medical Therapy. For patients who do not undergo surgical cure for hyperparathyroidism, several medical alternatives exist. These alternatives may help limit nonspecific symptoms of hypercalcemic hyperparathyroidism and, more importantly, may prevent skeletal loss.

Estrogen and progestogen therapy given to postmenopausal women may lower or even normalize serum calcium, reduce bone resorption, and increase skeletal mass. It represents a reasonable therapeutic option in older women without any contraindications for estrogen therapy (see Chapter 164). In women with a family or personal history of breast cancer, *tamoxifen* treatment has a beneficial effect on the skeleton and may be of therapeutic value.

Oral phosphate therapy, particularly for patients with moderate hypophosphatemia, may lessen fatigue and weakness and reduce urinary calcium excretion, thereby reducing the likelihood of renal stones. Serum calcium is lowered by the oral administration of phosphate, given as 250 mg to 500 mg of neutral phosphate four times daily. The most common side effect of this therapy is dose-related frequent bowel movements, which are often preferred to the constipation of hyperparathyroidism. Phosphate should be very cautiously administered in cases of renal insufficiency because the calcium phosphate solubility product of 65 might be exceeded and calcium be deposited in skeletal and extraskeletal sites. Phosphate therapy has a potential drawback: it increases PTH secretion and, theoretically, can accelerate bone resorption.

Diuretics, such as *furosemide* or *bumetanide*, increase renal calcium excretion. *Thiazides* may actually decrease PTH secretion and urinary calcium excretion. However, the risk for dehydration requires caution in the use of diuretic agents.

Calcitonin and *bisphosphonates* have *not* proved useful on a long-term basis in hyperparathyroidism. Tachyphylaxis develops with calcitonin therapy, and bisphosphonates result in only transient decreases in osteoclastic bone resorption and serum calcium levels.

Most physicians limit *dietary calcium* in patients with hyperparathyroidism. However, this restriction of dietary calcium may result in accelerated bone resorption as the body responds by maintaining the "set point" elevation of serum calcium with increased PTH secretion. It is prudent to increase the dietary calcium intake to 1 to 1.5 g daily in patients with hyperparathyroidism but no associated nephrolithiasis or increased levels of 1,25-dihydroxyvitamin D_3.

Patients who are taking phosphate or estrogen therapy or are being followed expectantly for hypercalcemia and the development of skeletal or renal disease should be instructed to maintain a *fluid intake* of at least 2 L daily and report any illness that might lead to dehydration and worsening hypercalcemia.

MANAGEMENT OF HYPERCALCEMIA OF MALIGNANCY

(See Chapter 92.)

INDICATIONS FOR REFERRAL AND HOSPITALIZATION

Because one cannot predict in which patients with asymptomatic hyperparathyroidism the progressive complications of disease will develop, recommendations for who should be referred for surgical cure cannot be rigidly applied. The decision to refer for surgery should take into account the patient's preferences and willingness to cooperate with the demands of long-term surveillance, and the availability of skilled surgical care. As noted above, the patients who should be urged to consider surgery are those who are younger than age 40, have a cortical bone density two standard deviations below normal, or have a urinary calcium excretion greater than 350 to 400 mg/24 h(which, on a restricted calcium intake, implies a negative calcium balance). Patients for whom surgical cure is being planned should be referred to surgeons experienced in the complexities of parathyroid surgery, not only for cure of potential hyperplasia and discovery of a parathyroid adenoma in an unusual location, but also for prevention of the complications of recurrent laryngeal nerve injury and hypoparathyroidism.

Hospitalization is necessary for patients with severe hypercalcemia. Hydration and bisphosphonates such as pamidronate that limit osteoclastic resorption of bone are helpful.

PATIENT EDUCATION

Several recommendations will prevent the likelihood of more severe hypercalcemia in patients with mild hyperparathyroidism. Adequacy of fluid intake and prevention of dehydration that might occur during an acute gastrointestinal illness should be encouraged. Although the administration of thiazide diuretics and calcium has been discouraged, thiazides may actually limit hypercalciuria and renal stone disease, and dietary calcium may decrease PTH secretion and limit negative calcium balance. Patients should be encouraged to remain active and avoid immobilization. The necessity of surveillance for PTH-induced skeletal disease and the delineation of symptoms that might represent manifestations of hyperparathyroidism (e.g., symptoms of nephrolithiasis and pancreatitis) should be carefully reviewed.

Sharing with patients information on the clinical course of hyperparathyroidism helps them choose among treatment options. The truly asymptomatic patient with mild disease needs to know that without surgery there is only a 25% chance of disease progression. Symptomatic patients are at greater risk.

CHAPTER 97 EVALUATION OF HYPOGLYCEMIA

Except in cases of diabetes, the workup for hypoglycemia is most often an exercise in ruling out underlying pathology, triggered by nonspecific symptoms (e.g., irritability, fatigue, sweats, confusion, palpitations, tremulousness) that are attributed to a "low blood sugar." At other times, the assessment is precipitated by the chance finding of a low blood glucose level. In the setting of diabetes, tight glucose control leading to hypoglycemic episodes is common and readily confirmed (see Chapter 102). In patients who do not have diabetes, confirmation may be more problematic, made difficult by a lack of glucose measurements taken during symptomatic periods and the nonspecific nature of the hypoglycemic symptoms. Compounding the diagnostic problem are unaddressed manifestations of psychopathology, which the patient may prefer to attribute to "hypoglycemia." Although true hypoglycemia in the absence of diabetes is rarely encountered in the office setting, its causes include serious, treatable conditions that must not be missed. These factors make the workup of hypoglycemia challenging. The primary care physician needs to know how to differentiate suspected from true hypoglycemia, and, in the nondiabetic patient, how to identify the rare case that requires an in-depth search for serious underlying disease. A cost-efficient strategy for assessment is needed because the question of hypoglycemia comes up all the time.

PATHOPHYSIOLOGY AND CLINICAL PRESENTATION

Mechanisms. Hypoglycemia can result from increased insulin secretion, enhanced glucose utilization, or inadequate functioning of one or more compensatory regulatory mechanisms. When hypoglycemia occurs, the liver responds with increased glycogenolysis and gluconeogenesis, stimulated by glucagon and epinephrine, which activate hepatic phosphorylase. In addition, the pituitary secretes growth hormone, which inhibits the utilization of glucose by muscle and enhances lipolysis, and adrenocorticotropic hormone (ACTH), which promotes cortisol production. The increased cortisol acts to stimulate gluconeogenesis and diminish muscle uptake of glucose.

No single threshold of glucose concentration invariably triggers hypoglycemic symptoms or characterizes patients with a disorder of glucose homeostasis. Glucose levels lower than 45 mg/dL (2.5 mmol/L) have been documented in metabolically normal men during prolonged exercise and in healthy asymptomatic women. More than 20% of normal patients demonstrate serum sugar levels below 50 mg/dL during glucose tolerance testing. Conversely, hypoglycemic thresholds may rise in poorly controlled diabetes, in which levels as high as 75 mg/dL (4.3 mmol/L) may trigger symptoms. This has led to the view that the onset of hypoglycemic symptoms is related to the robustness of counterregulatory responses in addition to the rate of fall in serum glucose and the absolute serum glucose concentration. In patients with intensively controlled insulin-dependent diabetes, the catecholamine response is blunted, and they may exhibit few symptoms until their glucose concentration falls to a very low level.

Clinical Manifestations of Hypoglycemia. Hypoglycemic symptoms are typically categorized as *neuroglycopenic* (confusion, lethargy, visual disturbances, behavioral changes, impaired performance of routine tasks) or *catecholamine-mediated* (anxiety, tremulousness, headache, palpitations, sweats). Adrenergic symptoms characteristically accompany acute, rapid falls in blood sugar, especially if levels drop to concentrations below 40 mg/dL. Neuroglycopenic symptoms can develop in the absence of premonitory adrenergic complaints.

In the outpatient setting, most cases of true hypoglycemia occur among persons who look well. Their condition is a consequence of insulin excess, and they may have no apparent symptoms indicative of the underlying cause. Those cases resulting from a failure of counterregulatory mechanisms usually occur in very ill patients, who are typically hospitalized with end-stage disease.

Exogenous Insulin or Oral Hypoglycemic Agents account for most of the cases of spontaneous hypoglycemia seen in clinical practice, which develops in persons attempting tight control of their diabetes. Although the hypoglycemia associated with diabetic therapy may occur at any time in relation to meals, it tends to be most severe in the fasting state. The hypoglycemia associated with the use of potent, long-acting oral agents can be particularly severe and prolonged (see Chapter 102). *Surreptitious administration* is seen among self-destructive persons, typically nurses with access to diabetic medications and syringes. Patients injecting insulin secretly may have high levels of immunoreactive insulin but very low serum levels of C-reactive protein or proinsulin because they produce little endogenous insulin. However, those taking excessive doses of oral hypoglycemic agents have high levels of insulin and C-reactive protein because the drugs stimulate endogenous insulin secretion. The diagnosis requires finding excessive amounts of oral agent and oral agent metabolites in the urine.

Early Adult-onset Diabetes. Postprandial hypoglycemia may occur 3 to 5 hours after meals as a consequence of delayed insulin release, a characteristic feature of type 2 diabetes. Insulin levels may be inappropriately high for the level of serum glucose at hand. In most type 2 diabetic patients, the mismatching of insulin and serum glucose levels is not sufficient to cause true symptomatic hypoglycemia, but on occasion it may be noted.

Insulinomas, a rare but important cause of uncontrolled insulin production, account for the large majority of patients with endogenous hyperinsulinemia. More than 85% of insulinomas are benign islet cell tumors. Many occur in the setting of multiple endocrine neoplasia type 1, which also includes parathyroid hyperplasia and pituitary adenoma. The clinical presentation of insulinomas can be confusing and highly variable in timing and severity. The only valid generalizations are that fasting and exercise may precipitate symptoms, and that profound degrees of hypoglycemia may ensue (leading to seizures in 10%). Levels of serum glucose are not always low after an overnight fast. In a series of 39 patients with proven islet cell tumors, about half still had glucose levels above 60 mg/dL after 10 hours of fasting. Another series found symptoms to occur with equal frequency early in the morning, late in the afternoon, and several hours after a meal. Nonetheless, evidence of hyperinsulinism is evident in more than 75% of patients after 24 hours of fasting, and 80% report a combination of neuroglycopenic and adrenergic symptoms. Serum levels of insulin and C-peptide (split from proinsulin) are high.

Non–Islet Cell Tumors. Some large mesenchymal tumors, hepatomas, gastric cancers, and adrenocortical carcinomas synthesize and release large amounts of the prohormone form of *insulin-like growth factor II* ("big" IGF-II). IGF-II inhibits the uptake of glucose by the liver and increases glucose uptake by the tumor itself and by insulin-responsive tissues (e.g., muscle and fat); hypoglycemia is the result. Insulin secretion is suppressed, so that levels of immunoreactive insulin in the serum become very low. The presentation is that of hypoglycemia in the setting of a known malignancy. Rarely, the tumor may be silent, but usually its presence dominates the clinical picture. Serum insulin and C-peptide levels are low. IGF-II may be detected in the serum in elevated quantities. Reduction in tumor bulk alleviates the hypoglycemia.

Defects in Glycogenolysis or Gluconeogenesis are uncommon in the office setting; they are seen predominantly among very sick and often hospitalized patients with advanced pituitary or adrenal insufficiency, end-stage liver or renal disease, or severe HIV infection. The common pathophysiologic denominator is failure of glucose counterregulatory mechanisms to maintain glucose homeostasis. Symptoms may be exacerbated by poor nutritional intake. On occasion, symptomatic hypoglycemia may be noted after severe binge drinking in the absence of food intake. Ill patients are particularly sensitive to the hypoglycemic effects of drugs, including pentamidine when given for *Pneumocystis* pneumonia, trimethoprim/sulfamethoxazole in the setting of renal failure, quinine or quinidine in the setting of malaria, and propoxyphene in renal failure.

True Reactive Hypoglycemia (after Gastric Surgery). Onset of true hypoglycemia 1 to 2 hours after eating characterizes the reactive hypoglycemia of patients who have undergone gastric surgery. About 5% to 10% of such patients experience a reactive hypoglycemia, believed related to pyloric sphincter incompetence and the excessively rapid entry of concentrated carbohydrates into the small bowel. Unidentified gut factors are stimulated, causing the release of excessive insulin. Symptoms should not be confused with those of the dumping syndrome (see Chapter 64), which consist of nausea, fullness, and weakness developing within an hour after eating. An occasional patient with a functional defect in gastric emptying may present in similar fashion.

Functional Reactive "Hypoglycemia" designates a common postprandial syndrome in which autonomic hypoglycemia-like symptoms occur within 2 to 4 hours after a meal and may be relieved by eating a snack. Patients may report that symptoms are especially likely to occur with the intake of concentrated sweets. Some authorities argue that the designation of "functional reactive hypoglycemia" is inappropriate because the serum glucose is usually normal at the time symptoms occur, so that the criteria of Whipple's triad are not met. Insulin secretion is normal, and no relation between glucose levels and symptoms can be demonstrated. The pathophysiology of this alimentary variant is unknown, but it may respond to a high-protein, low-carbohydrate diet. The "functional reactive hypoglycemia" label is also

sometimes applied inappropriately to asymptomatic patients who manifest a low serum glucose during a 5-hour glucose tolerance test, a normal occurrence in 10% to 20% of healthy persons.

DIFFERENTIAL DIAGNOSIS

The traditional classification of fasting versus reactive hypoglycemia is fading from use as it becomes increasingly appreciated that reactive hypoglycemia is not a diagnosis except in patients who have undergone gastric surgery. Proposed new classification schemes categorize causes of hypoglycemia according to "healthy versus ill-appearing patient" and "insulin-related versus non–insulin-related." For the purposes of office-based differential diagnosis by the primary care physician, the main diagnostic issue is less one of determining the cause of hypoglycemia than of confirming its presence. Nonetheless, categorizations can be helpful (Table 97.1).

Patient Looks Healthy/Insulin-Related
   Excessively tight diabetic control with insulin or sulfonylurea
     therapy
   Factious hypoglycemia induced by surreptitious insulin adminis-
     tration
   Sulfonylurea overdose
   Insulinoma
   Intense exercise
   Prior gastric surgery
   Early type 2 diabetes
Patient Looks Ill/Non–Insulin-Related
   End-stage renal disease
   End-stage liver disease
   HIV infection, severe
   Pituitary failure
   Alcohol binge, severe, with little food intake
   Hepatic dysfunction secondary to severe congestive heart fail-
     ure, sepsis, infiltrative disease
   Insulin-like growth factor II production by malignancy (most pa-
     tients are ill)
Patient Looks Ill/Drug-Related
   Pentamidine for *Pneumocystis* pneumonia
   Salicylates in renal failure
   Propoxyphene in renal failure
   Trimethoprim/sulfamethoxazole in renal failure
   Quinine in cerebral malaria

Table 97.1. Some Important Causes of True Hypoglycemia Seen in the Office Setting

Two important groups of nonhypoglycemic patients must be differentiated from patients who manifest genuine falls in glucose in conjunction with symptoms. One group comprises persons with *anxiety* or *depression* who have multiple bodily complaints of a functional or psychophysiologic nature (see Chapter 226, Chapter 227, and Chapter 230). The most common symptoms include fatigue, headache, spasms, palpitations, numbness,sweating, and mental dullness. These patients attribute their symptoms to "hypoglycemia" to explain their difficulties and avoid the psychosocial issues at hand. Requests for glucose tolerance testing are frequent. A second group is bothered by postprandial symptoms very similar to those experienced by patients with reactive hypoglycemia, but in the context of normal serum sugar levels.

WORKUP

The first task is to confirm that the patient with low blood glucose or "hypoglycemic" symptoms actually has true hypoglycemia. Complicating the evaluation is the difficulty of documenting the relationship between symptoms and blood glucose level. Once the criteria of Whipple's triad have been met, then the focus shifts to detecting important treatable disease, which may sometimes be obvious; however, in other cases, a search for occult disease or surreptitious patient behavior may be necessary.

Identifying True Hypoglycemia

Diagnostic Criteria (Whipple's Triad). The diagnostic criteria include (a) symptoms consistent with neuroglycopenia (blurred or double vision, confusion, odd behavior, lethargy) or adrenergic stimulation (anxiety, tremulousness, headache, palpitations, sweats); (b) a low serum glucose concentration (<50 mg/dL, 2.8 mmol/L) at the time of symptoms; and (c) relief of symptoms when the glucose level returns to normal. These criteria are sometimes referred to as *Whipple's triad*, named for the physician who first suggested them as a means of distinguishing normal persons from those with underlying disease. Simply having adrenergic symptoms or a low serum glucose level in the absence of symptoms does not suffice because many healthy persons may have an isolated glucose level below 50 mg/dL. The objective is to document the correlation between symptoms and a low serum glucose concentration. Without such documentation, one cannot make a diagnosis of physiologically significant hypoglycemia. The occurrence of symptoms in the presence of a normal blood glucose level rules out true hypoglycemia.

Testing and Confirming True Hypoglycemia. Determination of the *serum glucose at the time of symptoms* is essential for diagnosis and helps eliminate from consideration the large number of cases with symptoms that are not caused by hypoglycemia. In a study of patients referred with a presumptive diagnosis of reactive hypoglycemia, fewer than 20% actually had a serum glucose level below 50 mg/dL during symptoms—a finding that emphasizes the importance of a blood sugar determination at the time of symptoms. If the blood glucose level is above 50 mg/dL at the time of symptoms, then true hypoglycemia is ruled out. The traditional 5-hour oral *glucose tolerance test* is not indicated because it provides no useful information. Even if a low blood glucose level is detected during glucose tolerance testing (which occurs in up to 20% of normal persons), the number is meaningless in the absence of a correlation with symptoms. Thus, the glucose tolerance test can be skipped. More important is a determination of the glucose level at the time of symptoms.

Finger-stick methods have improved the ability to sample blood sugar at the time of symptoms, although reagent strip techniques may be inaccurate at low glucose concentrations and self-testing poorly performed when patients are symptomatic. Venipuncture is more accurate but less convenient. However, a sample is worth obtaining as long as symptoms are present because the serum glucose level is usually low in the presence of symptoms.

Patients not fulfilling criteria for hypoglycemia should be evaluated for other conditions. It is essential that one avoid mislabeling them as hypoglycemic, even if symptoms follow meals. In a study of 28 patients with suspected postprandial hypoglycemia, only 20% had abnormal glucose levels at the time of symptoms. Patients with no correlation between their symptoms and serum glucose levels are unlikely to have an underlying disturbance in glucose homeostasis. For them, an alternative explanation for symptoms should be sought. Symptoms of *anxiety* disorders, *depression*, and *hyperthyroidism* may mimic those of hypoglycemia. A story of early morning awakening, chronic fatigue, and disturbed appetite and libido in conjunction with a history of personally significant losses provides strong presumptive evidence for depression (see Chapter 227). Paroxysms of anxiety, palpitations, difficulty in breathing, and chest tightness unrelated to meals suggest a panic attack disorder (see Chapter 226). The presence of heat intolerance, weight loss despite normal food intake, constant nervousness unrelated to meals, and skin and hair changes point to hyperthyroidism (see Chapter 103).

Evaluating True Hypoglycemia

History. Once hypoglycemia has been established, the evaluation proceeds to determine whether the condition is insulin-related or not. In diabetics, the use of *insulin* and *sulfonylurea agents* needs to be reviewed (biguanides and thiazolidinediones do not in themselves confer a risk for hypoglycemia; see Chapter 102).As noted earlier, intensive insulin therapy may reduce the counterregulatory responses to hypoglycemia and lower the glucose level at which symptoms occur, so that a high index of suspicion is necessary. A person using such drugs surreptitiously is likely to deny any intake, but a *vocational history* of medical or paramedical work should raise one's index of suspicion. If *postprandial* symptoms develop, then one should check for a history of *type 2 diabetes* or *gastric surgery*. In a patient with a history of gastric surgery, onset within 1 to 2 hours after eating is very strong evidence for rapid emptying as the underlying pathophysiology. Symptoms beginning 3 to 5 hours after eating in a patient with a family history of diabetes or recent development of polyuria/polydipsia argues for early type 2 diabetes.

The physician checks for non–insulin-related causes by inquiring into recent *binge drinking* in the absence of food intake, end-stage *liver* or *kidney disease, adrenal insufficiency*, marked *hypopituitarism*, and a history of *malignancy*. Such persons are ill and the cause is usually evident, with symptoms of the underlying condition dominating the clinical presentation (see Chapter 71, Chapter 101, and Chapter 142).

Patients with *insulinomas* report few symptoms other than those related to their hypoglycemia, which typically worsen *after exercise* or in the *absence of food intake* (e.g., just before breakfast or late in the afternoon, especially with exercise). The occurrence of neuroglycopenic symptoms (blurred vision, diplopia, sweats, confusion, poor memory) during these periods should raise suspicion of the diagnosis. Because insulinomas often develop in the context of multiple endocrine neoplasia type 1, symptoms of hypercalcemia may be evident (see Chapter 96).

Physical Examination. In most cases of reactive hypoglycemia, few etiologically suggestive physical findings are noted. The exception is the upper abdominal

surgical scar in a patient who has undergone gastric surgery. Patients with fasting hypoglycemia should be checked for postural hypotension, alcohol on the breath, needle marks at common insulin injection sites, jaundice, ecchymoses, hyperpigmentation, visual field defects, abdominal mass, ascites, and other signs of hepatocellular failure (see Chapter 71). A careful neurologic examination is essential to rule out focal neurologic injury, which would indicate a cause of symptoms other than hypoglycemia.

Laboratory Studies can help in the differentiation between insulin-related and non–insulin-related causes. Concurrent measurements of serum *insulin, C-peptide* (formed as proinsulin and split during endogenous synthesis), and *glucose* at the time of symptoms are key to the differentiation. Often, an *overnight fast* is sufficient to elicit hypoglycemia and make possible these simultaneous determinations. Because exercise promotes a fall in serum glucose, it may be used in conjunction with fasting to elicit hypoglycemia and precipitate symptoms. In two thirds of patients with insulinomas, hypoglycemia develops within 24 hours; fewer than 5% have to fast for 72 hours (which requires an inpatient admission).

Inappropriately high levels of insulin in the presence of a low glucose level suggest an insulin-related cause; low or normal insulin levels are indicative of a cause other than insulin. An insulin-to-glucose ratio in excess of 0.3 is consistent with insulinoma and characteristically increases as fasting progresses. An insulin level above 6 to 10 mg/mL and a C-peptide level above 0.2 to 0.4 nmol/ml strongly suggest insulinoma but may also occur with surreptitious sulfonlyurea use, which can be identified by testing a urine or serum sample for the presence of *sulfonylurea*. A high insulin level in the setting of a low C-peptide level indicates an exogenous insulin source. When insulinoma is a concern and more laboratory evidence is desired, a *C-peptide suppression test* can be performed. Insulin is infused during 1 hour, and C-peptide levels are monitored. Failure to suppress C-peptide formation strongly suggests insulinoma.

Testing to locate an insulinoma can be difficult. In most settings, preoperative assessment by *ultrasonography* or *computed tomography* is adequate for lesions larger than 1.5 cm in diameter but insufficient for smaller lesions. A host of modalities for improved preoperative localization are being developed, but palpation by the surgeon with the aid of intraoperative ultrasonography remains the best means of localization at present.

The need for additional studies in patients with non–insulin-dependent hypoglycemia depends on the clinical context. *Cortisol* and *ACTH* determinations are indicated if hypopituitarism or adrenal insufficiency is suspected (see Chapter 101). Extensive liver function testing may be superfluous if the patient is floridly jaundiced and ecchymotic, but the prothrombin time and serum albumin remain the best measures of hepatocellular synthetic function (see Chapter 71). When tumor-induced hypoglycemia is suspected, an *IGF-II* determination can be considered; usually, the tumor has been identified earlier.

SYMPTOMATIC MANAGEMENT

Hypoglycemia is best treated by attending to the underlying cause (e.g., removing the insulinoma, debulking a tumor producing IGF-II, arranging for psychotherapy for self-destructive behavior, adjusting the diabetes treatment regimen; see Chapter 102). Those with postprandial hypoglycemia (e.g., *after gastric surgery*) may respond to dietary interventions, such as *frequent feedings* (six per day) and diets *high in protein* and *low in concentrated carbohydrate*. In addition, treatment with anticholinergic agents (e.g., 7.5 mg of propantheline before meals) delays gastric emptying; results are fair at best. Other approaches include administration a b-blocking agent before meals (e.g., 10 mg of propranolol), reversal of a 10-cm segment of the jejunum, and administration of pectin.

Patients who have postprandial symptoms without hypoglycemia (i.e., those previously labeled as having *functional reactive hypoglycemia*) may benefit from similar dietary measures, although no controlled studies have established the efficacy of any of these dietary manipulations. Some patients note that avoidance of concentrated sweets is helpful, but the mechanisms of symptom production and reduction remain unclear.

PATIENT EDUCATION

The patient who seeks medical attention because of a fear of hypoglycemia should be taken seriously, but once the diagnosis has been ruled out, reassurance and refocusing attention to other possible causes of symptoms should follow. Patients with underlying psychopathology may initially refuse to accept the fact that hypoglycemia is not responsible for their symptomsbecause the attribution serves as a psychologically comfortable explanation. One needs to explore their concerns sympathetically while redirecting further evaluation to an exploration of anxiety, depression, and somatization disorders (see Chapter 226, Chapter 227, and Chapter 230). The patient with "functional reactive hypoglycemia" whose glucose levels are normal during the occurrence of symptoms can be reassured that although the symptoms are "real," they are not related to low blood glucose or disturbances in glucose homeostasis, and that simple dietary recommendations (see above) may be helpful. Requests for glucose tolerance testing are common, but they are readily withdrawn when the lack of specificity of the test is explained. Patients with a suspected insulinoma appreciate being told that almost all cases are benign, and that removal of the tumor cures their condition, with little risk for relapse or recurrence.

INDICATIONS FOR ADMISSION AND REFERRAL

Patients with suspected insulinoma are at risk for a profound fall in serum glucose and should be referred promptly to an endocrinologist and surgeon familiar with the management of this rare condition. Those with severe symptoms (seizure, mental confusion) should be admitted immediately to the hospital for glucose infusion and detailed evaluation. Routine referral of patients with postprandial symptoms for glucose tolerance testing is no longer considered appropriate.

CHAPTER 98 EVALUATION OF HIRSUTISM

SAMUEL R. NUSSBAUM

Hirsutism in women is caused by increased androgenic activity and is characterized by the excessive growth of hormone-dependent pubic, axillary, abdominal, chest, and facial hair. Women are likely to present for evaluation when such hair growth is viewed as exceeding that of others in their societal, geographic, or racial environment. For a woman living in a society preoccupied with stereotyped perceptions of beauty, hirsutism may be extremely upsetting and connote loss of femininity and sexuality. For the primary physician, hirsutism raises the question of an underlying endocrinopathy, ranging in severity from minor changes in androgen metabolism to the development of a hormonally active neoplasm.

When confronted with women with excessive hair growth, the primary care physician must decide whom to begin evaluating for endocrine disease and whom to reassure or treat symptomatically. Women with signs of virilization, progressive hair growth beginning after age 25, or concurrent amenorrhea should undergo endocrine evaluation (see below).

PATHOPHYSIOLOGY AND CLINICAL PRESENTATION

Pathophysiology. Hirsutism is a manifestation of excessive androgenic effect. The hormonal stimulus for hair growth is *5-a-dihydrotestosterone*, a potent testosterone metabolite derived from the peripheral conversion at the hair follicle of testosterone by 5-a-reductase. d -4-Androstenedione and *dehydroepiandrosterone* (DHEA), produced by the ovaries and adrenal glands, are the *precursors* for 50% to 70% of circulating testosterone in women; the remainder of the testosterone is secreted directly by the ovaries or occasionally by the adrenals.

Hirsute women generally have *increased production rates* of *DHEA* and d-4-androstenedione, which are relatively weak androgens, or of *testosterone*, a more potent androgen. Serum measurements of the total concentrations of androgens reflect the binding of sex steroid hormones to sex hormone–binding globulin; however, only the free fraction, which in the case of testosterone is 1% of total testosterone, is biologically active. The source of enhanced androgen production may be the *ovary*, the *adrenal gland*, or both. *Hyperinsulinism* resulting from insulin resistance has been noted to trigger excess ovarian androgen production, providing a possible link between *obesity* and hirsutism, a common association. In addition, obesity leads to a reduction in the concentration of sex hormone–binding globulin.

Virilization (temporal hair recession, acne, deepening voice, increased muscle mass, and clitoromegaly) develops when autonomous androgen production originating in an adrenal or ovarian neoplasm results in extremely high levels of circulating androgens.

Clinical Presentation. Hair follicles are located over the entire body except for the palms and soles. Hair growth is of two types; lanugo (neonatal) or vellus hair is soft, unpigmented, and rarely more than 2 cm long, whereas terminal hair is coarse and pigmented and grows in excess of 2 cm. A survey of college women revealed that one fourth had easily noticeable facial hair, one third reported hair extending along the linea alba from the pubic area (male escutcheon), and 17% had periareolar hair. Three fourths of women over age 60 have a measurable growth of facial hair. Hirsutism has familial, ethnic, and racial patterns. Eastern European women are more hirsute than Scandinavian women; white women are more hirsute than black women, who have more body hair than Asian women. The *Ferriman-Gallwey scale* is used to define and grade hirsutism. Hair growth in each of nine androgen-dependent areas of the body is graded from 0 (no hair growth) to 4 (frankly virile growth). A score of 8 or more is generally accepted as indicative of hirsutism.

Ovarian Sources. The majority of women with nonvirilizing hirsutism in conjunction with oligomenorrhea or amenorrhea have *polycystic ovary disease.* Gonadotropin dynamics are abnormal, with a loss of pulsatile secretion of luteinizing hormone (LH), an increased ratio of LH to follicle-stimulating hormone (FSH), and elevated levels of LH. Concurrent obesity and insulin resistance are noted in many patients, which contribute to androgen excess. Both LH and insulin stimulate excessive secretion of ovarian testosterone and androstenedione. Large numbers of small ovarian follicles form, but follicular growth is abnormal and no preovulatory follicles develop. Menstrual abnormalities and infertility are the consequence (see Chapter 112). The ovaries may be of normal size or enlarged, and they characteristically contain multiple follicular cysts.

Ovarian hyperthecosis, which may be seen in association with the syndrome of acanthosis nigricans and insulin resistance, and *ovarian tumors*, including arrhenoblastomas and hilar cell tumors, are capable of causing *virilization* through an excess production of testosterone. The virilized patient often has testosterone levels exceeding 200 ng/dL.

Adrenal Sources. *Late-onset congenital adrenal hyperplasia* designates a heterogeneous group of mild disorders of cortisol biosynthesis (most commonly partial deficiency of 21-hydroxylase or 3-d-hydroxydehydrogenase) that are increasingly recognized as an important cause of adult-onset hirsutism. The enzyme deficiencies lead to the production of abnormal amounts of adrenal androgen. These conditions are inherited as an autosomal recessive trait closely linked to the HLA gene. Menstrual abnormalities are noted in conjunction with hirsutism, but clinically significant glucocorticoid deficiency does not occur.

Cushing's syndrome, especially if the underlying cause is an *adrenocortical carcinoma*, may produce virilization. Other causes of Cushing's syndrome are more likely to produce excess hair growth and typical cushingoid features without true virilization.

Androgen excess may accompany *hyperprolactinemia* because prolactin stimulates androgen production, particularly DHEA. Characteristic features are amenorrhea and galactorrhea (see Chapter 113).

Other Causes. Hirsutism in women with normal periods and normal plasma androgens is often labeled *idiopathic.* Although initially believed to be a consequence of overproduction of testosterone, idiopathic disease is now viewed as a condition of enhanced peripheral conversion of testosterone to dihydrotestosterone by increased 5-a-reductase activity in hair follicles and skin.

Drugs are another important cause of hirsutism. Most potent are the *anabolic steroids* (methyltestosterone, oxandrolone), used surreptitiously by some women engaged in competitive body building or athletics. The sex steroid precursor *androstenedione* is available without prescription and is very popular among adolescents; it is estimated that 2.5% of all adolescent girls take the drug regularly, especially those engaged in competitive athletics. When used in doses of 300 mg/d by young men, it results in increased levels of testosterone and estradiol. Similar increases in sex hormones are likely in young women, although they are not yet documented. Danazol, used to treat endometriosis, may also bring on hirsutism. In an occasional patient, oral contraceptives containing androgenic progestogens may stimulate hair growth (see Chapter 119), although this is not a frequent side effect. Phenytoin, glucocorticoids, cyclosporine, diazoxide, and minoxidil stimulate hair growth by poorly understood, nonandrogenic mechanisms.

DIFFERENTIAL DIAGNOSIS

The causes of hirsutism can be divided into those that do and do not cause virilization and categorized according to adrenal and ovarian sources of androgen excess (Table 98.1). In a series of 100 outpatients presenting to an endocrine unit for evaluation of true hirsutism, about 75% had polycystic ovary disease, 15% were labeled idiopathic, and 3% had late-onset congenital adrenal hyperplasia. In the remainder of the cases, Cushing's disease, ovarian tumor, prolactinoma, or drug use was identified as the cause. In addition, some patients with anorexia nervosa report an increase in body hair (see Chapter 234), and excessive tweezing (hypertrichosis) may traumatize the hair follicle and cause coarse hair to grow at the site of repeated injury.

CAUSE	MECHANISM
Hirsutism without Virilization	
Idiopathic	Increased peripheral conversion of androgens
Late-onset congenital adrenal hyperplasia	Adrenal androgen overproduction
Cushing's syndrome (ACTH-induced)	Adrenal androgen overproduction
Polycystic ovary disease	Ovarian androgen overproduction
Insulin resistance/obesity	Ovarian androgen overproduction
Drugs: anabolic steroids, danazol, minoxidil, phenytoin, diazoxide, glucocorticoids	Varies, ranging from direct androgenic activity to nonandrogenic effects
Hirsutism with Virilization	
Ovarian hyperthecosis	Autonomous ovarian androgen production
Ovarian neoplasms	Autonomous ovarian androgen production
Adrenal neoplasms, especially adrenal carcinoma	Autonomous adrenal androgen production

ACTH, adrenocorticotropic hormone.

Table 98.1. Differential Diagnosis of Hirsutism

WORKUP

The paramount objective in the evaluation of hirsutism is to identify the women who are likely to have important underlying endocrine disease.

History

Features suggestive of serious endocrine disease include *virilization* (voice change, temporal hair recession, increased muscle mass, acne); *rapid progression*, particularly a sudden increase in hair growth after age 25; *amenorrhea* or menstrual changes; and *galactorrhea*. The new onset of *hypertension* in the setting of hirsutism should also raise suspicion. A peripubertal onset of hirsutism is generally reassuring. A detailed *drug history* (anabolic steroids, oral contraceptives, danazol, phenytoin, corticosteroids, minoxidil, cyclosporine, diazoxide) is essential. Inquiry into any daily or regular use of nonprescription sex hormone precursors, such as *androstenedione*, is essential because the substance is popular among adolescent competitive athletes who take it to enhance their performance (estimated prevalence of regular use among adolescent women is 2.5%). *Southern European* or *Mediterranean ancestry* in conjunction with hirsutism of a similar degree in a mother, grandmothers, aunts, and sisters reduces the probability of serious disease. However, a positive family history may also be found in some patients with polycystic ovary disease and partial congenital adrenal hyperplasia.

Physical Examination

Terminal hair on the face, about the areolae, and on the lower abdomen is normal, but new growth, especially on the upper abdomen, sternum, upper back, and shoulders, suggests androgen excess and hirsutism. Virilization is indicated by temporal and vertical scalp hair loss, a deep voice, acne, an increase in muscle mass, and clitoromegaly. Cushing's syndrome should be suspected when centripetal obesity, muscle wasting with myopathy, and violaceous striae are encountered. Patients with oligomenorrhea require a pelvic examination to detect bilaterally enlarged cystic ovaries; however, a significant number of women with polycystic ovary physiology do not have palpable ovarian abnormalities. Women with virilization and amenorrhea should be examined carefully for a palpable adrenal or ovarian neoplasm. Most of these tumors are inefficient producers of androgens and do not result in high levels of circulating androgens until they become quite large.

Laboratory Studies

An abundance of costly endocrinologic hormonal assays may be performed in the evaluation of hirsutism. To avoid theexpense of unnecessary testing, it is important to define the likely diagnostic considerations and the goals of therapy for hirsutism so that appropriate hormonal evaluation may be obtained, rather than the indiscriminate measurement of all ovarian and androgen sex steroids and pituitary hormones. On the basis of the history and physical examination findings, patients can be categorized as likely to have idiopathic or familial, oligomenorrheic/amenorrheic, cushingoid, or virilizing forms of disease.

Idiopathic and Familial Forms of Hirsutism. A young woman with a minor increase in facial hair beginning in the peripubertal period but with perfectly regular ovulatory menses is most likely free of serious underlying disease and need not undergo detailed testing. The same pertains to the normally menstruating woman of southern European ancestry whose female relatives have similar amounts of facial and body hair.

Oligomenorrheic/Amenorrheic Disease. When amenorrhea or oligomenorrhea, obesity, and hirsutism occur, especially in the context of infertility, polycystic ovary disease needs to be considered. Because pelvic examination may not reveal bilaterally enlarged cystic ovaries, *pelvic ultrasonography* and laboratory testing can help to confirm the clinical suspicions. Testosterone, particularly *unbound testosterone*, and *ratios of LH to FSH* are increased. Because an increase in androgens suppresses sex hormone–binding globulin, measurement of the unbound or *free serum testosterone* is more valuable than measurement of the total testosterone. Free testosterone correlates best with testosterone production rates. Because testosterone secretion is episodic, *three serum samples* taken 15 minutes apart may be pooled for immunoassay.

Patients with menstrual irregularities but no evidence of polycystic disease should be evaluated for a late-onset congenital adrenal hyperplasia (most often 21-hydroxylase deficiency). This condition can be identified by performing an *ACTH stimulation test* and measuring the *plasma 17-hydroxyprogesterone* 30 to 60 minutes after the IV administration of one ampule (25 μg) of cosyntropin (synthetic ACTH). A pretest level of 17-hydroxyprogesterone above 300 ng/dL is suggestive, but many patients have normal levels, so that ACTH stimulation testing is necessary. A posttest level above 1,200 ng/dL at 30 minutes is diagnostic. Although these patients represent a minority of hirsute women, no distinguishing clinical features of this entity set it apart from the more common polycystic ovary syndromes. *Prolactin* should be measured in women with oligomenorrhea or amenorrhea, especially if galactorrhea is also present.

Cushingoid Appearance. Patients with clinical features of Cushing's syndrome should be screened with either a *24-hour urinary free cortisol determination* or an *overnight dexamethasone suppression test*. The 24-hour urinary free cortisol determination, which is the more specific study, is above 100 mg in Cushing's syndrome. *Urinary 17-ketosteroids* are elevated in adrenocortical carcinoma. For overnight dexamethasone suppression, the patient is given 1 mg of dexamethasone at midnight, and the plasma cortisol is measured at approximately 8:00 a.m. the next day. Cortisol should be suppressed to below 5 μg/dL. If the 24-hour urinary free cortisol is elevated, or an elevated cortisol is not suppressed by dexamethasone, more extensive dexamethasone testing to determine the likelihood and cause of Cushing's syndrome needs to be pursued.

Virilization. When virilization is present, *serum testosterone* and *urinary 17-ketosteroids* should be measured. The serum testosterone level will be above 200 ng/dL in women with masculinizing ovarian or adrenal neoplasms. Measurement of 17-ketosteroids detects elevated adrenal androgens, such as androstenedione and DHEA in adrenal cortical carcinoma. Although both the adrenals and ovaries can synthesize all the androgenic steroids, adrenal hormonal production is best assessed by measuring *DHEA sulfate*, as more than 90% is formed in the adrenal gland. A serum DHEA level above 800 μg/dL strongly suggests an adrenal tumor. Androstenedione is synthesized equally by the adrenal and ovary glands. When the presence of a tumor is suspected in one of these glands, *ultrasonography* or *computed tomography* is required. Before a search for tumor is begun, the history should again be checked for the regular use of exogenous androstenedione, as in competitive athletes, especially adolescent girls, for body building.

SYMPTOMATIC MANAGEMENT AND PATIENT EDUCATION

Alternative approaches to the management of hirsutism are based on the underlying pathophysiology. They include (a) supportive reassurance that no important underlying endocrine disease is present; (b) cosmetic manipulations, such as bleaching, waxing, use of depilatories, and electrolysis; (c) medical therapy with estrogens or glucocorticoids directed at suppressing ovarian and adrenal hormone overproduction; (d) medical therapy directed at antagonizing the action of androgens at the receptor level; and (e) definitive curative therapy of underlying diseases such as Cushing's syndrome or masculinizing ovarian neoplasms.

Supportive Measures and Cosmetic Manipulations. Patients free of significant endocrine disease can be effectively managed with *reassurance* that hirsutism does not impair sexuality or fertility. Adolescents taking exogenous sex hormone precursors such as androstenedione to enhance their athletic performance will benefit from a nonjudgmental review of the cosmetic and developmental consequences of taking these "natural" supplements.

If a woman is concerned about her appearance, cosmetic manipulation or medical therapy is appropriate. Hair may be bleached with a 6% *hydrogen peroxide* solution or commercially available cream bleaches. Shaving removes unwanted hair; however, because hair grows at the rate of 1 mm/d, "stubble" appears within several days. *Epilation* with tweezers or hot wax may retard hair growth for several months but may cause low-grade folliculitis. *Chemical depilation* may require the use of low-concentration hydrocortisone topically to prevent irritation. *Electrolysis*, the only permanent method of hair removal, involves electrocoagulation and destruction of the hair root. It is a costly and time-consuming process and should be performed only by a licensed electrologist.

Suppression of Ovarian and Adrenal Androgen Overproduction. *Oral contraceptives* containing estrogen and progestin suppress ovarian and adrenal androgen production by decreasing levels of FSH and LH. In addition, the estrogen increases sex hormone–binding globulin levels, competes with the cytosolic receptor for dihydrotestosterone, and limits (along with progestogens) endometrial hyperplasia in hyperandrogenic patients with *polycystic ovaries*. Oral contraceptives also work well for patients with *idiopathic disease* by reducing the amount of available androgenic substrate. Preparations containing at least 35 μg of ethinyl estradiol or 50 μg of mestranol are needed to reduce androgen levels; those with lower amounts of estrogen are less effective. The least androgenic progestins, such as norethindrone (1 mg) or ethynodiol acetate in combination with mestranol and ethinyl estradiol, are preferred. If the hormonal and clinical responses to these therapies, determined at 3 months, are inadequate, an oral contraceptive containing larger amounts of estrogen should be used. Side effects of these drugs, including an increased risk for thromboembolism in smokers (see Chapter 119), must be reviewed. A decrease in hirsutism is usually not evident for 3 to 6 months; a decrease in the rate of hair growth is noted initially, followed by a transformation to lighter, finer hair.

Glucocorticoids may reduce hirsutism and induce ovulation in partial *congenital adrenal hyperplasia*, in which the androgens are of adrenal origin. Adrenal suppression with a concomitant decrease in androgens can best be accomplished by administering 1 mg of dexamethasone at bedtime. Potential concerns with this form of therapy are suppression of the hypothalamic–pituitary–adrenal axis and induction of a cushingoid appearance. Alternate-day corticosteroid therapy may suffice and reduce the risk for such adverse effects. Following the changes in the 17-hydroxyprogesterone concentration is an effective means of monitoring therapy.

Weight reduction should be part of any program for the obese hirsute woman. Normalization of weight limits the peripheral conversion of androstenedione to testosterone by fatty tissue and reduces the hyperinsulinism that may contribute to ovarian production of androgens. Impressive results can be achieved.

Antagonizing Testosterone at the Target Tissue. *Spironolactone*, an antihypertensive diuretic, decreases androgen levels by decreasing testosterone biosynthesis and antagonizing peripheral action on the hair follicle. Dosages as high as 100 mg twice daily have been shown to diminish hirsutism during a 3-month observation interval but may cause menstrual disturbances. One might begin therapy with 50 mg twice daily taken from day 4 through day 22 of each menstrual cycle. The drug is teratogenic and should not be used in large doses by women of childbearing age. It is often given as an adjunct to oral contraceptives in patients with severe polycystic ovary disease.

Cimetidine, a histamine$_2$-receptor antagonist, competes with androgens for target tissue binding; it appears to be less effective than spironolactone.

Flutamide, a selective androgen receptor antagonist, and *finasteride*, a 5-a-reductase inhibitor, offer improved blockade of testosterone action at the target tissue. Studies are ongoing.

INDICATIONS FOR REFERRAL

Patients with virilization and elevated testosterone levels require evaluation by an endocrinologist and a gynecologist because a virilizing tumor may be present. If polycystic ovary syndrome is present and if infertility is an issue, referral for clomiphene therapy and evaluation for endometrial hyperplasia with endometrial biopsy is appropriate. Hyperprolactinemia necessitates coronal computed tomography or magnetic resonance imaging to recognize a prolactinoma or pathologic process interrupting the dopaminergic inhibition of prolactin. Patients with Cushing's syndrome should be referred for endocrinologic evaluation of a pituitary, adrenal, or ectopic origin.

CHAPTER 99 EVALUATION OF GYNECOMASTIA

Gynecomastia is defined as enlargement of the male breast as the result of an increase in glandular tissue, which distinguishes it from simple obesity. Some patients present out of fear of loss of masculinity or onset of breast cancer. Others may not have recognized the change and come to the physician at the suggestion of friends or family. Gynecomastia is a normal transient physiologic event in 70% of pubertal boys; its prevalence in adults is less than 1%. The primary physician must be able to recognize gynecomastia and initiate an evaluation to rule out such important potential causes as adrenal and testicular cancers, cirrhosis, and hyperthyroidism. In most instances, the cause is more benign and the tasks are to allay fears and help the patient decide about treatment.

PATHOPHYSIOLOGY AND CLINICAL PRESENTATION

Pathophysiology

Estradiol is the growth hormone of the breast. Gynecomastia represents a phenomenon of relative estradiol excess leading to the proliferation of breast tissue. Under normal circumstances, most estradiol in men is derived from the peripheral conversion of testosterone and adrenal estrone. The basic mechanisms of gynecomastia are a decrease in androgen production, an absolute increase in estrogen production, and an increased availability of estrogen precursors for peripheral conversion to estradiol. Blocking of androgen receptors and increased binding of androgen are additional modes of reduced androgen effect.

Reduced Androgen Production accounts for many cases seen in older men or men with testicular endocrine failure, as after bilateral orchiectomy and other forms of cancer therapy. Ketoconazole inhibits testosterone production in a dose-related manner. *Androgen availability is reduced* in both hyperthyroidism and cirrhosis because of an increase in the serum concentration of sex hormone–binding globulin. *Blockade of androgen receptors* accounts for the gynecomastia associated with use of spironolactone, cimetidine, flutamide, and perhaps marijuana.

Increased Estrogen Production may be seen with Klinefelter's syndrome, adrenal carcinomas, tumors producing ectopic human chorionic gonadotropin (hCG), and Leydigs cell tumors of the testes. Tumors that produce hCG stimulate the testicular production of estradiol. Teratomas of the testes and carcinomas of the lung, pancreas, and colon are known sources of ectopic hCG. The transient gynecomastia of puberty represents a brief physiologic increase in testicular estrogen secretion and lasts 1 to 2 years before receding.

Increased Estrogen Precursor Availability is the mechanism of gynecomastia in patients who have androgen-secreting tumors or congestive heart failure, or who use *exogenous androgen*, which leads to an increased conversion of testosterone and androstenedione to estradiol and estrone. This effect has been documented with the use of *androstenedione*, the popular "natural" sex hormone precursor supplement taken by body builders and adolescents. Hyperthyroidism causes an *increased peripheral conversion*. Much of the conversion takes place in fatty tissue. An *exogenous estrogen effect* is seen with the use of digitalis and synthetic estrogens. Ketoconazole and spironolactone cause a *release of free estrogen* by displacement from sex hormone–binding globulin.

Clinical Presentations

The most noticeable feature is an increase in breast tissue, unilateral in a third of cases. Tenderness may also be noted in a third of patients, but actual pain is less frequent. Enlargement is usually central and symmetric, although it is occasionally eccentric. Idiopathic and drug-induced gynecomastia is usually unilateral, whereas in pubertal and hormonal cases, the changes are often bilateral. It may be that asymmetry is a more accurate description than unilateral enlargement, based on the prevalence of bilaterally histologic but not clinically evident gynecomastia in autopsy series.

A few distinctive clinical presentations are noted. In *Klinefelter's syndrome*, gynecomastia develops around puberty in a patient with long limbs, small and firm testes, infertility, and normal or deficient secondary sex features. In cirrhosis, patients present with loss of libido, loss of body hair, and testicular atrophy (see Chapter 71).

Recovery from *malnutrition* or *serious chronic illnesses* (severe heart failure, renal failure, liver failure) leads to a picture resembling a second puberty, with development of transient gynecomastia.

Carcinoma of the male breast is distinct from gynecomastia; it is characterized by a unilateral, eccentrically located firm mass that may be fixed. Male breast cancer is rare; it is generally not more frequent in patients with gynecomastia, although the incidence in patients with Klinefelter's syndrome is higher.

DIFFERENTIAL DIAGNOSIS

In healthy pubertal boys, transient physiologic gynecomastia is the most likely explanation (Table 99.1). Testicular or adrenal tumors are rare in this age group, but Klinefelter's syndrome may account for a number of cases.

Table 99.1. Differential Diagnosis of Gynecomastia

The two most common causes of gynecomastia in adults are drugs and alcohol-related liver disease. Estrogens, androgens, androstenedione, spironolactone, digitalis preparations, flutamide, ketoconazole, cimetidine, and marijuana have all been associated with gynecomastia. The association also exists but is more tenuous with use of phenothiazines, amphetamines, reserpine, methyldopa, isoniazid, imipramine, phenytoin, and heroin. In one series, 22% of patients had a history of taking a drug associated with gynecomastia, and 26% had alcoholic liver disease.

Less common causes include recovery from malnutrition or a serious chronic illness. Much rarer forms are tumor-related ectopic hCG production and feminizing adrenal, testicular, and pituitary tumors. In just under 10% of cases, a probable cause is not identified. Gynecomastia must be distinguished from carcinoma of the male breast.

WORKUP

History. The onset, location, duration, and course deserve note. The most important aspect is a detailed inquiry into drug use, including chronic alcoholism and the use of cimetidine, spironolactone, flutamide, digitalis, ketoconazole, or exogenous estrogens or androgens. The use of androstenedione by adolescents and body builders is common and needs to be checked. Any symptoms of hyperthyroidism (see Chapter 103), heart failure (see Chapter 32), or hepatocellular failure (see Chapter 71) should be noted, as should the resolution of a chronic illness and any changes in libido, skin, voice, testicles, and hair quality and distribution. Weight loss, chronic cough, hemoptysis, change in bowel habits, headaches, or visual field disturbances can be important etiologic clues.

Physical Examination. Onset at puberty should trigger an examination for features of Klinefelter's syndrome (arm span greater than height, small and firm testes, absence of secondary sex characteristics). In adults, one needs to look at the skin for signs of hepatocellular failure (jaundice, spider angiomas, ecchymoses, pallor, palmar erythema) and hyperthyroidism (warm, sweaty skin and fine hair). The eyes are checked for exophthalmos, and the neck palpated for goiter.

During the breast examination, the glandular texture of true gynecomastia must be distinguished from the fatty consistency of breast enlargement related to obesity and the nodularity of a carcinoma. Asymmetry and nodules deserve special note, and careful palpation of the axillary nodes is necessary. The question of malignancy in the breast tissue must always be considered in gynecomastia. If the enlargement is unilateral and eccentric, the breast is particularly firm or nodular, or axillary adenopathy is present, then a biopsy should be performed.

On cardiopulmonary examination, one checks for signs of heart failure (see Chapter 32), and on abdominal examination for signs of cirrhosis (see Chapter 71). The abdomen must be palpated for masses and the stool tested for occult blood. The testicles are examined for atrophy and nodules. The presence of a testicular nodule requires workup for a carcinoma (see Chapter 131).

Laboratory Studies. Gynecomastia not associated with puberty, drugs, hyperthyroidism, hepatocellular failure, or another obvious cause requires further evaluation. Laboratory testing should begin with measurement of *serum gonadotropins* (*luteinizing hormone* and *follicle-stimulating hormone*).

High concentrations are consistent with testicular failure, Klinefelter's syndrome, and hCG-secreting tumors. Ectopic hCG production can be identified by finding elevated *serum b-hCG subunit* levels. This should trigger a search for the source of ectopic gonadotropin production (see Chapter 92). To check for Klinefelter's syndrome, a buccal smear is obtained and examined for chromatin positivity (Barr bodies). If the smear is negative, the diagnosis is most likely primary testicular failure or a chromatin-negative variant of Klinefelter's syndrome.

Low gonadotropin concentrations are more worrisome because they raise the question of autonomous androgen or estrogen production (in addition to exogenous sex steroid use). Repeated questioning of the patient regarding exogenous steroid use, including regular use of popular precursor preparations such as *androstenedione*, is critical. If the patient's responses are convincingly negative, then levels of *free testosterone* and *estradiol* should be measured, but with full cognizance of the pitfalls involved in interpreting the results. For example, total testosterone may be affected by the concentration of sex hormone–binding protein and not reflect the free testosterone concentration. Consequently, free testosterone must be measured. However, testosterone secretion can fluctuate greatly, so that three samples obtained during 15 minutes should be pooled for best results. The estradiol concentration measured may correlate poorly with the rate of estrogen production because of vagaries in peripheral uptake. Thus, normal levels do not necessarily rule out an estrogen-secreting tumor, although marked elevations are very suggestive, provided exogenous use has been ruled out. If serum estrogens are elevated, then adrenal cancer and Leydig cell tumor of the testes should be ruled out.

Normal gonadotropin and *sex hormone levels* make serious underlying endocrinopathy unlikely and can be followed expectantly with periodic reevaluation. It is important to keep in mind that gynecomastia may resolve after the condition that caused it resolves. The search for an underlying cause may yield few clues if the cause was transient and self-limited.

SYMPTOMATIC MANAGEMENT, PATIENT EDUCATION, AND INDICATIONS FOR REFERRAL

Removal of the offending drug usually produces regression of breast enlargement within a month or two. Counseling adolescents who are using androstenedione on a daily basis for body building is especially important because it may help prevent adverse developmental consequences (see Chapter 238). The gynecomastia that accompanies puberty or refeeding after starvation is a transient phenomenon that can be managed by providing reassurance. Resolution of gynecomastia usually follows treatment of hyperthyroidism. Gynecomastia attributable to alcoholic liver disease or Klinefelter's syndrome is not likely to respond to any treatment. When hCG-secreting tumors are discovered, resection of the tumor is indicated if possible.

The persistence of gynecomastia may produce cosmetic problems. Patients who are considerably bothered by breast enlargement may elect to undergo *mastectomy*, but this should be performed only after the underlying cause has been elucidated. Experimental use of the antiestrogen tamoxifen has been useful in reducing breast size in patients with painful gynecomastia.

When a benign condition such as drug-induced gynecomastia is discovered, the patient can be reassured that the condition is not a reflection of loss of maleness or a carcinomatous process. It must be remembered that some conditions that produce gynecomastia may reduce potency; this situation must be confronted and discussed with the patient. No evidence of carcinomatous degeneration in gynecomastia has been found except in Klinefelter's syndrome. Pain, irritation, or social problems that may arise should be dealt with symptomatically and sympathetically.

Consultation with an endocrinologist is essential when a case of Klinefelter's syndrome is suspected, and also when ectopic hCG production is a concern or autonomous sex hormone production is under consideration (low gonadotropin levels). Referral is also indicated when treatment of gynecomastia is being considered, be it medical therapy or surgery.

CHAPTER 100 EVALUATING GALACTORRHEA AND HYPERPROLACTINEMIA

Discharge of milk or colostrum from the breast in the absence of nursing is referred to as *galactorrhea*. When it is accompanied by disturbed menses or infertility, it suggests the possibility of hyperprolactinemia and the associated risk for pituitary neoplasm. When a patient presents with galactorrhea, underlying pituitary disease must be carefully considered.

PATHOPHYSIOLOGY AND CLINICAL PRESENTATION

Galactorrhea. Normal milk production involves the interplay of prolactin and breast tissue primed by estrogen and progestin. Prolactin secretion is under hypothalamic control, mediated by inhibitory dopaminergic transmission. Other hormones (e.g., thyroxine, insulin) are thought to play supporting roles in facilitating lactation. Galactorrhea can occur in the setting of a normal or elevated serum prolactin level. The normal range for serum prolactin is 1 to 20 ng/mL.

Normoprolactinemic Galactorrhea is believed to be a consequence of local breast stimulation or irritation in women with hormonally primed breast tissue. It is hypothesized that stimulation of the breast may cause a mild, transient elevation in prolactin secretion, although this is not sustained. Many cases are associated with a distant pregnancy or the use of oral contraceptives. Gonadal function is preserved, with menses and fertility remaining normal. Galactorrhea in the absence of sustained hyperprolactinemia is usually noted as an isolated symptom or an incidental finding on breast examination.

Hyperprolactinemic Galactorrhea develops as a consequence of excessive prolactin production, caused either by a loss of hypothalamic inhibition of lactotrophs in the anterior pituitary or by the development of an autonomously functioning pituitary adenoma. In rare instances, hyperprolactinemia results from a decreased clearance of prolactin (as in renal failure). Even in the context of high prolactin levels, galactorrhea does not occur unless the breast is primed by estrogen, which accounts for the rarity of the condition in men. Amenorrhea is a common accompaniment, which develops when high prolactin levels suppress the secretion of hypothalamic gonadotropin-releasing hormone (GnRH).

Hyperprolactinemia. Very high serum concentrations of prolactin are associated with autonomously functioning *prolactinomas*, derived from lactotrophs in the anterior pituitary. The degree of hyperprolactinemia tends to correlate with tumor size. Prolactinomas larger than 10 mm in diameter ("macroadenomas") are associated with extremely high prolactin levels (>1,000 ng/mL). Except in pregnancy, serum prolactin in excess of 300 ng/mL is almost always the result of a prolactinoma. Microadenomas (<10 mm in diameter) may produce less impressive elevations. They typically have a benign course and undergo little additional enlargement.

Moderate degrees of hyperprolactinemia are characteristic of conditions that interfere with hypothalamic control of the anterior pituitary. In nonpregnant patients with galactorrhea, only slightly more than half of those with prolactin levels above 100 ng/mL had a functioning pituitary tumor; the remainder had a problem that compromised hypothalamic inhibition. Interruption of hypothalamic inhibition can occur with use of a centrally active *dopaminergic blocking agent* (e.g., a phenothiazine), with *anatomic interference* by a sellar or suprasellar mass, and in *hypothyroidism*, in which thyrotropin-releasing hormone (TRH) stimulates lactotrophs in the anterior pituitary. Transient prolactin elevations have been observed in patients undergoing emotional stress, physical trauma, and nipple stimulation.

Because patients with hyperprolactinemia are at risk for hypogonadism, they may experience, in addition to galactorrhea, disturbed menses, *amenorrhea, infertility*, and *osteoporosis*. In hyperprolactinemic men, galactorrhea is rare, but *impotence* is common. Those with a substantially enlarging sellar mass may complain of *headache* or a *visual field cut*.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of galactorrhea can be organized according to whether prolactin is elevated or not, and according to whether an elevation in prolactin is the result of a decrease in hypothalamic inhibition or overproduction by a functioning adenoma (Table 100.1). Only 20% of patients with galactorrhea have hyperprolactinemia. In patients with galactorrhea, amenorrhea, and hyperprolactinemia, prolactinoma is a leading cause. Other causes originating in the region of the pituitary include empty sella syndrome, craniopharyngioma, pinealoma, and parasellar sarcoidosis. Nonprolactinomic disease about and within the pituitary accounts for about one third of cases of galactorrhea and amenorrhea. Persistent galactorrhea after childbirth accounts for just under 10% of cases. Drugs associated with galactorrhea include oral contraceptives and agents with central dopaminergic-blocking activity (phenothiazines, haloperidol, metoclopramide) and, less commonly, reserpine, methyldopa, isoniazid, and imipramine.

Table 100.1. Differential Diagnosis of Galactorrhea

WORKUP

History and Physical Examination. The workup for galactorrhea should include careful questioning about menstrual pattern, recent pregnancy, infertility, medications, change in libido, symptoms of hypothyroidism (see Chapter 104), breast stimulation, chest trauma, and the presence of headache or visual complaints. A careful review of drug use, particularly oral contraceptives and drugs that block central dopaminergic transmission (see above), needs to be pursued. The physical examination should include a detailed examination of the breasts to be sure the discharge is indeed milky and not caused by local breast disease, although no increased risk for breast cancer has been found in patients with true galactorrhea. Confrontation testing of the visual fields and funduscopic examination are important, although the findings are usually normal. Any signs of hypothyroidism (see Chapter 104) should be noted and then confirmed by measuring the thyroid-stimulating hormone (TSH) level.

Laboratory Testing. The development of accurate prolactin assays and the association of galactorrhea with high prolactin levels and pituitary tumors have made determination of the *serum prolactin concentration* an essential part of the diagnostic evaluation. However, caution is warranted in obtaining and interpreting a prolactin level. The prolactin concentration may be transiently elevated by stress, time of day, sleep, meals, or breast stimulation. Accuracy is enhanced by placing a catheter in the patient's vein and having the patient rest in a recumbent position for an hour before the sample is drawn. The morning is the best time. The patient with galactorrhea and amenorrhea is at increased risk for a pituitary neoplasm, and her prolactin concentration must be measured unless the explanation for both is

apparent (e.g., recent pregnancy, medication).

Patients with galactorrhea, menstrual irregularities, and an otherwise unexplained elevation in serum prolactin should undergo neuroimaging of the sellar region. *Magnetic resonance imaging* (MRI) *with gadolinium enhancement* is the procedure of choice, although *computed tomography* (CT) is a reasonable alternative if MRI is unavailable. Gadolinium enhancement of MRI of the sellar structures is based on differences in vascularity between normal pituitary tissue and adenomas. Nonetheless, microadenomas can be difficult to detect, although the absence of a visible lesion rules out an anatomically threatening neoplasm. Even patients with modest unexplained elevations of prolactin (<200 ng/mL) should undergo neuroimaging of the pituitary region because another type of sellar or parasellar mass can be responsible for the mild elevation. Finding a lesion in excess of 10 mm in a patient with a modest rise in prolactin necessitates consideration of other types of pituitary tumors. The prolactin rise is likely to represent compression of the pituitary stalk.

Formal visual field testing should be performed in all patients with a sellar mass or visual symptoms.

From a practical standpoint, regular menses and a normal prolactin level in a patient with galactorrhea make the likelihood of a clinically important pituitary tumor remote. Patients in whom the likelihood of tumor is low can be followed carefully with periodic determinations of prolactin, usually at 1-year intervals; if prolactin levels become elevated, neuroimaging of the sella can be pursued.

SYMPTOMATIC MANAGEMENT

No Evidence of a Mass Lesion. Patients with normal periods and normal prolactin levels need no treatment. They can be reassured and followed. For patients with galactorrhea secondary to the use of a dopaminergic-blocking agent, a reduced dose of the drug can be tried, although full cessation may be necessary to terminate symptoms. If hypothyroidism is the contributing factor, it should be corrected (see Chapter 104). Symptomatic patients with *idiopathic disease* (galactorrhea, abnormal periods, elevated prolactin, normal MRI findings, no other evident disease) who want relief from their symptoms can be treated as if they have a microadenoma (see below).

Prolactinoma. The treatment approach depends on the size of the lesion and its natural history. *Microadenomas* (<10 mm in diameter) have an excellent prognosis. Long-term studies of untreated patients demonstrate that in 80% to 90% of cases, the size of a microadenoma remains the same, or the tumor regresses with time; only 10% to 20% continue to grow. Prolactin levels follow a similar pattern. However, with microadenomas that grow, the correlation between tumor size and prolactin level may not be close, so that close monitoring of both parameters is necessary.

Despite the favorable prognosis, many patients with stable microadenomas may be bothered by menstrual irregularities, severe galactorrhea, and infertility. As noted earlier, osteoporosis is also a risk. The treatment of choice for such symptomatic patients is the dopaminergic agonist *bromocriptine*. The drug inhibits prolactin synthesis, secretion, and cellular proliferation. In many instances, prolactin levels return to normal, galactorrhea ceases, tumor size decreases, menses resume as gonadal function returns, and osteoporosis recedes. For control of symptoms, continuous bromocriptine administration is required, although in some patients the tumor undergoes spontaneous regression. A 2-year course of treatment followed by a trial of cessation is a common approach to bromocriptine therapy for patients with a symptomatic microadenoma. The doses needed to control symptoms range from 2.5 to 10 mg/d, although smaller doses often suffice for maintenance. Dopaminergic agonists with fewer side effects are under development. An alternative to bromocriptine therapy when pregnancy is not desired is the use of *oral contraceptives*, the benefits of which include regular periods, birth control, and the prevention of osteoporosis.

Macroadenomas are also treated initially with *bromocriptine*. In many instances, the drug suffices to control symptoms and shrink the adenoma. The doses needed to establish control range from 5 to 20 mg/d. Tumor size and prolactin concentration decline substantially. Lower doses (0.625 to 10 mg/d) are effective for maintenance. Indefinite treatment is the rule because spontaneous regression is rare. *Surgery* is reserved for patients with rapidly progressing visual loss or symptoms refractory to bromocriptine therapy. Because the recurrence rate after surgery is high, its use is limited. *Radiation therapy* is sometimes considered.

PATIENT EDUCATION AND INDICATIONS FOR REFERRAL

Patients with pituitary adenomas understandably worry about further tumor growth. Concern can be lessened by explaining the very favorable prognosis for the vast majority of microadenomas and the excellent response of most prolactinomas to bromocriptine. The patient with galactorrhea and amenorrhea should be informed that numerous options for induction of fertility are available and that these may be pursued according to the patient's wishes. By providing accurate information, moral support, and close follow-up, the primary physician can spare the patient a great deal of unnecessary concern.

Although the basic evaluation of galactorrhea and hyperprolactinemia can be effectively carried out by the primary physician, a consultation with the endocrinologist is indicated in a number of situations (e.g., macroadenoma, suspected pituitary neoplasm other than prolactinoma, failure to respond to bromocriptine, visual loss, desire to become pregnant).

CHAPTER 101 EVALUATION OF SUSPECTED DIABETES INSIPIDUS

When a patient presents with polyuria and polydipsia, the primary care physician needs to include diabetes insipidus (DI) in the differential diagnosis. DI is characterized clinically by the excretion of large volumes of inappropriately dilute urine. Although uncommon, DI may be a manifestation of important hypothalamic–pituitary disease or renal tubular dysfunction. The primary care physician needs to know how to screen for DI in a patient with polyuria and polydipsia and how to proceed with the basic elements of the diagnostic investigation.

PATHOPHYSIOLOGY AND CLINICAL PRESENTATION

Plasma osmolality is carefully regulated to maintain a level of 285 to 290 mOsm/kg. Any increase to much above 290 mOsm/kg stimulates hypothalamic osmoreceptors, following which *antidiuretic hormone* (ADH), also called *vasopressin*, is released from the posterior pituitary. ADH increases renal distal tubular permeability to water, so that water resorption is enhanced. Osmoreceptor stimulation also triggers *central thirst mechanisms*. These actions serve to reestablish normal serum osmolality. A lesion in any portion of this osmoregulatory system can result in DI and its attendant water diuresis. Dehydration and hypertonicity may ensue unless the thirst mechanism remains intact and access to water is adequate.

Clinically, DI is characterized by the excretion of large volumes of dilute urine in conjunction with thirst and polydipsia. A true polyuria occurs, defined as the excretion of more than 3 L/24 h. Craving for ice water is common (especially with central DI). The urine is almost always colorless, even in the morning, because of its dilute nature. Urine osmolality is inappropriately low (<250 mOsm/kg). Nocturia is common. Serum osmolality may be increased, especially if the thirst mechanism is impaired.

Central or Neurogenic Diabetes Insipidus is the most common form of DI, occurring in the context of an injury to the hypothalamus or posterior pituitary. Mechanisms of central DI include idiopathic degeneration of vasopressin-secreting neurons, destruction by malignant or granulomatous disease, vascular insult, and pituitary surgery. Because the thirst center is situated near the hypothalamic osmoreceptors, it too may be involved, although in many cases the thirst mechanism is preserved and dehydration avoided. Anterior pituitary adenomas usually do not cause DI unless they extend posteriorly or beyond the sella.

Nephrogenic Diabetes Insipidus results from conditions or medications that damage renal tubulointerstitial function and concentrating ability (e.g., hypercalcemia, hypokalemia, sickle cell disease, lithium, obstruction, pyelonephritis). ADH levels are appropriate, but the renal response is impaired.

Primary Polydipsia also produces polyuria, but unlike DI, this condition appears to originate with an altered perception of thirst. It is particularly prevalent among patients with chronic psychiatric disturbances (especially schizophrenia) but is also seen with organic brain disease (e.g., multiple sclerosis). Detailed study of such patients has revealed multiple defects in the regulation of osmolality, including problems with urinary dilution, regulation of water intake, and ADH secretion. Increased thirst and fluid intake are followed by polyuria, although some patients may hide this behavior. A fall in serum osmolality (<285 mOsm/kg) may be accompanied by hyponatremia. Symptoms tend to be episodic.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis for patients with polyuria and polydipsia in the outpatient setting includes *diabetes mellitus* (see Chapter 102), *diuretic use, DI*, and *primary polydipsia*. The differential can be organized as follows: (a) whether the diuresis is related to water or solute; (b) if related to water, whether it is a manifestation of DI or primary polydipsia; and (c) if DI, whether it is central or nephrogenic (Table 101.1). Other causes of urinary frequency unaccompanied by polydipsia (e.g., *urinary tract infection, bladder dysfunction*) need to be ruled out (see Chapter 133, Chapter 134, and Chapter 140).

Solute Diuresis
  Diabetes mellitus
  Diuretics

Water Diuresis
  Diabetes insipidus
    Central
      Idiopathic
      Trauma
      Tumor (local or metastatic to the sellar region)
      Granulomatous disease (sarcoidosis, tuberculosis)
      Postsurgical (removal of pituitary adenoma)
      Vascular (Sheehan's syndrome, old stroke)
    Nephrogenic
      Drugs (lithium, demeclocycline, amphotericin)
      Tubulointerstitial disease (pyelonephritis, polycystic kidney
        disease, sickle cell disease, obstructive uropathy)
      Metabolic (hypercalcemia, hypokalemia)
    Primary polydipsia
      Psychogenic (schizophrenia)
      Central nervous system disease (multiple sclerosis)
      Idiopathic

Table 101.1. Differential Diagnosis of Polyuria/Polydipsia in the Outpatient Setting

WORKUP

The initial diagnostic evaluation of the patient with polyuria can proceed logically and efficiently by addressing a set of basic questions:

Is This True Polyuria or Just Urinary Frequency? A history of frequently voiding large volumes of dilute (colorless or pale) urine, both day and night, suggests true polyuria, whereas frequent voiding of small volumes of concentrated urine is indicative of bladder dysfunction caused by infection or other local disease. A *24-hour urine collection* provides objective confirmation of true polyuria when the volume exceeds 3 L.

If True Polyuria, Is This a Water Diuresis or a Solute Diuresis? Measurement of the *urine osmolality* is very helpful. Patients with a concentrated urine (>350 mOsm/L) have a condition causing a solute diuresis. Those with a dilute urine (*<250 mOsm/L*) have a water diuresis. Patients with a urine osmolality between these levels may have either. To differentiate, one calculates the *total solute excretion* (urine volume per day multiplied by the average urine concentration). If it is less than 1,200 mOsm/d, then a water diuresis is likely. If a solute diuresis is suspected, checking the urine for glucose and electrolytes can be confirmatory.

If a Water Diuresis, Is This Diabetes Insipidus or Primary Polydipsia? Measurement of the *serum osmolality* can be helpful. A clearly elevated serum osmolality (*>290 mOsm/L*) in the context of inappropriately dilute urine (osmolality *<275 mOsm/L*) suggests DI, although many patients with DI and an intact thirst mechanism and access to water have a serum osmolality close to normal. A low serum osmolality suggests primary polydipsia. Direct measurement of the *serum vasopressin* (ADH) would help to clarify the situation, but reliable assays are not widely available. Very low levels would occur with central DI; very high levels would indicate renal DI; inappropriately elevated levels would suggest primary polydipsia.

The clinical context may help suggest the cause of the water diuresis. When it occurs in the setting of known renal tubulointerstitial disease or drug use, nephrogenic DI is likely. A central mechanism is suggested when the patient presents with other manifestations of pituitary disease or has a condition that may damage the central nervous system (e.g., cancer, granulomatous disease). Onset in a patient with mental illness raises the probability of primary polydipsia.

Desmovasopressin Testing. When the cause remains uncertain and in the absence of a reliable measure of ADH, it may be necessary to admit the patient for a *trial*

of *desmovasopressin* (DDAVP), an ADH analogue. The response to DDAVP helps clarify the underlying mechanism of the water diuresis. A 50% decrease in urine volume, an increase in urine osmolality, and a return of serum osmolality toward normal confirm central DI. Lack of response identifies renal DI. DDAVP also causes a decrease in polyuria and an increase in urine osmolality in patients with primary polydipsia, but the serum osmolality will decrease to subnormal levels and hyponatremia may ensue. Because of such risks and the need to monitor fluid intake and excretion closely, inpatient testing is usually recommended for a DDAVP trial.

Pituitary–Hypothalamic Imaging. Biochemical evidence of central DI is an indication for neuroimaging to determine if a mass lesion or other disease is compromising the integrity of the pituitary. *Magnetic resonance imaging* (MRI) with *gadolinium* enhancement is the procedure of choice, although *computed tomography* (CT) is a reasonable alternative if MRI is unavailable or cost is a major issue. Gadolinium enhancement of MRI of the sellar structures is based on differences in vascularity between normal and abnormal tissues.

Is This Definitely Primary Polydipsia? When primary polydipsia is suspected (low–normal or low serum osmolality, polyuria, low urine osmolality, concurrent psychiatric disease), an inpatient *water restriction test* can be confirmatory; all parameters will return to normal when water is restricted. Because such dehydration testing can be very dangerous for patients with other causes of a water diuresis, it is necessary to conduct this test in a carefully supervised inpatient setting. Supervised water restriction is also necessary because patients with primary polydipsia tend to be psychotic and drink surreptitiously.

SYMPTOMATIC RELIEF

The advent of *DDAVP* as a *nasal spray* has greatly facilitated the treatment of central DI. The intranasal vasopressin is taken before bed to eliminate nocturnal polyuria. The dose is adjusted to allow normal amounts of daytime urination. Excessivedoses can lead to a DDAVP-induced syndrome of inappropriate secretion of ADH.

Drugs that enhance ADH secretion (clofibrate, chlorpropamide, carbamazepine) are also helpful. Somewhat paradoxically, *thiazide diuretics* relieve the symptoms of DI. By inducing a mild sodium diuresis, they enhance the proximal resorption of sodium and water, so that the amount of water that reaches the distal tubule is reduced. *NSAIDs* are sometimes helpful in nephrogenic DI. By inhibiting renal prostaglandins (which are active in settings of renal disease), they reduce water delivery to the distal tubule. Treatment of the underlying psychiatric disturbance is the only treatment at present for primary polydipsia.

INDICATIONS FOR ADMISSION AND REFERRAL

As noted above, patients requiring DDAVP testing or a trial of water restriction need to be admitted. An endocrinologic consultation can be helpful in further planning the diagnostic evaluation and in interpreting its results. Patients in whom central DI is suspected are candidates for neuroimaging of the sella region (MRI is best) and endocrinologic consultation for further testing of the hypothalamic–pituitary axis. Renal DI suggests extensive renal tubulointerstitial disease and the need for further investigation and consultation. The patient with primary polydipsia should undergo a careful psychiatric workup to search for an underlying thought disorder.

CHAPTER 102 APPROACH TO THE PATIENT WITH DIABETES MELLITUS

ALLAN H. GOROLL

INTRODUCTION

Diabetes mellitus, the most prevalent endocrinologic problem encountered in primary care practice, is characterized by hyperglycemia, a relative or absolute deficiency of insulin, insulin resistance, and a propensity to the development of long-term microvascular and macrovascular complications. If recent trends showing a dramatic increase in prevalence (believed to be a consequence of a decline in physical activity and excessive caloric intake) continue, then the condition will soon affect nearly 20 million people in the United States. The primary physician is in the unique position to provide comprehensive care to the diabetic patient. The ultimate goals of therapy are the prevention of microvascular and macrovascular complications, consequences of diabetes that make the condition a major risk factor for cardiovascular disease, stroke, visual impairment, renal failure, impotence, peripheral neuropathy, limb loss, and death.

Effective management requires care that is thoughtful and meticulous, incorporating intensive patient education. Euglycemic control, with the level of hemoglobin A$_{1c}$ (HbA$_{1c}$) kept below 7.0 mmol/L, has emerged as a major treatment objective because of its association with a marked reduction in the risk for microvascular complications. The challenge for the primary care physician is to design a therapeutic program that is safe, practical, and acceptable to the patient. Important decisions include determining when to initiate pharmacologic therapy, selecting among available agents, and setting an achievable goal for glycemic control. Practical tasks include creation of an effective means for diabetic surveillance and provision of education and encouragement that enable the patient to become a partner in management.

PATHOPHYSIOLOGY, CLINICAL PRESENTATION, AND COURSE

Diagnostic Criteria. The increasing appreciation of the pathologic significance of hyperglycemia and the importance of early diagnosis has resulted in a revision of diagnostic criteria by the Expert Committee on the Diagnosis and Classification of Diabetes Mellitus. The threshold for diagnosis based on the *fasting blood glucose level* has been revised downward from 140 mg/dL to *126 mg/dL*) to increase the sensitivity of this determination. The 2-hour-postprandial glucose determination conducted as part of a glucose tolerance test is more sensitive for the diagnosis of diabetes than the fasting glucose level is, but it is less convenient to perform, especially in the evaluation of populations. Thus, for populations, the fasting glucose level with a reduced threshold is now deemed the preferred measurement. For individuals, the diagnosis can be made based on the presence of any one of three glucose abnormalities found on two separate days:

1. Fasting plasma glucose >126 mg/dL
2. Random plasma glucose >200 mg/dL in a person with diabetic symptoms, or
3. Two-hour-postprandial plasma glucose level >200 mg/dL after administration of the equivalent of a 75-g glucose load

If the fasting blood glucose is between 100 mg/dL and 126 mg/dL, the diagnosis can be made on the basis of a 75-g oral glucose tolerance test showing a *2-hour-postprandial plasma glucose and one other value between 0 and 2 hours above 200 mg/dL* .

Classification. The major forms of diabetes may be classified pathophysiologically. The use of the terms *insulin -dependent* and *non–insulin-dependent* is now discouraged because exogenous insulin may be needed to treat either form of the disease, so that the terms are meaningless. The major classifications of diabetes are as follows:

Type 1 Diabetes. Type 1 diabetes is characterized by an absolute deficiency of insulin. Patients are *ketosis-prone* and require insulin to live. Onset is typically in youth but may occur at any age.

Type 2 Diabetes. Type 2 diabetes Insulin is present, but in amounts insufficient to meet metabolic needs in a timely fashion. Because they have some insulin, these patients are *not ketosis-prone* (except under severe stress of infections or surgery). They exhibit *impaired insulin secretion* at any plasma glucose concentration and "*insulin resistance*" (impaired insulin action at the level of the insulin receptor or signal transudation). *Obesity*, which is present in 60% to 80% of patients with type 2 diabetes, is believed to play a major role in insulin resistance.

Impaired Glucose Tolerance. Patients are identified on the basis of a *fasting glucose* between *110 mg/dL* and *126 mg/dL* or a *2-hour-postprandial glucose* between *140 mg/dL* and *200 mg/dL*. The risk for the development of overt type 2 diabetes is increased (1% to 5% annually), as is the risk for cardiovascular disease. Microvascular complications do not develop in those who do not progress to diabetes.

Gestational Diabetes. In pregnancy, even minor degrees of glucose intolerance can be important (see below). Screening for the condition is conducted at 24 to 28 weeks of gestation by testing for a plasma *glucose above 140 mg/dL at 1 hour after oral administration of a 50-g glucose load* .

Pathogenesis. The basic pathogenesis of diabetes remains incompletely understood; genetic and acquired factors have been identified. The principal lesion in type 1 disease is pancreatic b -*cell failure*, which leads to a loss of insulin production. Type 2 disease is characterized by defects in both the production and peripheral action of insulin; *impaired insulin secretion, decreased muscle glucose uptake*, and *inappropriate hepatic glucose production* are the pathophysiologic hallmarks. The latter two features are sometimes characterized as manifestations of *insulin resistance* because they occur despite the secretion of insulin. Insulin resistance is an important component of the broader metabolic perturbations that are features of diabetes, including weight gain, dyslipidemia, hypertension, and a strongly increased risk for macrovascular atherosclerotic disease. Coronary risk is two to four times greater in diabetic than in nondiabetic persons.

Weight gain is an important contributor to type 2 disease, exacerbating insulin resistance. Glucose intolerance in diabetic patients may also be worsened by infection, stress, thiazides, glucocorticoids, and pregnancy. Excess secretion of growth hormone, cortisol, catecholamines, or glucagon may contribute to glucose intolerance, as can diseases that destroy a substantial portion of the pancreas (e.g., chronic pancreatitis, hemochromatosis, cystic fibrosis).

Clinical Presentation and Course. Type 2 diabetes is often discovered as an incidental finding on screening urinalysis or blood sugar measurement. Occasionally, the diagnosis is made during an evaluation for cardiovascular, renal, neurologic, or infectious disease. A complication such as myocardial ischemia, stroke, intermittent claudication, impotence, peripheral neuropathy, proteinuria, or retinopathy may be the initial manifestation. Sometimes, fatigue is the predominant symptom. In patients with more significant hyperglycemia, polyuria, polydipsia, and polyphagia with weight loss are encountered. The natural history of both type 1 and type 2 diabetes is characterized by the relentless progression of b-cell failure with time, even in the setting of tight glycemic control. The most important determinant of daily glycemia is the fasting glucose level, so that efforts to normalize it are given top priority. A reduction is also important, but the postprandial glucose level is a lesser determinant of overall control.

Complications. Complications of diabetes occur with a very high frequency. Most correlate with the magnitude and duration of hyperglycemia; there does not appear to be any glycemic threshold for the development of such complications. The major complications of diabetes can be categorized as vascular, neurologic, ocular, and infectious. Diabetic vascular disease includes both *large-vessel* atherosclerotic disease and *microangiopathic* occlusive changes.

Macrovascular Disease. As noted, the increase in the risk for coronary events is marked and similar to that of a nondiabetic patient who has had a previous myocardial infarction. Premature atherosclerosis may develop in large and medium vessels, leading to coronary ischemia, stroke, and peripheral arterial insufficiency. The effects of smoking, hypertension, and other risk factors for vascular disease appear to be synergistic with those of hyperglycemia. The pathophysiology remains poorly understood. Current hypotheses include hyperglycemic alteration of lipid deposits to make them more atherogenic. In addition, it has been suggested that the

insulin resistance of type 2 disease leads to a state of *hyperinsulinism*, with its associated adverse cardiovascular effects of *increased blood pressure, reduced levels of high-density lipoprotein* (HDL) *cholesterol*, and *increased levels of very low-density lipoprotein* (VLDL) *cholesterol*—an atherogenic phenotype termed *syndrome X*. It is suspected but remains to be proved that tight control reduces the risk for large-vessel atherosclerosis. However, major reductions in the risk for coronary events and stroke can be achieved by correcting other major cardiovascular risk factors, such as smoking, hypertension, and hyperlipidemia. Effective treatment of such risk factors appears more important than normalization of glucose *per se* in the prevention and limitation of cardiovascular complications.

Microvascular Disease. Microvascular disease accounts for much of the morbidity of diabetes, causing nephropathy, retinopathy, and neuropathy. The risk for these microvascular complications can be markedly reduced by achieving tight glucose control (see below).

Diabetic nephropathy is one of the leading causes of end-stage renal failure in adults, accounting for 25% of cases (see Chapter 142). Characteristic renal changes include glomerular basement membrane thickening and mesangial proliferation. Mesangial proliferation correlates strongly with the onset of proteinuria and hypertension. Subclinical and histologic findings for diabetic nephropathy are present long before the stage of clinical proteinuria. An elevated glomerular filtration rate (hyperfiltration), genetic determinants, and hypertension contribute to the progression of renal impairment. With persistent proteinuria, hypertension becomes established and glomerular filtration begins to decline at the rate of 1 mL/min per month.

The risk for the development of nephropathy correlates with the duration of disease and the degree of hyperglycemia. Renal failure eventually develops in 30% to 50% of type 1 diabetics and 6% to 9% of type 2 patients. Tight control of the blood glucose can reduce the risk for renal failure, particularly if instituted early. It can reverse mild proteinuria in insulin-dependent diabetics who do not yet have renal insufficiency. In the presence of significant proteinuria (>500 mg/d), near-normalization of the plasma glucose may not slow the rate of renal deterioration. Bladder dysfunction and resultant urinary tract infections can also contribute to renal impairment in patients with diabetic neuropathy.

Retinopathy. The risk for retinopathic changes (see Chapter 209) is related to the duration and degree of hyperglycemia. After 20 years of diabetes, all age groups show a 75% to 80% prevalence of retinopathy. The cumulative incidence of retinopathy can be reduced by more than 50% with intensive insulin therapy. Reversible changes in the lens configuration occur with wide fluctuations in plasma glucose and may cause transiently blurred vision. In addition, cataracts and glaucoma occur with increased frequency (see Chapter 207 and Chapter 208).

Neuropathy may lead to a peripheral sensory deficit, autonomic dysfunction, or a mononeuritis. Mechanisms include *myoinositol depletion* in nerve cell membranes (which prolongs conduction time) and hyperglycemia-induced *sorbitol accumulation* in nerve tissues that have a polyol pathway for glucose metabolism (e.g., Schwann cells). *Microangiopathic changes* that decrease the blood supply to the myelin sheaths are believed responsible for the mononeuropathy. The *peripheral neuropathy* is predominantly sensory; sensation is reduced in the lower extremities, and the condition may progress to cause pain and dysesthesias. *Autonomic neuropathy* most commonly presents as impotence. Gastrointestinal motility disturbances, orthostatic hypotension, and urinary retention are other potential manifestations. Autonomic neuropathy is almost always seen in association with distal polyneuropathy. Its presence is an important predictor of foot and other infections. Diabetic *mononeuropathy* involves discrete cranial or peripheral nerves, singly or as a mononeuritis multiplex. Cranial nerves III and VI are most commonly affected. In contrast to other diabetic neuropathies, mononeuropathies resolve almost completely within 1 year of onset.

Increased susceptibility to infection in diabetics appears to result from impaired leukocyte function, compromised vascular supply, and neuropathy. Cellulitis and candidiasis occur, with infections of ischemic foot lesions especially serious because they may lead to osteomyelitis, which requires amputation. Overall, the occurrence of perioperative infections correlates with end-organ involvement by diabetes and marked degrees of hyperglycemia. Recent studies show a sixfold increase in all perioperative complications (stroke, infection, and renal insufficiency) in patients with end-organ disease. Urinary tract infections are common in patients with an autonomic bladder (see Chapter 134).

PRINCIPLES OF MANAGEMENT

Prevention

Prevention of type 2 disease is an achievable and important consequence of improved screening for diabetes. In the landmark Diabetes Prevention Program trial, high-risk obese persons (mean body mass index of 34) with fasting and postprandial glucose levels approaching those of frank diabetes mellitus achieved a marked improvement in glycemic control and prevention or at least delay in onset of frank type 2 disease when they implemented *lifestyle modifications.* A supervised program of modest weight reduction (sustained 7% weight loss), regular aerobic exercise (2.5 hrs/wk of moderately brisk walking), and a low-fat, low-calorie diet proved successful when fully implemented and maintained. *Metformin* also proved effective, but less so than lifestyle modification. These results underscore the importance of diet, exercise, and weight in the genesis, prevention, and treatment of type 2 disease.

Treatment Goals and Strategy

Treatment Goals. The goals of therapy in diabetes are *normalization of blood glucose* and prevention of multisystem complications that may result from hyperglycemia. The Diabetes Control and Complication Trial (DCCT) and the U.K. Prospective Diabetes Study (UKPDS), landmark prospective clinical trials comparing standard with tight-control regimens in types 1 and 2 disease, respectively, convincingly demonstrated that maintaining blood glucose concentrations close to the normal range (e.g., HbA_{1c} <7.0%) delays the onset and limits the progression of the long-term microvascular complications of diabetes—retinopathy, nephropathy, and neuropathy. In addition, a strong trend was noted in the UKPDS toward a reduction in coronary events.

Based on these data, the *American Diabetes Association* recommends a *treatment goal of HbA_{1c} <7.0%.* Although tight glucose control can markedly decrease the morbidity associated with small-vessel disease, it remains to be proved whether it can reduce the serious large-vessel consequences of diabetes (which cause death in the majority of patients with type 2 diabetes). Nonetheless, normalization of carbohydrate metabolism stands as a major treatment objective for all diabetics. The challenge is how to accomplish normalization and reduce risk, given the still imperfect treatment modalities and monitoring methods currently available. Strong patient motivation and close support are essential. Advances in treatment promise to facilitate achievement of control.

Normalization of blood sugars to nondiabetic postprandial and fasting levels is an ideal objective that is not without risk. The risk for hypoglycemia with intensive insulin therapy is a serious concern; it can be especially dangerous in patients who have underlying coronary or cerebrovascular disease. However, the goal of safe and convenient glucose normalization is becoming easier to achieve. Until implantable glucose sensors and insulin delivery systems automate the control process, the maintenance of normoglycemia still requires attention to the details of diet, exercise, weight control, and the many facets of medical therapy to achieve the best possible outcome.

Treatment Strategy. The strategy is pathophysiologically based, with a focus on the importance of establishing euglycemia as quickly as possible, as diabetic complications are mostly a function of the degree and duration of hyperglycemia. Because the fasting glucose level is the most important determinant of daily glycemia, efforts to normalize it are given top priority. A reduction in postprandial glucose is also important, but the postprandial glucose level is a lesser determinant of overall control. For type 1 disease, the emphasis is on intensive insulin therapy to make up for the loss of insulin production. In type 2 disease, the treatment strategy is multidimensional; impaired insulin secretion is countered by the therapy with sulfonylurea, repaglinide, or insulin; decreased muscle glucose uptake and inappropriate hepatic glucose production are treated with diet, weight reduction, exercise, and biguanides or thiazolidinediones. Combination programs are often necessary to attain the treatment goals of a fasting glucose level below 140 mg/dL and an HbA_{1c} level < below 7.0%, especially as the disease advances.

Diet and Exercise

The cornerstone of therapy for all overweight patients with type 2 diabetes is *weight reduction* through calorie restriction and exercise. Achieving ideal body weight is the single most important goal for the physician to encourage and advance to achieve metabolic control. Weight loss has been shown to enhance the sensitivity of peripheral insulin receptors to endogenous insulin and reduce the requirements for administered insulin. It is not possible to predict the exact improvement in glucose control from each pound lost, but a reduction of body weight may lead to an improvement in glucose tolerance.

The hyperglycemia of most type 2 diabetics can be controlled by achieving an ideal body weight; however, such weight reduction is often difficult to maintain, as a permanent restriction in caloric intake is required. Rigidly developed and prescribed diets should be avoided in favor of diets adapted to the patient's lifestyle. The goal is gradual, sustained weight reduction of approximately 1 to 2 lb each week (see Chapter 233).An effective *exercise program* (see Chapter 18) is another cornerstone of treatment. Exercise enhances weight loss by increasing caloric consumption, which is important in obese persons, who may require fewer calories to maintain their body weight. In addition, aerobic exercise facilitates glycemic control independent of its effect on weight, reducing insulin resistence in liver and muscle in patients with type 2 disease. **Updated: 11/9/01**

Diet Composition. Diet composition for type 2 diabetics is less critical than achieving an ideal body weight. At present, the American Diabetes Association recommends diets high in carbohydrate, up to 60%, with a significant amount of polyunsaturated fats. In mild glucose intolerance, isocaloric increases in carbohydrate, up to 80%, may improve glucose tolerance, particularly when complex carbohydrate, high-fiber diets are consumed. Hypertriglyceridemia secondary to the increase in carbohydrates has not been a problem, and in several studies, triglycerides and cholesterol levels have fallen substantially. Recent studies in type 2 diabetics, however, show unchanged or worsened glycemic control with high-carbohydrate diets and increases in VLDL triglyceride and cholesterol. All carbohydrates are not similar; some, such as those from potato, cause greater increases in blood glucose than do those from beans or wheat. Even the inclusion of sucrose or ice cream in mixed meals does not necessarily adversely affect glucose control. Preliminary data suggest that *vitamin E* and *b-carotene* supplements may decrease the oxidation of polyunsaturated fatty acids and help prevent the accelerated atherogenesis of diabetes (see Appendix to Chapter 26).

High-fiber diets, generally associated with a higher intake of complex carbohydrates and a decreased intake of refined carbohydrates and animal fats, are associated with a low prevalence of diabetes mellitus. *Increasing dietary fiber content* with unprocessed natural foods that include cereals, grains, fruits, and vegetables results in improved glucose tolerance in type 2 diabetics and decreased insulin requirements in type 1 diabetics. The likely mechanism for this improvement in glycemic control is delayed absorption.

Exercise. Exercise has important effects on glucose control in diabetes. It increases glucose consumption and reduces insulin resistance. As noted, its benefits extend beyond those attributable to weight loss alone. All forms of aerobic exercise, even walking and other forms of nonvigorous activity, improve insulin sensitivity. Significant improvement in glycemic control has been demonstrated from a program of moderate aerobic exercise performed 3 times per week for 30 to 60 minutes. A few precautions are worth noting in those who may engage in more vigorous activity. The increased absorption of insulin in an exercising limb may precipitate hypoglycemia in patients on insulin; therefore, the abdomen should be used as the site for insulin injection. Because of the possibility of underlying ischemic heart disease, an exercise electrocardiogram (ECG) should be considered before a rigorous exercise program is undertaken by a sedentary person with longstanding diabetes or other atherosclerotic risk factors (see Chapter 18 and Chapter 36). **Updated: 11/9/01**

Special Considerations for Patients on Insulin. For type 1 *insulin -requiring diabetics* who are at ideal body weight, the essential aspect of dietary therapy is the *regularity of caloric intake* and the spacing of meals. Three meals, supplemented by snacks midmorning, midafternoon, and before bed, are needed to provide a source of glucose during the sustained presence of exogenously administered insulin. The commonly used American Diabetic Association diets recommend 2/9 of calories at breakfast, 2/9 at lunch, 4/9 at dinner, and 1/9 as snacks. The timing of meals must match peak insulin effects and activity schedules; increased activity requires increased food intake or a decrease in insulin dosage to prevent hypoglycemia. Simple sugars are generally restricted because they worsen postprandial hyperglycemia; however, patients should carry a source of simple sugar, such as fruit juice or sugar candy, to limit an insulin reaction. Patients who are not taking insulin do not require elaborate exchange systems, careful timing of meals, or other special dietary accommodations.

Drug Therapy: Oral Agents

If diet, exercise, and weight reduction to an ideal body weight fail to control of blood sugar reasonably well (i.e., fasting glucose >140 mg/dL, postprandial glucose >160 mg/dL, or HbA_{1c} >7.0%), relieve symptoms, or prevent ketosis, then drug therapy is indicated. Drug therapy is also indicated if it is unlikely that the patient can lose weight or if the patient is pregnant. Insulin remains the agent of first choice in persons with severe hyperglycemia (fasting glucose >240 mg/dL), whether from type 1 or type 2 disease. Oral agents—the sulfonylureas, biguanides (e.g., metformin), thiazolidinediones (e.g., the glitazones), and glucosidase inhibitors (e.g., acarbose)—are effective in type 2 disease with moderate hyperglycemia (fasting glucose between 140 and 240 mg/dL). The recommended American Diabetes Association glycemic goals of drug treatment based on the DCCT and UKPDS data are a *fasting glucose level below 140 mg/dL and an HbA_{1c} level below 7.0%*.

Sulfonylureas. With the advent of potent, long-acting, second-generation preparations and increasing evidence of their efficacy and safety, the sulfonylureas have become a mainstay of treatment for *mild to moderately severe type 2 disease* (*fasting glucose between 140 and 240 mg/dL*). An absolute average reduction in HbA_{1c} of 1.5 to 2.0 percentage points, along with a reduction in fasting glucose of 60 to 70 mg/dL, is achieved in most cases.

Mechanism of Action. The sulfonylureas acutely increase the sensitivity of b-cells to glucose and stimulate endogenous insulin release. This action can lead to hypoglycemia—hence the term *oral hypoglycemic agents*. These agents are effective in persons who require additional insulin secretion and have an adequate b-cell reserve. Enhancement of basal insulin secretion inhibits basal hepatic glucose production and improves the fasting glucose level. Efficacy declines with time as b-cell function deteriorates, so that glycemic control worsens despite the use of maximum doses. Although these agents also increase insulin receptor binding and enhance tissue sensitivity to insulin, such effects are minor compared with the stimulation of insulin release and are insufficient to sustain glycemic control when insulin release declines.

Preparations. The *first-generation sulfonylureas* (e.g., chlorpropamide, tolbutamide, tolazamide) have given way to *second-generation agents*, such as *glyburide* (Micronase, DiaBeta), *glipizide* (Glucotrol), and *glimepiride* (Amaryl), in the treatment of type 2 diabetes. Second-generation drugs are more potent and longer-acting. All are of equal efficacy. Although they cost 5 to 10 times more than first-generation drugs, they remain the least costly of the oral agents; all are similarly priced. These drugs are non-ionically bound to plasma proteins and are less variable in their bioavailability than the earlier oral agents. They are inactivated by the liver and consequently should be used with caution in reduced dosages in patients with liver disease. Glyburide is excreted in bile and urine, which is a potential advantage in patients with renal insufficiency. Glipizide releases insulin slightly more rapidly than the others, but this feature provides no special long-term advantage. In contrast to chlorpropamide, the second-generation agents do not cause inappropriate secretion of antidiuretic hormone, and only rarely cause disulfiram (Antabuse)-like effects. Like those of their predecessors, the effects of these agents may be potentiated by sulfonamides, salicylates, and clofibrate, or inhibited by warfarin.

Dosing Schedules. Dosing schedules for these agents are convenient because the duration of action is 12 to 24 hours. A sustained-release glipizide preparation allows for once-daily dosing, which is a marginal convenience benefit but a means of reducing the cost of therapy if used in place of a twice-daily program. The duration of action of glimepiride is slightly longer than that of other preparations (16 to 24 hours), so that once-a-day dosing is also possible. A lower-dose formulation is available for glimepiride than for sustained-release glipizide, which facilitates its use in the elderly and those with mild hyperglycemia. The starting doses of the second-generation agents are 2.5 mg for glyburide, 5.0 mg for glipizide, and 1 mg for glimepiride, taken once daily in the morning. Treatment is started at low doses and increased every 1 to 2 weeks, with monitoring of fasting and postprandial sugars. Failure to demonstrate any reduction in glucose early on suggests that oral agent therapy will probably fail, even at increased doses. The maximum daily dose is 15 to 20 mg/d for glipizide and glyburide, usually given on a twice-daily schedule for optimal effectiveness. For glimepiride, the maximum dose is 8 mg, given once daily. Monitoring of blood sugars and HbA_{1c} is required (see below).

Efficacy. In about 25% of patients, treatment goals are achieved with sulfonylurea therapy alone. In another 50% to 60% of patients, the initial response is good, but an additional agent is required over time to achieve treatment goals. The 15% who fail to exhibit a primary response probably have more advanced disease or slowly progressive type 1 diabetes. Predictors of a good response include newly diagnosed diabetes, mild to moderate disease, good b-cell function (high levels of C-peptide), and no history of prior insulin therapy or presence of islet cell antibodies. In the UKPDS, when the goals of intensive therapy were reached, reductions in long-term microvascular complications could be demonstrated, although no decreases in the risk for macrovascular disease were noted.

In careful side-by-side comparisons, second-generation sulfonylureas can achieve results comparable with those of single-dose NPH (neutral protamine Hagedorn) insulin in lowering HbA_{1c}. However, as b-cell function declines with time, pharmacologic coaxing of further insulin output is less likely to succeed. In the UKPDS, only 24% of patients on sulfonylurea monotherapy had adequate control 9 years after diagnosis. Addition of a second agent is usually necessary, either one that reduces peripheral resistance to endogenous insulin (e.g., metformin) or one that provides exogenous hormone (see below).

Adverse Effects. The principal risk of sulfonylurea use is *hypoglycemia* (a result of increased insulin release). Hypoglycemia (which tends to be prolonged) occurs at a frequency of 4% with the use of glyburide and 2% to 4% with glipizide. Occasionally, patients whose diabetes has become refractory to a first-generation sulfonylurea may benefit from substitution with a second-generation agent. Doses in excess of 15 to 20 mg/d provide little additional control. The risk for hypoglycemia is greatest with potent, long-acting sulfonylureas, which can cause sustained, severe hypoglycemia. Under study conditions, about 5% of patients experience

hypoglycemia with sulfonylurea use. Outside study settings, the risk is likely to be higher.

Concern about an increase in *cardiovascular risk* was suggested by data from the University Group Diabetes Project (UGDP), which revealed a small but significant increase in the rate of cardiovascular death in patients on long-term tolbutamide therapy. Questions about the UGDP study design and the veracity of the finding triggered an extensive controversy. Oral agent use declined for several years because of concern about this observation, and a new generation of sulfonylureas was developed. The controversy appears to have been put to rest by new long-term data from the UKPDS, which found, after 10 years of follow-up, no increase in the incidence of coronary events associated with the prolonged use of oral agents.

The effect on cardiovascular risk factors is important to note. *Weight gain* is an important consequence of the enhanced insulin secretion stimulated by oral agent therapy. Weight gain may be on the order of 5 to 10 lb with most agents, although there is some suggestion that it may be less with long-acting glipizide. *Triglycerides* decrease modestly, but overall effects on *lipids* are minimal.

Patient Selection. These agents are commonly prescribed as initial pharmacologic therapy for patients who remain moderately hyperglycemic (fasting glucose between 140 and 240 mg/dL) despite dietary and exercise measures. The insulin requirements of such patients may be increased, especially if they are obese, and they initially benefit from the increased release of endogenous insulin. The best results are achieved in patients who are not obese. The sulfonylurea drugs are a first choice for oral agent therapy and the least costly. Their convenience of use in comparison with insulin and their minimal side effects make them a popular choice for patients with type 2 diabetes. In the very elderly, they should be prescribed with care because of the increased vulnerability of these patients to the adverse consequences of hypoglycemia.

Biguanides (e.g., Metformin). These agents, also referred to as *oral antihyperglycemics*, differ from the oral hypoglycemics in that they do not stimulate endogenous insulin secretion; rather, they enhance tissue responsiveness to insulin. Consequently, they are less likely to induce hypoglycemia and are effective in the treatment of patients with tissue resistance to insulin, such as obese persons.

Mechanism of Action. These drugs facilitate insulin uptake by peripheral tissue, especially muscle, and decrease hepatic gluconeogenesis and basal glucose output, thereby helping to lower fasting glucose levels. Glucose utilization also improves in adipose and intestinal tissues. The net result is an improvement in fasting and postprandial hyperglycemia. Insulin demand declines as glucose utilization improves. Serum lipid abnormalities also improve.

Preparations. *Metformin* is the only biguanide currently approved in the United States for the treatment of type 2 diabetes. The drug is well absorbed and excreted unchanged by the kidneys. Impaired renal function (creatinine >1.5 mg/dL in men and >1.4 mg/dL in women) is a contraindication for use. The drug is not metabolized by the liver. Its cost is about two to three times that of the oral hypoglycemics. The original biguanide, *phenformin*, is no longer marketed because of its associated risk for lactic acidosis (see below).

Dosing. The starting dose of metformin is 500 mg twice daily, given with the two largest meals of the day to minimize gastrointestinal upset. The dose is increased by 500 mg every 2 weeks until treatment goals are met or the maximum dosage of 2,000 to 2,500 mg/d is reached.

Efficacy. The efficacy of metformin is about the same as that of a second-generation sulfonylurea used as monotherapy in an obese person with moderate glucose intolerance; it lowers fasting glucose and glycosylated hemoglobin levels to the same degree (see above). Metformin has a synergistic effect when combined with sulfonylurea therapy in patients who do not respond well to monotherapy. Unlike the sulfonylureas, metformin is effective even in severe fasting hyperglycemia (>300 mg/dL), indicative of poor b-cell responsiveness. In the UKPDS, obese diabetics who attained tight control with metformin treatment exhibited a reduction in *microvascular disease*, and they were also the only group to show a reduced risk for *macrovascular* complications (i.e., myocardial infarction, stroke and cardiovascular death). Plasma triglycerides and LDL cholesterol levels were decreased.

Adverse Effects. The most common side effect of biguanide therapy is dose-related *gastrointestinal upset* (nausea, diarrhea, abdominal discomfort). The risk for serious prolonged *hypoglycemia* is minimal. *Lactic acidosis* represents the most potentially serious adverse effect. One of the original biguanides, *phenformin*, was taken off the market by the Food and Drug Administration in 1977 because of its association with fatal episodes of lactic acidosis. The risk for lactic acidosis associated with metformin is 5% that of phenformin (three cases per 100,000 patient-years of use). The risk is greatest in the setting of hypoxemia and in renal insufficiency (creatinine >1.5 mg/dL). Accumulation of the drug secondary to reduced excretion results in impaired hepatic metabolism of lactate. Other risk factors include binge drinking, use of IV radiologic contrast agents, hepatic failure (lactate is metabolized by the liver), and serious underlying illness, particularly heart failure. Long-term data on safety have yet to be accumulated. Because insulin secretion is not increased with metformin use, weight gain does not occur; some patients may even lose weight.

Patient Selection. Obese patients are particularly good candidates for metformin therapy because the drug helps reverse their insulin resistance. Peripheral responsiveness to insulin improves and insulin needs decrease, so that hyperinsulinism and its adverse effects, including weight gain, are minimized. The typical candidate is a *moderately obese person with type 2 diabetes* who has persistent moderate hyperglycemia (fasting glucose between 140 and 240 mg/dL, glycosylated hemoglobin >7.0%) despite a full program of diet and exercise. Other candidates for metformin include obese patients who do not achieve tight control while taking a sulfonylurea at maximal doses. In this setting, metformin is *added to the oral hypoglycemic program* to improve control through its complementary mode of action. The sulfonylurea dose is reduced to lessen the risk for hypoglycemia. Combination therapy is most effective when initiated before the onset of symptomatic hyperglycemia (fasting glucose >250 mg/dL). If delayed, combination programs offer little benefit in altering disease progression or delaying the need for exogenous insulin. Patients who become unresponsive to maximal doses of a sulfonylurea may have exhausted their b-cell reserve and can be *switched to metformin* or considered for exogenous insulin therapy (sometimes in conjunction with metformin). The same pertains to the severely hyperglycemic obese patient (fasting glucose >300 mg/dL). Some diabetologists use metformin to *supplement an insulin program* in obese type 2 diabetics who require large insulin doses and have difficulty losing weight. The combined program helps to reduce insulin requirements and the appetite stimulation and weight gain that accompany hyperinsulinism. Caution and careful patient monitoring are required when a patient already taking exogenous insulin is started on metformin; the insulin requirement may drop considerably, putting the patient at risk for hypoglycemia.

Thiazolidinediones. Thiazolidinediones, (e.g. troglitazone, pioglitazone, rosiglita-zone) are a new class of oral agents for treatment of type 2 diabetes. They appear to work predominantly by reducing insulin resistance in peripheral tissues, including fat and muscle, affording an additional opportunity to counter insulin resistance. They have become very popular because they are generally well-tolerated, do not cause hypoglycemia, and can enhance glycemic control when used in conjunction with other oral agents or insulin. The major concern surrounding their use has been idiosyncratic hepatocellular injury, occurring in such high frequency with troglitazone use that the drug has been withdrawn from the market.

Mechanism of Action. The main sites of action are muscle and fat, with improved sensitivity to insulin. Compared to metformin, there is less of an effect on hepatic responsiveness, which might account for the reduced efficacy. Adipocytes proliferate, possibly accounting for the observed increase in weight.

Efficacy. These drugs have about half the effectiveness of sulfonylureas and metformin in terms of lowering the fasting glucose and glycosylated hemoglobin. Onset of action may be evident by 7 days, manifested by a drop in fasting blood sugar, but full effect may take 4-6 weeks. About 25 percent of patients manifest no benefit; most have a low fasting C-peptide level. All thiazolidinediones have about the same degree of efficacy; 15-20 percent reductions in serum glucose levels can be expected. Modestly favorable improvements in triglyceride and HDL cholesterol levels occur, but LDL cholesterol may also increase, offsetting any improvement in lipid profile.

Adverse Effects. Because both short-term and long-term use of troglitazone is associated with rapid onset of *idiopathic hepatocellular injury* severe enough to result in death or require liver transplantation, the manufacturer has withdrawn the drug from the market. So far, the newer drugs in this class have not demonstrated this degree of hepatocellular risk, but experience with them is still limited. Careful, regular monitoring of hepatocellular enzymes is recommended at this time until there is sufficient experience with their use to better determine overall risk of liver injury. Any increase in ALT level beyond 1.5 to 2.0 times the upper limit of normal is an indication for weekly ALT monitoring and considering cessation of therapy. *Weight gain* occurs, especially when used in combination with sulfonylureas.

Preparations, Dosing, and Patient Selection. With troglitazone removed from the market, the two newer drugs in this class remain available for use. *Pioglitazone* is begun at 15 mg/day and *rosiglitazone* at 2 mg/day. Treatment is advanced on a monthlyl basis until maximum doses are reached (45 mg/d for pioglitazone and 8 mg/d for rosiglitazone). With the exception of troglitazone, these agents are approved for use both as *monotherapy* and in *combination* with either insulin or the sulfonylureas. Until more experience with them accumulates and hepatocellular safety is more firmly established, they should be used cautiously and only in patients

without underlying liver disease who are willing to have their liver function monitored regularly.

Acarbose. Acarbose is a poorly absorbed complex oligosaccharide of bacterial origin. When taken at the beginning of a meal, it interferes with the pancreatic enzymatic hydrolysis of dietary carbohydrates (particularly disaccharide and complex carbohydrates), thereby slowing absorption. Glucose uptake from the bowel occurs more slowly and more distally, so that absorption can be better matched with insulin release in type 2 disease. Less than 1% of the drug is absorbed. Significant additional reductions in levels of postprandial glucose and glycosylated hemoglobin have been noted when acarbose is used in conjunction with diet, oral agents, or insulin. Its efficacy is about midway between that of diet alone and that of oral agents. Few data are available regarding its use in type 1 disease.

The principal side effects are gastrointestinal (abdominal cramping, distention, flatulence, and diarrhea) and are caused by the fermentation of unabsorbed carbohydrate by colonic bacteria. The effect is dose-related and seems to decrease with time. Occasional impairment of iron absorption may lead to microcytic anemia. Use with oral hypoglycemics or insulin may increase the risk for hypoglycemia, which must be treated with glucose because the drug interferes with the absorption of sucrose and other sugars. Concurrent use with metformin is problematic because acarbose potentiates the bioavailability of metformin and exacerbates its gastrointestinal side effects. The drug does not cause significant weight loss. The starting dosage is 25 mg three times daily, taken at the beginning of meals. The maximum dosage is 50 to 100 mg three times daily, depending on weight. The cost is about two to three times that of the oral hypoglycemics and similar to that of metformin.

Although acarbose can improve glycemic control in persons with type 2 disease and complement other forms of therapy, its gastrointestinal side effects limit its clinical acceptability for long-term use. Nonetheless, it represents an additional treatment option that can be useful in selected cases. Recent interest in postprandial hyperglycemia as an independent risk factor for cardiovascular disease and hypertension and its treatment as a means of reducing such risk has stimulated interest in acarbose, because it can lower postprandial glucose levels. However, the association of postprandial hyperglycemia with cardiovascular risk and the efficacy of its treatment remain to be confirmed before acarbose therapy can be recommended as a potentially significant component of diabetes management. **Updated: 08/15/03**

Repaglinide (Prandin). This agent, like the sulfonylureas, increases b-cell secretion of insulin; it is not yet known whether its effects are additive with those of the sulfonylureas, but its efficacy is similar. The onset of action is rapid and the duration short, so that use just before a meal is possible. The starting dosage is 0.5 mg three times daily; doses are taken 15 minutes before meals. The main adverse effect is hypoglycemia, which tends to be slightly less frequent and severe than in sulfonylurea therapy. Weight gain is noted; effects on lipids are minimal. The cost is 2.5 times that of brand name sulfonylureas.

Drug Therapy: Insulin

Insulin is the drug therapy of choice for diabetics in whom ketosis develops, for patients with symptomatic type 2 diabetes whose disease cannot be controlled by diet alone or a program of oral agent therapy, and for diabetics in whom near-normalization of blood sugar is a goal of therapy.

Preparations. In 1980, *highly purified* insulins prepared by high-performance liquid chromatography and containing less than 1 ppm of proinsulin were introduced. In 1982, *human recombinant insulin* was approved by the U.S. Food and Drug Administration. The increased use of human recombinant insulin and highly purified insulins has led to a decline in the incidence of local reactions, insulin allergy, immune resistance, and lipoatrophy. In some patients, human insulin may be absorbed more rapidly than animal insulins and have a shorter duration of action. Although antibody formation is less pronounced against human insulin than against insulin from animal species, a measurable increase in anti-insulin antibodies in a minority of patients treated with the recombinant preparation has been noted. More favorable pricing has made the cost of recombinant insulin similar to that of animal insulins, so insulin therapy should be initiated with human insulin.

Standard Preparations. Insulin is available in short-, intermediate-, and long-acting preparations. Intermediate types of insulin, *NPH* and *Lente*, with a peak action at 6 to 12 hours and an effect lasting 24-hours, are the most commonly used. The traditional short-acting insulins, *regular* (*crystalline zinc insulin*, or CZI) and *Semilente*, have an earlier onset of action that peaks at 2 to 4 hours and lasts for a shorter time (5 hours). Traditional long-acting insulins, such as *Ultralente* insulin, may be most useful when given in intensive insulin therapy programs to provide a basal release of insulin in conjunction with multiple injections of short-acting insulin. Intermediate-acting Lente insulin contains crystalline structures that have absorption characteristics similar to those of NPH insulin, which makes it possible to avoid the use of a foreign protein that delays the absorption of NPH insulin.

New Insulin Analogs (Insulin Lispro and Insulin Glargine). Insulin lispro, a newly synthesized preparation, has a faster onset and shorter duration of action. The positions of lysine and proline are switched in the B-chain of the molecule, which makes it less likely to polymerize; it is therefore more readily absorbed into the systemic circulation after SQ injection. The net result is a faster-acting insulin (45 to 60 minutes to peak) with a shorter duration of action (3 hours). Dosing is more convenient and compliance probably improved because insulin can be administered 10 to 15 minutes before a meal (in comparison with 30 to 45 minutes for regular insulin). In addition, the frequency of hypoglycemic episodes is modestly reduced (10% to 15%) in patients with type 1 disease because of a better match in the timing of insulin administration and food intake (no reduction in frequency of hypoglycemia noted with use in type 2 patients). Overall glycemic control and fasting glucose levels are significantly improved because the drug has no effect on basal insulin levels. Insulin lispro must be taken in combination with a longer-acting basal insulin program; it can be mixed with NPH or ultralente, but not with insulin glargine. Candidates for insulin lispro are persons with type 1 disease who have achieved tight control with intensive insulin therapy but are at high risk for hypoglycemia. Such patients, especially those with a very active life-style and unpredictable schedule, appreciate the convenience and freedom of action afforded by insulin lispro. Patients with poor control and little risk for hypoglycemia are not candidates. Other potential users include those with a recent onset of type 1 disease who retain some basal insulin secretion. Fetal safety is not established, so that insulin lispro must be avoided by women of childbearing age unless they are utilizing birth control. The cost is considerably more than that of regular insulin.

Insulin glargine is a recently introduced long-acting insulin analog that provides a steady absorption of insulin over 24 hours without a period of peak activity. This characteristic makes it potentially useful as a source of basal insulin in type 1 patients undertaking intensive insulin therapy who are bothered by nocturnal hypoglycemia (see below). A typical intensive insulin program with this long-acting insulin analog involves its administration at bedtime, supplemented by short-acting insulin taken before meals. A disadvantage of insulin glargine is that it cannot be mixed with other insulins, necessitating an extra daily injection. Mixing impairs its absorption. Initial evidence points to reductions in nocturnal hypoglycemia. **Updated: 4/29/02**

Insulin Programs. Insulin is the treatment of choice for type 1 disease, an option as initial therapy for type 2 diabetes, and an essential component for the later stages of type 2 disease (Table 102-1). Because of the increasingly recognized value of tight glycemic control, traditional insulin regimens have been reexamined and new programs developed that provide better control. The goal is to enhance control of blood glucose without increasing the frequency and severity of hypoglycemic episodes. Both basal and prandial components of the insulin regimen must be considered.

Table 102-1. Common Insulin Regimens

Basal Insulin. The basal program is essential because it influences the fasting glucose level, the principal determinant of overall glycemic control. Typically, *twice-daily* ("*split*") doses of an *intermediate-acting insulin* (NPH or Lente) or a *single dose* of a *long-acting insulin* (Ultralente or *insulin glargine*) is administered to

maintain normoglycemia during the fasting state.

A principal problem with such basal regimens is that increasing the dose to improve control increases the risk for *hypoglycemia* because the action of these insulin preparations often peaks at times of fasting rather than at times of food intake. A typical twice-daily split-dose program of NPH insulin taken before breakfast or dinner will produce peak insulin effects between 4 to 10 hours after injection, depending on whether the patient is an early (type A), normal (type B) or late (type C) reactor to insulin. The time of peak action with such basal regimens can be the very time when food intake is least likely (e.g., afternoon, early morning). Unless the timing of dosing or food intake is changed (e.g., moving the evening dose to before bed or having a good lunch and/or a late afternoon snack), the likelihood of hypoglycemia increases as control is tightened. Paradoxically, fasting *hyperglycemia* may be noted as a consequence of nocturnal hypoglycemia leading to rebound glucose production (i.e., the *Somogyi effect*). Hyperglycemia may also ensue if the insulin effect peaks too early (e.g., when the dose is taken with dinner) or if the dose is insufficient to suppress morning hepatic glucose production ("dawn phenomenon"). In type 1 diabetics taking a regimen of intensive insulin therapy, changing the timing of NPH administration to bedtime reduces risk of nocturnal hypoglycemia and improves glycemic control. Use of insulin glargine at bedtime for the basal regimen may have a similar benefit. **Updated: 4/29/02**

If twice-daily intermediate insulin proves inadequate, the traditional alternative was to try Ultralente insulin. Ultralente use is sometimes made problematic by an uneven absorption pattern, with peak levels at 4 to 6 hours after administration. Safe basal control requires achieving a constant basal insulin level. The increasing desire to achieve tight control has led to interest in the development of ultralong-acting insulin preparations that provide a more constant rate of release (e.g., insulin glargine) and of novel delivery systems, such as inhaled preparations, pumps, and implants.

Prandial Insulin In traditional single- or split-dose programs, *regular insulin* (CZI) is often used in conjunction with a basal insulin program to provide better postprandial glycemic control. In many instances, regular insulin is mixed with a longer-acting preparation and administered as a single injection to minimize the number of daily injections. The addition of regular insulin makes it necessary to administer the *mixed insulin regimen* at least 30 to 45 minutes before breakfast and dinner to ensure that the peak action of CZI is properly timed and not too late. The CZI timing requirement can be awkward for persons whose mealtimes are irregular or unpredictable; poor compliance and postprandial hyperglycemia or hypoglycemia are often the result. Also because of the CZI timing requirement, administration of the longer-acting insulin preparation can be timed poorly (as noted above). The net result is a wide daily fluctuation in blood sugar with periods of hypoglycemia and hyperglycemia and suboptimal overall control. The advent of insulin lispro (see above) provides short-acting insulin with a more rapid onset of action, reducing risks of postprandal hyperglycemia and fasting hypoglycemia. It can be administration 5 to 15 minutes before a meal. **Updated: 4/29/02**

Intensive Insulin Therapy. Intensive insulin therapy attempts to overcome the limitations of basal and prandial control associated with typical mixed and split insulin regimens. An intensive regimen is based on frequent home glucose monitoring, multiple daily injections of short-acting insulin before meals to provide better prandial control, and use of a long-acting insulin preparation for basal control. Prandial control traditionally relies on use of regular insulin, but its required lead time of 30 to 45 minutes before a meal is inconvenient for those with erratic meal schedules and may compromise compliance. Moreover, its 4- to 6-hour duration of action increases the risk for hypoglycemia. When problematic, these disadvantages can be overcome by use of a very fast-acting, short-duration insulin (e.g., insulin lispro; see above). Insulin lispro is a very rapidly absorbed insulin analog, allowing injection 5 to 15 minutes before a meal. Its period of peak activity is shorter than that of regular insulin, reducing the risk of hypoglycemia but contributing minimally to basal insulin levels. Such short duration of action places additional importance on having an effective basal insulin program. **Updated: 4/29/02**

Basal control requires use of a long-acting insulin, such as a single dose of *Ultralente* insulin in the evening or one to two daily doses of *NPH*. The advantages of Ultralente and NPH are their low cost and ability to be mixed with regular insulin, minimizing the number of daily injections needed. Their principal disadvantage derives from difficulty achieving constant basal insulin levels with these insulin preparations, leading to periods of hypo- or hyperglycemia. Approaches to overcoming this difficulty include postponing the evening NPH dose to bedtime (necessitates an additional dose) and use of *insulin glargine*, the long-acting insulin analog with very steady absorption and no period of peak activity. Glargine's disadvantages include increased cost and inability to be mixed with other insulins. Intensive insulin therapy requires careful self-monitoring of glucose to adjust dose and schedule. A 3 a.m. blood glucose determination is occasionally added to ensure that nocturnal hypoglycemia is not occurring. The major complication of intensive insulin therapy remains frequent and relatively severe *hypoglycemia*. **Updated: 4/29/02**

Intensive therapy is indicated in pregnancy because of the proven benefit of glucose control in limiting fetal morbidity and mortality and the potential for preventing congenital malformations, which are increased in children of diabetic mothers. Type 1 diabetics and younger, sophisticated, motivated patients without established complications may also be considered for intensive therapy. The expansion of intensive insulin therapies and the resources needed to apply intensive therapies across the entire diabetic population will increasingly involve discussions and decisions regarding broad health care and public policy.

Open-Loop Pump Therapy. Pump therapy represents an attempt to duplicate the normal physiologic pattern of insulin release. Insulin infusion devices (worn externally and connected to an indwelling catheter) and multiple daily injections are being widely applied in gestational diabetes and in patients with type 1 diabetes that is difficult to control. This therapeutic approach requires patient motivation and sophistication, close monitoring, and careful supervision to be safe and effective. Comparable control of glycemia can be achieved by insulin pump and conventional intensive therapy. The major advantage of insulin pumps is that they facilitate frequent insulin administration. Complications include catheter infection, inadvertent catheter displacement from the skin, and cost.

Combined Oral Agent and Insulin Programs. In type 2 disease, with its multiple mechanisms of glucose intolerance, combination programs are a logical consideration when maximal doses of insulin or oral agents prove insufficient. In patients with type 2 disease who require very large insulin doses and experience unacceptable weight gain, the addition of *metformin* can improve glycemic control and reduce insulin requirements by countering insulin resistance in liver and muscle. Weight gain and other adverse effects of hyperinsulinism can be minimized. Likewise, a patient whose oral agent program is ineffective may benefit substantially from supplementation with a single modest dose of *NPH insulin* administered before bed. The small amount of insulin suppresses early morning hepatic glucose production (the dawn phenomenon), thereby reducing morning hyperglycemia without inducing hypoglycemia; overall glycemic control improves significantly.

Initiation of Therapy. Insulin therapy can be started safely on an ambulatory basis as long as the patient is reliable, nonketotic, and not severely hyperglycemic with intercurrent illness. Treatment should be initiated with 10 to 15 U of an intermediate-acting insulin and increased by approximately 2 U each day, depending on the results of urine or, preferably, blood sugar monitoring performed by the patient. Double-voided urine glucose determinations, commonly used in the past, have limitations (see below).

Technique and Storage. Insulin is injected SQ and is absorbed directly into the circulation. The abdomen and limbs are convenient injection sites; rotation among sites minimizes discomfort and, rarely, lipoatrophy. Rotation among multiple abdominal *injection sites* is preferable to limb injections in athletically active diabetic patients because of the possibility of more rapid insulin absorption from an exercising limb. Insulin, best *stored* in the refrigerator, may be left at room temperature for up to 12 hours without loss of biopotency.

Degree of Control. As noted earlier, the large-scale, long-term, randomized, controlled DCCT (for type 1 disease) and UKPDS (for type 2 diabetes) have firmly established that normalization of glycemia (HbA$_{1c}$ <7.0%) significantly reduces the risks for microvascular complications. Very tight control (HbA$_{1c}$ between 6.0% and 7.0%) is the objective of intensive insulin regimens. Whether and under what conditions such control can also reduce the risk for macrovascular complications remains to be determined. So far, only obese patients achieving tight glycemic control with metformin have experienced significant reductions in cardiovascular and stroke risk. That the weight gain seen with intensive insulin therapy might be a manifestation of the insulin resistance syndrome, which includes hypertension and an increased coronary risk, is a concern. Efforts to counter such insulin resistance may be necessary to achieve a reduction in coronary risk. More study is needed.

The practical issue is whether such tight control can be accomplished safely in a given patient and whether the means of therapy currently available are compatible with patients' life-styles and personal choices for therapy. In type 1 disease, an intelligent, well-motivated, reliable person can be taught to regulate daily insulin doses, but less capable patients risk hypoglycemic reactions when tight control is attempted. In type 2 diabetes, the advent of well-tolerated agents that turn off hepatic gluconeogenesis and peripheral insulin resistance has made it possible to improve control with a lesser risk for hypoglycemia.

Worsening Hyperglycemia during Insulin Therapy. In a patient taking a previously adequate dose of insulin, hyperglycemia requires prompt attention (Table 102-2). Although important changes in caloric intake or failure to take insulin properly may be the explanation for worsening hyperglycemia, occult infection (especially in the urinary tract), coronary ischemia, severe emotional stress, and Somogyi phenomenon (rebound hyperglycemia) must be investigated. A recently recognized phenomenon, worsening hyperglycemia in the early morning hours, is caused by the surges in growth hormone levels that occur during sleep. An

intermediate-acting insulin given at bedtime can provide excellent coverage for such early morning hyperglycemia.

Inadequate dose
Increased caloric intake
Failure to take insulin properly
Occult infection (especially urinary tract)
Coronary ischemia
Severe emotional stress
Use of corticosteroids
Somogyi phenomenon
Insulin resistance
Growth hormone surge in early morning

Table 102-2. Important Causes of Worsening Hyperglycemia During Insulin Therapy

The Somogyi Phenomenon. The Somogyi phenomenon, in which rebound hyperglycemia and possibly ketosis occur after insulin-induced hypoglycemia, may be mistaken for inadequate control. The hypoglycemia usually goes unnoticed because it occurs at night or in a patient with severe autonomic neuropathy. Hypoglycemia is followed by several days of poor control. Clues to recognizing nocturnal hypoglycemia include night sweats, poor sleep, nightmares, and morning headaches. Urinary monitoring reveals negative urinary glucose and ketones in the evening followed by trace urinary sugar and large ketones in the morning. The best way to recognize the Somogyi effect is to be cognizant of its potential existence and to measure blood glucose at a time of suspected hypoglycemia. Appropriate therapy, which involves slowly decreasing the dosage of insulin, may be commenced after hypoglycemia has been documented. If detection is impractical, a diagnostic trial of reduced insulin may be used to confirm the clinical suspicion. Doses of insulin should be decreased slowly each day rather than precipitously because a dramatic decrease in insulin dosage will cause hyperglycemia to worsen.

Insulin Resistance. Insulin resistance is occasionally the cause of poor control. It is arbitrarily defined as the requirement for *more than 200 U of insulin daily*. Most cases of insulin resistance result from obesity; restoring normal weight is the best treatment. As noted earlier, the hepatic and muscle refractoriness to insulin seen in type 2 disease may respond to therapy with metformin or a thiazolidinedione. More classic insulin resistance is immunologically mediated by antibodies directed at bovine or porcine insulin, or against protamine or protamine-insulin complexes. There appears to be no increased frequency of antibody production against insulin lispro.

For patients with immunologic insulin resistance, switching therapy to a Lente insulin preparation or to human recombinant insulin may be advantageous. At times, high-dose glucocorticoids (80 to 100 mg of prednisone daily) may be necessary. Most patients respond, and steroid therapy can often be rapidly tapered. Immunologic insulin resistance is commonly seen in patients who have been receiving insulin in intermittent treatment programs. In patients who receive insulin for limited intervals only (e.g., during myocardial infarction or weight reduction for obesity), human insulin represents the best choice of therapy to limit antibody development.

Hypoglycemia and Insulin Reactions. When food intake is delayed or diminished, physical activity is increased, or the insulin dose is excessive, hypoglycemia may ensue. Symptoms include those of increased sympathomimetic activity: sweating, palpitations, tremor, and weakness. In addition, *neuroglycopenic symptoms* (fatigue and changes in mentation) may be seen with a less precipitous decline in blood sugar. Profound hypoglycemia may lead to loss of consciousness. If autonomic neuropathy is present, or if a patient is taking a b-adrenergic blocker, many hypoglycemic symptoms will be masked and mental confusion may be the paramount symptom. Patient and family education and the availability of a syringe containing glucagon are important (see below). In patients who experience frequent hypoglycemic episodes, an apparent decline in the blood glucose level that occurs with time triggers an autonomic response, so that careful home glucose monitoring is necessary when patients engage in a program of intensive insulin therapy.

Insulin Allergy. Insulin allergy, manifested as cutaneous reactions to insulin, occurs in approximately 5% of patients. Urticaria, angioedema, or anaphylaxis is rare. Insulin allergy may be treated by a change to human insulin administered with antihistamines. Desensitization may be necessary if systemic allergic manifestations have occurred. Lispro insulin has not been associated with an increased risk for insulin allergy.

Insulin and Surgery. In the management of the diabetic patient during surgery, modest hyperglycemia is allowed and hypoglycemia and ketosis are assiduously avoided. The preoperative medical evaluation is critical because most perioperative complications relate not to hyperglycemia or hypoglycemia, but rather to coexisting cardiac or renal disease. Importantly, the potential for infection must be considered carefully and sources of fever, such as pulmonary, skin, and urinary tract infection, need to be investigated. Many insulin programs for operative management have been advanced. In general, the dose of insulin should be reduced by approximately one third to one half on the morning of surgery and carbohydrate supplied as IV 5% dextrose at the rate of 150 mL/h. Surgery should, if possible, be performed early in the day, with postoperative monitoring of blood sugar and renal function. An ECG should be obtained because of the higher incidence of silent myocardial ischemia and infarction in diabetics. Until the patient resumes eating, the insulin dosage may need to be decreased unless an increased secretion of counterregulatory hormones (e.g., growth hormone, cortisol, catecholamines) worsens hyperglycemia and an increased dose is necessary. A risk for infection has been found in patients whose HbA$_{1c}$ is 11.5%, an indication of marked hyperglycemia in the preoperative interval.

Control of Associated Cardiovascular Risk Factors

As noted earlier, control of hyperglycemia prevents or limits the microvascular, neurologic, and renal complications of diabetes. Except in obese patients with type 2 diabetes who achieve tight control with metformin, it has not yet been proved that the risk for macrovascular disease is similarly reduced by tight control. Consequently, it is most important that all associated risk factors for the development of coronary artery disease be meticulously controlled. Diabetes confers a degree of coronary risk similar to that associated with prior myocardial infarction. In diabetics, aggressive efforts to control hypertension, reduce hypercholesterolemia, and cease smoking (see Chapter 26, Chapter 27, and Chapter 54) result in marked reductions in the risk for coronary events and stroke and in all-cause mortality. With 75% of deaths in diabetic patients caused by cardiovascular problems, the importance of reducing atherosclerotic risk factors cannot be overemphasized. These efforts are even more productive than attempts at tight control of blood sugar and must not be overlooked. Nonetheless, there is interest in tight glycemic control as an additional means of reducing cardiovascular risk. Emerging data suggest that postprandial hyperglycemia may be an independent risk factor for coronary artery disease and hypertension. The view is supported by report of significant reductions in rates of myocardial infarction and hypertension associated with correction of postprandial hyperglycemia in both diabetics and nondiabetics. These provocative findings require confirmation before change in glycemia management can be recommended; the literature bears close watching.

Hypertension. The treatment of hypertension in diabetics requires attention not only to the degree of control achieved but also to its effects on metabolic control, recognition of hypoglycemia, and "renal hyperfiltration." The drugs of choice inhibit the angiotensin system and include the *angiotensin-converting enzyme* (ACE) *inhibitors* and *angiotensin-receptor blockers* (ARBs). They appear to limit hyperfiltration and preserve renal function (see below). Patients must be monitored for hyperkalemia. The *thiazide* diuretics may modestly compromise glucose intolerance, which makes them less desirable as first-line agents than agiotensin blockade, especially in full doses. In smaller doses, they have few adverse effects on blood glucose and may facilitate blood pressure control. b-*Blockers* are effective but can mask the sympathomimetic warning symptoms of hypoglycemia. They should be used with care in patients undergoing intensive insulin therapy. Impotence and postural hypotension are features of diabetes that may affect the choice of antihypertensive therapy (see Chapter 26).

Lipid Disorders. Lipid abnormalities are a consequence of diabetes and sometimes also of treatments for diabetes. HDL cholesterol is often low, and VLDL and LDL cholesterols and triglycerides increased. Effective control of hyperglycemia often improves the lipid profile by reducing triglycerides and raising HDL cholesterol, but intensive insulin therapy that causes weight gain may actually increase LDL cholesterol and lower HDL cholesterol. Metformin use is associated with reductions in triglycerides and LDL cholesterol and slight increases in HDL cholesterol. The thiazolidindiones decrease triglycerides and raise HDL cholesterol, but they also increase LDL cholesterol. The sulfonylureas and acarbose have no effects on lipids. The drugs used to treat lipid disorders are usually well tolerated in diabetes; the

statins can very effectively lower LDL cholesterol and modestly raise HDL cholesterol; the fibrates are effective for reducing triglycerides and raising HDL cholesterol (see Chapter 27), but they should not be used with statins. Niacin is effective for raising low HDL cholesterol but can exacerbate glucose intolerance (see Chapter 27).

Management of Complications

Renal Failure. *ACE inhibitors* reduce proteinuria and significantly slow the progression of azotemia. The beneficial effect on nephropathy occurs even in normotensive patients and is independent of reduction in blood pressure. It is believed related to afferent arteriolar dilation and reduced hyperfiltration. Control of hypertension still remains important, particularly as renal function declines (see Chapter 26). Studies suggest that treating all diabetic patients prophylactically with an ACE inhibitor may be cost-effective, irrespective of renal sediment findings. *Protein restriction* (0.5 mg/kg) may also reduce hyperfiltration in early nephropathy, but ACE inhibitor therapy is likely to be more acceptable. The progression to renal failure may be inexorable once heavy proteinuria (>3 g/d) develops. However, the primary care physician may still be able to prevent some forms of late renal insufficiency, such as that associated with bladder dysfunction, pyelonephritis, and acute papillary necrosis, and the contrast-induced acute renal failure that occurs in diabetics with moderate to advanced renal insufficiency. Prompt and aggressive *treatment of urinary tract infections* (see Chapter 133 and Chapter 140), therapy to *limit urinary retention*, which increases the risk for infection (see Chapter 134), and avoidance of unnecessary contrast studies all help to prevent renal insults. If *dye studies* are necessary, *hydration* must be maintained, as small a dye load as possible used, and mannitol administered after the study. Nephrotoxic antibiotics and *NSAIDs* (which can inhibit renal prostaglandin activity) should be avoided. *Metformin* use needs to be restricted in the setting of renal insufficiency (creatinine >1.5 mg/dL in men, >1.4 mg/dL in women) because it is excreted by the kidneys and high doses increase the risk for lactic acidosis.

During the past decade, the outlook for the diabetic patient undergoing hemodialysis or renal transplantation has improved, although the mortality rate for diabetics on these treatment modalities remains higher than that of nondiabetics. Continuous ambulatory *peritoneal dialysis* has been offered to diabetic patients because of concerns that the heparin used in hemodialysis may worsen diabetic retinopathy. However, early information suggests that infection rates are higher in diabetic patients on continuous peritoneal dialysis.

Peripheral Vascular Disease. The microvascular and macrovascular complications of diabetes are readily evident in the limbs. Ischemic skin ulcers, claudication, and limb loss are common complications. Amputation of a lower extremity is often the consequence of peripheral vascular disease and neuropathy in patients with diabetes. In comparison with a control diabetic population, diabetic amputees had more severe neuropathy and vascular impairment and lower HDL cholesterol levels, and they had received less outpatient diabetic education. Management includes tightening glycemic control, reducing atherosclerotic risk factors, exercising, quitting smoking, and maintaining meticulous foot care (see Chapter 34).

Foot Problems. Because of vascular insufficiency and neuropathy, diabetic patients have unique foot care problems. Early detection of diminished sensation is facilitated by testing with a standardized monofilament, which is superior to the conventional physical examination for detecting protective foot sensation. Meticulous foot care is essential to prevent cellulitis, osteomyelitis, and the need for amputation. Feet must be kept clean, interdigital spaces dry, calluses pared down, and toenails carefully trimmed. Frequent inspection for skin breakdown and cellulitis by the patient needs to be stressed, as does the importance of wearing properly fitting shoes. Before bathing, diabetic patients should use their hands to test the water temperature, so that scalding injuries that may occur because of a loss of temperature sensation in the lower extremities can be prevented. Regular podiatric care is a well-considered preventive measure for all diabetics, especially those who are elderly or have poor eyesight, a history of foot infection, or a significant loss of sensation.

Neuropathy. Neuropathic *pain* has been treated with phenytoin, carbamazepine, tricyclic antidepressants, and phenothiazines, but no singularly effective treatment program has emerged. The tricyclic *amitriptyline* is the standard treatment. Initial data from placebo-controlled studies of *gabapentin* are very encouraging; comparative study is required to assess its relative benefit. *Phenytoin* seems to cause the least toxicity and should be tried first. The *postural hypotension*, impotence, and urinary retention associated with autonomic neuropathy are usually permanent. Postural hypotension may respond to the synthetic mineralocorticoid *Florinef*. *Impotence* is a reasonable indication for consideration of *sildenafil* (Viagra), which can be moderately effective in diabetic men (see Chapter 132). Anxiety and depression, which are often superimposed on neurologic dysfunction, must be excluded (see Chapter 132 and Chapter 229).

Enteropathy. Gastrointestinal motility problems, which include *gastroparesis* and *diabetic diarrhea*, can be difficult to treat. Small, frequent feedings and cholinergic drugs such as *cisapride* may lessen the symptoms of gastroparesis. Patients with diarrhea caused by bacterial overgrowth of the bowel can be treated with a trial of a broad-spectrum antibiotic (e.g., *neomycin*). *Cholestyramine* has been found to be of benefit in controlling the diarrhea of diabetic autonomic neuropathy. Fortunately, refractory nocturnal diarrhea often resolves spontaneously.

Regular dental examinations are a necessity because of the higher incidence in diabetic patients of *pyorrhea* and abscesses, which may also reduce diabetic control.

Ophthalmopathy. Diabetic *retinopathy* is the most important systemic disease causing blindness. Proliferative retinopathy accounts for the majority of cases of blindness among type 1 diabetics, whereas *macular edema* resulting from nonproliferative retinopathy accounts for most cases of blindness in type 2 diabetes. Prevention is the best treatment, achieved by a reduction in hyperglycemia. Even partial normalization of glucose levels is helpful. Photocoagulation with laser therapy can retard visual loss by 50% (see Chapter 209). Cataracts and glaucoma are also important complications (see Chapter 207 and Chapter 208 for a discussion of management).

Glucose Intolerance and Pregnancy

Fetal hyperglycemia contributes to excessive fetal growth, which increases the risks for birth trauma, asphyxia, neonatal respiratory distress syndrome, and death *in utero*. In addition, the need for cesarean section is increased. Maintenance of blood sugars in the physiologic range (60 to 120 mg/dL) takes on added importance during pregnancy because the complications of fetal hyperglycemia can be prevented and perinatal mortality reduced to the rate seen in nondiabetics. Even in nondiabetic pregnant women in whom an otherwise insignificant degree of hyperglycemia (2-hour-postprandial blood sugars in the range of 140 to 160 mg/dL) develops, the risk for macrosomia and its complications is increased. Women with postprandial readings in excess of 165 mg/dL have an increased incidence of diabetes in later life.

The importance of glucose intolerance during pregnancy has led to the recommendation by the American Diabetic Association that all pregnant women be screened for glucose intolerance by the 24th to 28th week of gestation. Data from the Nurses' Health Study have shown an advanced maternal age, family history, nonwhite ethnicity, higher body mass index, weight gain in early adulthood, and cigarette smoking identified to be independent risk factors. Screening is conducted with a 50-g oral glucose load, which can be given at any time of day. Patients with a 1-hour serum glucose level in excess of 140 mg/dL should be given a 100-g glucose tolerance test and treated if the level is above 165 mg/dL at 2 hours. Some argue, on the basis of studies showing an increased fetal risk associated with levels of glucose intolerance previously considered "normal" (120 to 160 mg/dL), that even more modest elevations are grounds for therapy, at least with dietary measures.

All patients with glucose intolerance should be treated with diets that limit simple sugars and total calories (35 to 38 calories per kilogram of ideal weight before pregnancy) and tested for elevation of blood sugar every 1 to 2 weeks until delivery is indicated. Patients showing fasting sugars in excess of 105 mg/dL or postprandial levels above 120 mg/dL should be considered for insulin therapy; consultation with a diabetologist is indicated.

For diabetic patients already on insulin, adjustments in dose may be necessary. During the first trimester, the insulin dose of a patient with type 1 diabetes should be reduced because insulin requirements decrease and the risk for hypoglycemia is increased. In the second trimester, the type 1 diabetic requires more insulin as the diabetes becomes more labile and the chances for the development of ketoacidosis (with its associated risk for fetal death) rise. Third-trimester dose requirements usually do not change, but the increase in the glomerular filtration rate can lower the tubular threshold for glucose and make urine testing unreliable. Within a few hours of delivery, insulin requirements fall considerably, returning completely to prepregnancy levels within 1 to 2 weeks. Optimal control is facilitated by the use of home glucose monitoring (see below).

Infection

Diabetes increases the risk of infection, particularly that associated with foot ulcers, the urinary tract, and fungi. Purported mechanisms include impairment of neutrophil function and compromise of antioxidant-dependent systems. An increased frequency of micronutrient (vitamin and mineral) deficiency is hypothesized to contribute to this increased risk. Use of a daily multivitamin supplement has been found in diabetics to significantly reduce risk of infection. Diabetic patients in whom a dietary history reveals likelihood of micronutrient deficiency are reasonable candidates for a vitamin and mineral supplement containing 100% of recommended daily allowances.

Monitoring

Monitoring must address three parameters: glycemic control, diabetic complications, and adverse drug effects.

For Control of Glycemia. The traditional means of monitoring was the double-voided urine test for glucose and ketones, usually performed before breakfast and before the evening meal by patients taking insulin. The technique requires voiding fully, then voiding again an hour later and testing the urine sample by means of tape or tablets; a colorimetric response indicates the urine glucose and ketone concentrations. At best, the correlation between urine and serum glucose concentrations is approximate. It varies from patient to patient and from time to time in the same patient because of differences and changes in the renal tubular threshold for glucose, renal blood flow, and urine volume. Moreover, the test result is compromised in patients with bladder dysfunction who have a postvoid residual.

Home Glucose Monitoring. The finger-stick method represents a marked improvement in monitoring. The patient obtains a finger-stick sample of capillary blood, which is tested for glucose concentration by colorimetric reading of a reagent strip to which a drop of blood is applied. More sophisticated meters and color charts are now available for the glucose determination. Insurance companies are increasingly covering the costs. Measurements are most useful for patients on insulin therapy; hour-to-hour and day-to-day adjustments can be made based on the results of blood sugar monitoring. Frequent measurements, both in the fasting state and at several intervals postprandially, are valuable when an insulin program is being started or adjusted and also during periods of illness or worsening control. Most patients can be taught the method. Numerous devices automatically perform the finger-stick. Once a stable insulin dose has been achieved, a single measurement need be taken only once every several days, typically before breakfast. Patients who are capable of adjusting their own insulin doses can use home monitoring to keep their sugars in the mid-100 range after a meal. Home monitoring does not obviate the need to inform the patient carefully about symptoms of hyperglycemia and hypoglycemia (see below).

Hemoglobin A$_{1c}$. Hemoglobin A$_{1c}$ is the glycosylated form of hemoglobin in the red cell. The degree of glycosylation reflects the glucose concentration in the red cell environment during the life span of the cell. Measurement of the HbA$_{1c}$ concentration allows an assessment of overall glycemic control for the preceding 2 to 3 months. It correlates well with the results of frequent blood glucose determinations. Levels of less than 8.0% indicate blood sugar levels of less than 200 mg/dL; values of 11% to 12% correlate with glucose levels in excess of 300 mg/dL and indicate poor carbohydrate control. This test has superseded the *random blood sugar* determination as the best means of assessing control over time. For the patient with mild non–insulin-dependent diabetes, a periodic HbA$_{1c}$ determination suffices for monitoring glycemia control. Patients taking insulin require both short- and long-term measurements of blood sugar.

Checking for Complications. Patients with diabetes should undergo at least an annual office evaluation that includes a check of the blood pressure for elevation; the skin for infection; the eyes for background retinopathy (see Chapter 209); the cardiovascular system for evidence of carotid, coronary, and peripheral vascular disease; and the feet for ischemic lesions. The evaluation should conclude with a careful neurologic examination for signs of neuropathy. Of particular importance is the need to test for and vigorously treat other risk factors for vascular disease, such as hypertension (see Chapter 14), hypercholesterolemia (see Chapter 15), and smoking (see Chapter 54). More frequent office visits are usually necessary for patients on insulin therapy and with complications of diabetes. Laboratory monitoring should include a urinalysis to check for proteinuria and sediment and a determination of blood urea nitrogen and creatinine to estimate renal function. A diabetic summary sheet placed in the patient's record makes it possible to note quickly the extent, severity, and progression of the disease and its complications. Teaching the patient to watch for skin, eye, neurologic, and cardiovascular changes is an important part of the monitoring effort (see below).

Monitoring for Adverse Effects of Drug Therapy. Patients prescribed *troglitazone* and other thiazolidinediones require regular monitoring of *serum liver enzymes* (e.g., ALT; see above). Testing should be conducted biweekly at the start of troglitazone therapy and continued monthly for the first year. Any ALT elevations in excess of three times the upper limit of normal are an indication for immediate cessation of therapy, and cessation should also be considered if any sustained increases are noted. The *renal* and *hepatic* function of patients on *metformin* must be monitored. The onset of renal or hepatic insufficiency necessitates that metformin therapy be discontinued because of the increased risk for lactic acidosis.

PATIENT EDUCATION

The success of a program for metabolic control depends on patient compliance. Because *weight reduction* to ideal body weight is the most important therapy that can be offered to patients with type 2 diabetes, instruction about *diet* and choosing healthful foods should take place in a setting that includes both patient and family. Sample diets can be obtained from the American Diabetic Association. The emphasis on diet therapy for the type 2 diabetic should focus more on caloric restriction than on actual percentages of carbohydrate or simple sugars.

The patient receiving insulin requires continuous education and encouragement, particularly as more intensive insulin treatment programs are applied to patients with type 2 diabetes to limit the end-organ consequences of hyperglycemia. In many hospital-based practices and several office practices, a nurse specializing in diabetes education offers patients careful instruction in drawing up insulin into syringes (particularly if the patient is visually impaired), insulin injection techniques, and the complications of excess insulin administration, and is readily available for telephone communication with patients. Some physicians consider deliberately creating mild insulin reactions in their patients so that they are able to recognize their own unique warning symptoms of hypoglycemia. A *syringe with glucagon* for IM injection is given to each patient in the event that the patient becomes profoundly hypoglycemic. Oral administration of juices to an unconscious and obtunded patient may lead to pulmonary aspiration.

The importance of skin and foot care must be emphasized (see Chapter 34). Referral of elderly diabetic patients with vision loss to podiatrists for regular foot care is indicated.

INDICATIONS FOR ADMISSION AND REFERRAL

Patient care programs that encourage communication between patients and health care professionals reduce the need for hospitalization for dehydration, marked hyperglycemia, ketoacidosis, and infection. Making diabetes management a collaborative process involving the complementary efforts of teams including nurses or physician assistants also helps in this regard; controlled trials have demonstrated improved glycemic control.

Acute hospitalization for IV administration of fluids is necessary for diabetic patients with protracted nausea and vomiting who are becoming dehydrated and hyperglycemic. Often, cellulitis of the foot requires IV antibiotic therapy, as does acute pyelonephritis. In general, elderly diabetic patients with pneumonia or urinary tract infections benefit from brief hospitalizations. Referral to an endocrinologist is indicated for the diabetic patient who is subject to marked fluctuations in blood sugar, with frequent episodes of hypoglycemia and hyperglycemia. When proteinuria is in the nephrotic syndrome range and the creatinine level begins to rise above 2.5 mg/dL, referral to a nephrologist for consideration of dialysis or transplantation is necessary. Indications for coronary artery bypass grafting are not different for the diabetic patient. Because of the potential severity of cholecystitis and ascending cholangitis, cholecystectomy for cholelithiasis may be a reasonable clinical choice, although more recent experience favors watchful waiting for asymptomatic cholelithiasis (see Chapter 69). Ophthalmologic referral is indicated when background diabetic retinopathy first becomes evident.

THERAPEUTIC RECOMMENDATIONS

Prevention

- Screen high-risk persons (e.g., obese, sedentary, hypertensive, hyperlipidemic) for diabetes by performing fasting and postprandial blood glucose determinations (see Chapter 93). Updated: 3/4/02
- Prescribe a program of lifestyle modification for those with fasting glucose approaching 125 mg/dL and postprandial glucose approaching 200 mg/dL. Updated: 3/4/02

- Implement lifestyle modification with a program of modest weight reduction (7% sustained weight loss), moderate exercise (2.5 hrs/wk of walking at moderate pace), and low-fat, low-cholesterol diet. **Updated: 3/4/02**
- Consider adding metformin (50 mg bid) if glycemic control not sufficiently improved or lifestyle modification not successfully implemented; most effective in persons who are markedly obese. **Updated: 3/4/02**

All Diabetic Patients

- Attempt to normalize hyperglycemia; the goal is an HbA_{1c} concentration below 7.0% and a fasting glucose level below 126 mg/dL.
- Emphasize the importance of maintaining ideal body weight. For those who are obese, institute caloric restriction without compromising the regularity of meal timing.
- Prescribe regular aerobic exercise and a low-saturated fat, reduced-calorie, balanced diet. **Updated: 11/9/01**
- Pay assiduous attention to the diagnosis and treatment of all additional atherosclerotic risk factors, such as hypertension, hyperlipidemia, and smoking (see Chapter 26, Chapter 27, and Chapter 54).
- Teach all diabetic patients, especially those on insulin therapy, how to monitor glycemic control daily with *home blood glucose determinations*.
- Assess long-term glucose control with HbA_{1c} *measurements* performed every 3 to 4 months. **Updated: 11/9/01**
- Carefully investigate the causes of worsening hyperglycemia (Table 102-2).
- Perform a comprehensive history, physical examination, and selected laboratory studies (blood urea nitrogen, creatinine, HbA_{1c}, cholesterol, urinalysis of microalbuminuria and hematuria) at least annually for evidence of coronary artery disease, cerebrovascular disease, peripheral vascular disease, neuropathy, renal impairment, and retinopathy. **Updated: 11/9/01**
- Carefully monitor *renal function* for azotemia and check the *urinary sediment* for proteinuria and microscopic hematuria. Promptly institute tighter control of hyperglycemia and prescribe angiotensin block by means of an *ACE inhibitor* or *ARE* at the first sign of nephropathy. Even for patients with no sign of nephropathy or hypertension, consider instituting prophylactic ACE inhibitor therapy if they are middle-aged to reduce the risk for development of nephropathy. When the serum creatinine level reaches 3 mg/dL, obtain a nephrology consultation regarding candidacy for dialysis or transplantation. **Updated: 11/9/01**
- Exercise caution in the use of *iodinated contrast agents*, especially in the setting of renal impairment.
- Refer all diabetic patients for annual ophthalmologic diabetic retinal examination) see Chapter 209) to test for early detection of proliferative retinopathy. Also refer promptly diabetic patients who have background retinopathy and type 1 patients who have had diabetes for 5 to 10 years and never had an eye examination to an ophthalmologist for *indirect ophthalmoscopy* and, if necessary, fluorescein angiography. **Updated: 11/9/01**
- Emphasize *foot care* to diabetic patients with neuropathy or vascular insufficiency. Arrange regular podiatric care for such patients.
- Perform a careful perioperative assessment of diabetic patients undergoing surgery. Pay particular attention to worsening hyperglycemia and diligently observe for infection and occult coronary artery disease, particularly in those with evidence of microvascular disease.
- Consider including a well-trained nurse, nurse practitioner, or physician assistant in the long-term management program to complement and support physician efforts at achieving glycemic control.

Patients with Type 1 Disease

- Consider early institution of *intensive insulin therapy* as soon as the "honeymoon period" ends (rising nocturnal insulin requirements) to achieve very tight control (HbA_{1c} 6.0% to 7.0%), especially for highly motivated patients willing to perform multiple glucose determinations each day and self-administer insulin according to the results of each test. Consider less intensive insulin therapy or infusion pump technology for those unable to carry out an intensive insulin regimen.

For those attempting intensive insulin therapy and starting treatment as an outpatient:

- For basal control, start with a modest dose of long-acting insulin, such as NPH, Ultralente, or insulin glargine, administered once daily in the evening (before dinner or at bedtime). Initiate therapy at a dose of 15 U and increase in increments of 2 U, based on fasting and 3 a.m. glucose determinations and HbA_{1c} levels. If using NPH, consider giving the dose at bedtime, especially if fasting hypoglycemia is a problem. If using insulin glargine, do not mix the dose in the syringe with another insulin.
- For prandial glycemic control, begin a program of short-acting insulin, such as regular (CZI), Semilente, or insulin lispro, starting at 5 U administered 15 to 45 minutes before each meal (depending on the type of preparation) and adjusted according to the results of postprandial home glucose measurements. Short-acting regular insulins can be mixed with NPH and Ultralente, but not with insulin glargine.
- Prescribe human recombinant insulin for newly treated diabetics to minimize risks for insulin allergy, insulin resistance, and antibody development.
- Consider prescribing insulin lispro (or another fast-onset, very short-acting insulin), administered 5 to 15 minutes before each meal, to patients achieving tight control but bothered by frequent hypoglycemic episodes or the inconvenience of a standard regimen of regular insulin.

For those unable to carry out an intensive insulin program or who may still be in the honeymoon period, where nocturnal insulin requirements remain small:

- Begin a twice-daily insulin regimen at a total daily dose of 0.5 to 1.0 U/kg body weight consisting of an intermediate-acting insulin (e.g., NPH or Lente) mixed with a short-acting preparation (e.g., CZI or Semilente), administered before breakfast and before the evening meal; two-thirds of the daily dose should be given in the a.m. and one-third in the p.m. The dose ratio of NPH to regular insulin should be 2:1 in the morning and 1:1 in the evening. If nocturnal hypoglycemia develops, split the evening dose, prescribing regular insulin before dinner and NPH before bed.
- Adjust doses according to fasting, 4 p.m., and 3 a.m. glucose determinations.
- Teach the importance of regular caloric intake and regular spacing of meals to match peak insulin effects and activity schedules.

Patients with Type 2 Disease

- Emphasize *weight reduction* to ideal body weight as the cornerstone of therapy for type 2 diabetes. The composition of the diet *per se* is less important, but the diet should have a high ratio of polyunsaturated to saturated fat and contain cholesterol and complex carbohydrates. Diets low in protein may be beneficial in averting diabetic nephropathy (see Chapter 132).
- Prescribe a practical program of regular exercise that fits the patient's life-style (see Chapter 18). Consider a program of regular moderate aerobic exercise performed 3 times per week for 30 to 60 minutes. Continue exercise program irrespective of any weight loss achieved by diet alone. **Updated: 11/9/01**

If after 4 to 8 weeks of diet and exercise the treatment goals have not been achieved and the patient shows *mild to moderate glucose* intolerance (fasting glucose <240 mg/dL), then:

- Begin oral agent therapy with either a *second-generation sulfonylurea* (e.g., 2.5 mg of *glyburide*, 5 mg of *glipizide*, or 1 mg of *glimepiride*) or a *biguanide* (e.g., 500 mg of *metformin* twice daily, with breakfast and the evening meal). Choose metformin if the patient is obese.
- Increase the oral agent dose every 1 to 2 weeks as needed. Consider twice-daily dosing for glyburide and glipizide to maximize control or once-daily dosing of a sustained-release glipizide. Advance until glycemic goals are achieved or maximum dose is reached (20 mg/d for glyburide and glipizide, 8 mg/d for glimepiride).
- If after 4 to 8 weeks of monotherapy glycemic goals have not been achieved, then add a second oral agent from a different class (e.g., metformin if a sulfonylurea was given first and vice versa) or add a small dose of an intermediate-acting insulin taken before bedtime (e.g., 10 U of NPH). If the sulfonylurea was the starting drug, reduce the sulfonylurea dose to avoid the risk for prolonged hypoglycemia.
- If after 4 to 8 weeks of two-drug oral agent therapy control has not been achieved, then consider adding either a dose of *intermediate insulin* before bed (e.g., 10 U of NPH) or a third oral agent (e.g., a thiazolidinedione or acarbose).
- If adding a *thiazolidinedione* (e.g., *pioglitazone*, *rosiglitazone*) start with a low dose (for pioglitazone, 15 mg/day, and for rosiglitazone, 2 mg/day, and monitor liver function (ALT) monthly for at least the first several months, halting therapy at the first sign of persistent elevation. Until proven hepatically safe, consider thiazolidinediones only if all other attempts to date have failed to achieve reasonable glycemic control and the patient is reliable, free of underlying liver disease, and willing to have close monitoring of liver function tests.
- If a program of insulin supplementation is considered, be aware that initially supplementing oral agent therapy with a small bedtime dose of insulin may suffice but usually latter stages of type 2 disease require insulin as the mainstay of the treatment program, supplemented by a thizolindinedione (eg. pioglitazone, rosiglitazone) or metformin to reduce insulin resistance and keep the insulin dose manageable.

If after 4 to 8 weeks of diet and exercise treatment goals have not been achieved and the patient is very symptomatic or manifests *moderate to severe glucose*

intolerance (fasting glucose >240 mg/dL), then:

- Begin *insulin* therapy with an intermediate-acting insulin preparation (Lente or NPH) at a modest once-daily dose (e.g., 10 U before breakfast).
- Specify human recombinant insulin for newly treated diabetic patients to minimize the risks for insulin allergy, insulin resistance, and antibody development.
- Advance the insulin program according to glucose monitoring results with reference to target levels.
- If high doses of insulin, poor control, and weight gain become problems, consider adding metformin to the insulin program to improve tissue responsiveness and reduce insulin requirements and weight gain. A thiazolidinedione can also improve insulin responsiveness and control, but does not halt weight gain.

CHAPTER 103 APPROACH TO THE PATIENT WITH HYPERTHYROIDISM

Hyperthyroidism is the clinical expression of a heterogeneous group of disorders that produce elevations of free thyroxine (T_4), triiodothyronine (T_3), or both. Well-recognized causes of hyperthyroidism include diffuse toxic goiter (Graves' disease), toxic multinodular goiter, toxic single nodular goiter (toxic nodule), and excessive doses of levothyroxine. Transient hyperthyroidism has been noted in the settings of chronic lymphocytic (Hashimoto's) thyroiditis and subacute (granulomatous) thyroiditis.

Hyperthyroidism is relatively common and much more likely to occur in women than in men. Community-based studies have found a prevalence of 1.9% in women and 0.16% in men. Approximately 15% of recognized cases occur in persons over the age of 60. The clinical presentation of hyperthyroidism in the elderly is often atypical. The primary physician should be able to recognize hyperthyroidism, identify its cause, and design a therapeutic program appropriate to the patient's underlying pathophysiology, age, clinical condition, and personal preferences. The indications and limitations of surgery, radioiodine therapy, and antithyroid agents must be understood.

PATHOPHYSIOLOGY, CLINICAL PRESENTATION, AND COURSE

The pathophysiologic common denominator of hyperthyroidism is an excess of circulating thyroid hormone. The mechanisms responsible for this excess include increased production of thyroid-stimulating hormone (TSH), stimulation of thyroid TSH receptors by immunoglobulins, autonomous thyroid hormone production, increased release of thyroid hormone without increased production, and intake of exogenous hormone.

Thyroid hormone stimulates calorigenesis and catabolism and enhances sensitivity to catecholamines. Excessive amounts of the hormone lead to the classic picture of heat intolerance, nervousness, tremor, increased appetite, weight loss, excessive sweating, lid lag, stare, and muscle weakness. Diarrhea or, more precisely, frequent defecation may also ensue.

In the elderly thyrotoxic patient, the characteristic manifestations of hyperthyroidism may be absent and the clinical picture dominated instead by apathy, weight loss, and otherwise unexplained atrial fibrillation. This *apathetic hyperthyroidism of the elderly* has been mistaken for depression and occult malignancy.

Elevations in alkaline phosphatase and angiotensin-converting enzyme may accompany thyrotoxicosis and persist even after treatment. The pathophysiologic significance of these elevations remains unclear, but the findings might suggest thyroid disease and save extensive workup when other explanations for their occurrence are lacking.

Graves' Disease is an autoimmune condition in which an apparent deficiency of thyroid-specific suppressor T-cell lymphocytes allows *a thyroid-stimulating immunoglobulin G antibody* (TSab) to form. TSab binds to TSH receptors on the surface of thyroid cells and triggers the synthesis of excess thyroid hormone. Graves' disease is the most common disorder causing hyperthyroidism and accounts for about 90% of cases seen in persons younger than age 40.

Ophthalmopathy can be a troubling accompaniment of Graves' disease, affecting about 40% of patients. It is a consequence of antibody-mediated inflammation and infiltration. TSab does not appear to be directly involved, although the onset of ophthalmopathy generally parallels that of the hyperthyroidism. Antibodies to extraocular muscle and orbital fibroblasts capable of inducing *in vitro* the pathologic changes found in *vivo* have been detected. The inflammatory infiltrate causes the extraocular muscles to enlarge; they in turn cause proptosis by displacing the eye forward and orbital edema by compressing orbital veins. In general, the eye problems develop concurrently with the onset of hyperthyroidism and change little once established, although up to 20% of patients may experience a gradual worsening with treatment (see below). Manifestations range from mild periorbital edema and conjunctival inflammation to extraocular muscle dysfunction, corneal injury, and optic nerve damage. The lid lag and stare of hyperthyroidism may make the ophthalmopathy look worse than it actually is. Other associated ocular symptoms include pain, diplopia, proptosis, and blurred vision. The cosmetic changes may be among the most disturbing. The proptosis is a true one, differentiated from the stare, lid lag, and apparent proptosis that may accompany other forms of hyperthyroidism.

Pretibial myxedema is a less common immune-mediated infiltrative process that affects an occasional patient with Graves' disease. The onset typically occurs years after treatment for hyperthyroidism, usually in patients with a history of ophthalmopathy. The condition is characterized by the appearance of erythematous, mildly scaly plaques limited to the skin of the ankles and pretibial area. The plaques are indurated but not tender. They usually resolve spontaneously.

The thyroid gland in Graves' disease is diffusely enlarged, and a bruit may be heard in severe cases. The classic symptoms and signs of thyrotoxicosis are common. The skin is velvety and the hair silky. Onycholysis, vitiligo, and gynecomastia are found in some cases and may suggest the diagnosis. Cardiac complications are infrequent because of the relative youth of the patient population, but a reversible cardiomyopathy has been identified, manifested by a fall in the ejection fraction with exercise. Heart failure is rare, but impaired exercise tolerance is often reported, perhaps caused by the decreased ejection fraction.

The clinical course of Graves' disease waxes and wanes, with exacerbations and remissions of unpredictable duration. After many years, mild hypothyroidism may ensue, especially in patients with small goiters and mild hyperthyroidism at the time of onset.

Toxic Multinodular Goiter (Plummer's Disease) accounts for an increasing proportion of cases of hyperthyroidism in middle-aged and elderly persons. The condition is often associated with a long-standing simple goiter. The gland is clinically and pathologically indistinguishable from the gland of patients with nontoxic multinodular goiters. Cardiovascular symptoms may dominate the clinical presentation; new onset of heart failure, atrial fibrillation, or angina is not uncommon and reflects the high prevalence of coexisting organic heart disease in this older population. In a series of 85 hyperthyroid patients between ages 60 and 82, two thirds experienced heart failure and 20% reported angina. Only a minority evidenced the more typical symptoms of hyperthyroidism; for example, fewer than 11% had polyphagia. On the other hand, 33% had anorexia, and constipation was as prevalent as diarrhea. Lid lag may be noted on occasion, but exophthalmos does not occur. Sometimes, apathy and weight loss are the most prominent clinical features and can be so profound as to suggest occult malignancy or severe depression.

An increased risk for the development of thyrotoxicosis on exposure to iodides (including iodinated contrast agents) has been demonstrated in elderly patients with large, nontoxic nodular goiters. The problem is most prevalent among patients who come from areas where iodine intake is low (e.g., Europe) but can also occur in nonendemic cases of multinodular goiter and thyroid adenoma. The mechanism involves an increased release of stored hormone. The clinical course is self-limited. Laboratory findings include a low uptake of radioactive iodine and an absence of antithyroid antibodies.

Single Toxic Nodule ("Hot" Nodule). The autonomously functioning toxic nodule presents clinically much like the toxic multinodular goiter. The principal difference is the finding of a "hot" nodule surrounded by suppressed gland on radioiodine thyroid scan. The larger the nodule, the greater its propensity to cause thyrotoxicosis, with the risk quite high once the nodule reaches 3 cm in diameter. Often, the onset of toxicity is first manifested by an isolated increase in serum T_3 levels; later, T_4 levels rise. Sometimes, hemorrhagic infarction terminates the overproduction of hormone and limits the progression to thyrotoxicosis.

Triiodothyronine Toxicosis is an important entity to consider when patients with clinically apparent hyperthyroidism have normal T_4 levels. The condition has been reported in association with both diffuse and nodular goiters. The clinical presentation is no different from that of hyperthyroidism caused by elevations in T_4. Isolated elevations in T_3 concentration may also occur in euthyroid patients who have no underlying thyroid disease (see below).

Transient Hyperthyroidism may occur in association with subacute (granulomatous) or chronic (lymphocytic) thyroiditis. As noted above, the mechanism appears to be uncontrolled release of hormone from an inflamed gland. Iodine uptake is reduced during the period of hyperthyroidism. The clinical manifestations of

hyperthyroidism are usually mild. The course is self-limited, and hypothyroidism often follows as intrathyroidal stores of the hormone are depleted.

Subacute Thyroiditis typically follows a viral illness, producing a tender, multinodular gland. The occasional case associated with hyperthyroidism has an abrupt onset characterized by thyrotoxic symptoms. The erythrocyte sedimentation rate is high, and a thyroid scan characteristically shows little or no uptake of radioiodine.

Lymphocytic Thyroiditis resulting in hyperthyroidism is thought to be an uncommon variant of Hashimoto's disease. In some cases, it may be caused by coexisting Graves' disease. High titers of antibodies to microsomes and thyroglobulin are present. The prevalence is highest in middle-aged women and among the elderly, in whom it may go unrecognized. The gland feels rubbery and is enlarged, sometimes asymmetrically. Hypothyroidism eventually develops in a substantial number of cases.

Postpartum (Subacute Lymphocytic) Thyroiditis, a previously unappreciated but surprisingly frequent problem (incidence as high as 5% in one series) can precipitate transient mild hyperthyroidism. The onset is within 3 to 6 months of delivery, and the condition often is mistaken for anxiety associated with the stress of caring for a new baby. The gland is nontender and may resemble that of Hashimoto's thyroiditis. A low uptake of radioactive iodine and the detection of antithyroid antibodies suggest an immunologic mechanism. The condition may persist for months before eventually resolving. A period of hypothyroidism may occur before the condition abates. It tends to recur with subsequent pregnancies.

Overproduction of Thyroid-stimulating Hormone. A small number of *pituitary adenomas* produce excessive TSH. The result is a diffusely enlarged gland simulating that of Graves' disease, but ophthalmopathy does not occur. A similar clinical picture may be caused by a tumor producing human chorionic gonadotropin (hCG), such as a *hydatidiform mole* or a *choriocarcinoma*. The thyroid-stimulating activity of hCG is weak, but when it is produced in massive quantities, it can cause hyperthyroidism.

Ectopic Thyroxine Production and Intake of Exogenous Hormone. When the source of excess thyroid hormone is extrathyroidal, the thyroid gland will appear small because of the absence of TSH stimulation. A dermoid tumor of the ovary, *struma ovarii*, with elements of thyroidlike tissue, is the only neoplasm regularly capable of synthesizing excessive amounts of thyroid hormone. (Rarely, thyroid cancers can cause hyperthyroidism, but only in the context of a massive tumor burden.) The intake of thyroid hormone in excess of daily requirements (>200 µg of levothyroxine per day) will make a person hyperthyroid. Sometimes, the intake is surreptitious. The gland is small, and TSH is absent.

Subclinical Hyperthyroidism is characterized by low or undetectable levels of TSH in the setting of normal levels of free T_4 and T_3. The most common cause is suppressive thyroid hormone therapy. Other causes include an autonomously functioning goiter and mild Graves' disease. Progression to thyrotoxicosis is rare. The risks associated with this state are a moderately increased frequency of atrial fibrillation in the elderly and osteoporosis in postmenopausal women.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of hyperthyroidism can be organized according to pathophysiology (Table 103.1). The most common cause is Graves' disease, followed by multinodular goiter, toxic adenoma, thyroiditis, and exogenous thyroid hormone. Pituitary adenoma, struma ovarii, and chorionic cancers are very rare causes.

PATHOPHYSIOLOGY	CAUSE
Autonomous hormone production	Toxic multinodular goiter Toxic adenoma
Increased hormone release	Subacute thyroiditis Lymphocytic (Hashimoto's) thyroiditis Iodide exposure
Increased glandular stimulation	Graves' disease (TSab) Functioning pituitary adenoma (TSH) Choriocarcinoma (hCG)
Exogenous hormone intake	Intake of >20 µg of levothyroxine per day
Extraglandular production	Struma ovarii Metastatic thyroid cancer

TSab, thyroid–stimulating antibody; TSH, thyroid–stimulating hormone; hCG, human chorionic gonadotropin.

Table 103.1. Causes of Hyperthyroidism

WORKUP

Diagnosis of Hyperthyroidism. Clinical recognition of hyperthyroidism can sometimes be difficult, especially when symptoms are mild or when the condition occurs in an elderly or pregnant patient. Moreover, the correlation between symptoms and thyroid hormone levels is often poor, so that careful laboratory confirmation of the diagnosis and the severity of the condition are necessary.

Thyroid-stimulating Hormone Assay. The *serum TSH* determination has become the test of choice for screening patients for hyperthyroidism. A marked improvement in the sensitivity of the TSH assay through the use of radioimmunologic techniques now makes it possible to diagnose hyperthyroidism solely on the basis of an absence of detectable TSH. As long as the hypothalamic–pituitary axis is intact, an absence of TSH represents the appropriate response to too much circulating thyroid hormone. A normal TSH level by radioimmunoassay virtually rules out hyperthyroidism unless a functioning pituitary adenoma is present. A low TSH level (<0.1 mIU/L) suggests subclinical hyperthyroidism resulting from suppressive thyroxine therapy or an autonomously functioning gland (e.g., thyroid adenoma, subclinical Graves' disease). It may also be seen in older persons without hyperthyroidism. Undetectable TSH by second- or third-generation assay is diagnostic of hyperthyroidism.

Thyroid Hormone Levels. The sensitivity of second- and third-generation TSH assays has markedly reduced the need for thyroid hormone determinations in screening for hyperthyroidism. They can, however, help to confirm the diagnosis and determine the severity of disease and should be obtained when the TSH level is low or undetectable. The *free T_4* or *free T_4 index* (an excellent proxy for the free T_4, calculated by multiplying the serum T_4 by the T_3 resin uptake) is the most useful and consequently the preferred determination of circulating thyroid hormone. Measurement of the serum total T_3 is usually not necessary unless the patient is clinically thyrotoxic in the setting of normal or only slightly elevated levels of free T_4. Routinely measuring the serum T_3 is probably wasteful because T_3 toxicosis is uncommon.

As useful as thyroid hormone levels are for diagnosis, overreliance on them and failure to use the TSH assay can be misleading. *Euthyroid hyperthyroxemia* occurs when an increase in thyroid-binding globulin (e.g., pregnancy, estrogen use, liver disease) produces an increase in total T_4, while the free T_4 remains normal. More confusing are euthyroid states with increases in both free and total T_4. Patients with autoantibodies against thyroid hormones may manifest surprisingly high levels of free hormone because of interference by these immunoglobulins with the standard radioimmune assays for thyroid hormones. Acute medical, surgical, and psychiatric illnesses, in addition to intake of high doses of propranolol, amiodarone, and gallbladder dyes, can impair the peripheral conversion of T_4 to active T_3 and lead to a rise in free T_4 concentration in conjunction with a reduction in T_3 and an increase in reverse T_3. An unexpectedly normal or low T_3 level in a patient who is clinically euthyroid but has elevated T_4 and free T_4 levels should suggest the possibility of euthyroid hyperthyroxemia. The T_3 concentration helps in the differentiation.

Thyrotropin-releasing Hormone stimulation testing is sometimes used when hyperthyroidism is suspected but serum thyroxine levels are equivocal. In patients with genuine hyperthyroidism, the TSH response to thyrotropin-releasing hormone (TRH) is minimal or absent. This reflects suppression of the pituitary by elevated levels of thyroid hormone. However, cortisol hypersecretion can also suppress the TSH response to TRH, simulating the pattern seen with hyperthyroidism. With the advent of a very sensitive TSH assay, TRH stimulation testing is rarely necessary, but it remains among the most sensitive of tests for the detection of hyperthyroidism.

Identifying the Underlying Cause. Etiologic assessment should proceed once the diagnosis of hyperthyroidism has been confirmed because treatment based on such an assessment is usually the most successful.

History. Inquiry should be made into goiter, thyroid nodule, use of iodides or thyroid hormone, eye changes, recent pregnancy or viral illness, and known ovarian, pituitary, or thyroid neoplasm. A review of systems should include a search for symptoms of a pituitary tumor (see Chapter 100 and Chapter 101).

Physical Examination focuses on the *thyroid gland*, with a check for overall size and nodularity. A diffusely enlarged, nontender gland suggests Graves' disease; in rare instances, a TSH-secreting tumor may be responsible for such diffuse glandular stimulation. A bruit may accompany the diffusely enlarged gland of Graves' disease. An exquisitely tender, diffusely enlarged gland occurring in the context of a viral illness points to subacute thyroiditis. The gland in lymphocytic thyroiditis is nontender and diffusely, but only modestly, enlarged. A small gland indicates an extrathyroidal source of hormone. Multinodularity is consistent with a toxic multinodular goiter and also occurs in patients with Hashimoto's thyroiditis. An otherwise atrophic gland with a single nodule, especially if larger than 3 cm in diameter, strongly suggests toxic adenoma.

Extrathyroidal findings may be of diagnostic significance and should be noted. *True proptosis* (eye protrusion of >20 mm from the orbital bone) is a hallmark of Graves' disease, as is *pretibial myxedema*. Lid lag and stare are nonspecific consequences of hyperthyroidism and may simulate proptosis. The neck nodes should be checked for adenopathy. Painless cervical lymphadenopathy raises the question of a thyroid malignancy. A pelvic examination and visual field testing are important to check for ovarian and pituitary sources.

Laboratory Studies. The *thyroid scan* can help differentiate among possible causes when the clinical picture remains uncertain. A toxic adenoma will be identified as a "hot" nodule, with little uptake by the rest of the gland. Uptake will be low in patients with thyroiditis, exogenous hormone intake, extraglandular hormone production, and iodide exposure. Uptake will be diffusely increased in patients with Graves' disease or a functioning pituitary adenoma.

Antithyroid antibodies (including those directed against microsomal peroxidase) are increased in both Graves' disease and lymphocytic (Hashimoto's) thyroiditis, so that their diagnostic utility is limited. *Serum thyroglobulin* determination serves as an elegant yet simple means of detecting a patient who is surreptitiously taking thyroid hormone. Exogenous hormone use results in the suppression of thyroglobulin synthesis. *Whole-body scanning* will identify the rare cases of extrathyroidal hormone synthesis, such as occurs in a struma ovarii or a metastasis from a thyroid malignancy.

A host of nonspecific hematologic and serum chemistry abnormalities accompany hyperthyroidism, but they are of little etiologic significance. They include a mild degree of anemia, granulocytosis, lymphocytosis, hypercalcemia, transaminase elevation, and alkaline phosphatase elevation.

Screening for Osteoporosis. Excessive amounts of thyroid hormone are associated with an increased risk for osteoporosis, especially in cortical bone, because of increased bone turnover. The risk for thyroid-induced osteoporosis and hip fracture is greatest in postmenopausal women with a history of hyperthyroidism or thyroid suppressive therapy. Such women should have a screening bone density examination of the hip or wrist (sites with a predominance of cortical bone).

PRINCIPLES OF THERAPY

The goals of therapy are to correct the hypermetabolic state with a minimum of side effects and the smallest possible incidence of hypothyroidism. For definitive therapy, one must choose among antithyroid drugs, radioiodine, and thyroidectomy. b-Blocking agents are useful for prompt, temporary control of hyperadrenergic symptoms. Hyperthyroidism should not go untreated, particularly in the elderly, who are at risk for cardiovascular complications. Moreover, not only are symptoms uncomfortable, but thyrotoxic crisis may ensue if the untreated patient unexpectedly encounters a severe stress, such as emergency surgery or acute sepsis.

Therapeutic Modalities

b-Blocking agents inhibit the adrenergic effects of excess thyroid hormone. As such, they provide excellent, prompt, symptomatic relief from many of the catecholamine-mediated manifestations of hyperthyroidism (e.g., tremor, palpitations, heat intolerance, nervousness). However, b-blockers have no intrinsic antithyroid activity, except perhaps at very high doses (which may slow the peripheral conversion of T_4 to T_3). Control of symptoms can often be achieved within a few days, so that these agents are an excellent choice for first-line therapy and preoperative treatment. b-Blockers may suffice for the treatment of transient hyperthyroidism, but they must be used in conjunction with other treatment modalities for the definitive control of persistent disease.

b-Blockers are particularly valuable for minimizing the major cardiac complications of hyperthyroidism (e.g., atrial fibrillation and angina; see Chapter 28 and Chapter 30). Patients with rate-related heart failure will also benefit from b-blockade, but the condition of those with heart failure resulting from myocardialpathology will worsen with such therapy. Consequently, b-blockade must be administered with care in elderly patients and those with preexisting heart disease (see Chapter 32).

Of the b-blockers, propranolol remains the most widely used for control of hyperthyroidism, but other agents in this class (e.g., atenolol, metoprolol, nadolol) demonstrate comparable efficacy. Those with a more sustained half-life (e.g., atenolol) are particularly useful for patients who are to undergo surgery. Adequacy of the dose is determined by monitoring the resting and exercise heart rates and the degree of symptomatic relief.

One important benefit of b-blockade is that it becomes possible to proceed safely with thyroid surgery within 1 to 2 weeks. With antithyroid drugs (see below), 6 to 8 weeks of preoperative treatment is required. The addition of *potassium iodide* to b-blocker therapy produces more rapid and greater preoperative control in patients with Graves' disease who are to undergo thyroidectomy; it is especially useful in those whose condition is not adequately controlled on b-blockers alone (control being defined as a resting pulse of <90 beats/min and a blunting of exercise-induced tachycardia).

Antithyroid Drugs. *Methimazole* and *propylthiouracil* (PTU) are the most important antithyroid agents. PTU acts by interfering with the synthesis of T_4 and blocking the peripheral conversion of T_4 to T_3, although at conventional doses, this latter effect does not appear to be clinically important. Methimazole does not have any peripheral effect but is more potent. Both drugs suppress thyroid autoimmunity and decrease circulating TSab. A biochemical response to the antithyroid drugs is detectable within 1 to 2 weeks; the clinical response typically takes 4 to 8 weeks.

These antithyroid agents are widely used in *young* and *middle-aged patients*, particularly for the long-term control of *Graves' disease*. They are also used for preoperative control and in many instances for therapy before and after radioiodine ablation. The average initial dosage of PTU is 300 mg/d (100 mg every 8 hours). For methimazole, the starting dosage is 15 mg/d, which can be given as a single dose because its half-life is much longer. Therapy is adjusted as needed to attain clinical and biochemical control. Once control is achieved, the dose can be tapered to the lowest amount needed to maintain a euthyroid state. Usually, treatment is continued for 12 to 24 months and then halted to see if relapse occurs.

The chance for long-term remission in Graves' disease is enhanced by 1 to 2 years of antithyroid drug therapy. PTU induces a remission in approximately 50% of patients with Graves' disease who are treated for 1 to 2 years, but one third to one half of those who respond eventually relapse. Reports of a remission rate of 40% after only 3 to 5 months of antithyroid therapy initially raised hopes that a shorter course of treatment might suffice, but longer-term follow-up revealed increased rates of relapse. Combination programs in which higher doses of antithyroid medication are given in conjunction with thyroxine have not proved advantageous, and they increase the risk for adverse effects of antithyroid drugs. The risk for inducing hypothyroidism is low. For patients who relapse or fail to achieve remission, radioiodine or surgical therapy must be considered.

Common adverse effects include skin rash, fever, and arthralgias; these are usually not of major clinical significance. However, the rare (0.3% to 0.6% of patients) but potentially fatal complication of *agranulocytosis* necessitates careful patient selection and close monitoring of therapy. The risk for agranulocytosis increases with age (beginning at about age 40) and is independent of the dose for PTU but dose-dependent for methimazole. Onset is usually within 2 months, rarely beyond 4 months. The development of agranulocytosis has not been reported in any patients taking less than 30 mg of methimazole per day, so this drug is the safer of the two.

Because the drop in granulocyte count is precipitous, it is not clear that close monitoring of blood counts is beneficial, but many clinicians consider it advisable during the first 4 months of therapy. Mild leukopenia is common, occurring in up to 10% of patients, and does not require cessation of treatment. If the leukocyte count falls below 1,500/mm^3, therapy should be withheld.

Choice of antithyroid agent has been a subject of debate. With proper monitoring, either antithyroid drug is a reasonable choice. Although PTU is more widely prescribed, *methimazole* appears *preferable* in terms of cost, hematologic side effects, and ease of administration. It also has no adverse effect on the response to radioiodine therapy when used before ablative therapy, an effect sometimes seen with PTU. At doses up to 30 mg/d, methimazole is about 30% lower in cost than a

comparable dose of PTU, is much less likely to induce agranulocytosis, and needs to be taken only once daily. PTU is preferable during pregnancy and breast-feeding (see below).

Ablation with Radioactive Iodine (Iodine 131), an important form of therapy, was first introduced in 1942 and is widely used today, especially for older hyperthyroid patients, in whom the long-term effects of radiation exposure are not a major concern. It is indicated for patients with Graves' disease when antithyroid drugs do not suffice, when they are elderly or noncompliant or have a solitary toxic nodule, and when surgery is contraindicated or the patient is reluctant to undergo surgery. Advantages include established efficacy, relative safety, and ease of administration. Disadvantages are delayed control of symptoms and a high incidence of hypothyroidism following therapy.

Among the *side effects* of radioactive iodine therapy, the most common complication is *hypothyroidism.* High-dose radioiodine provides predictable relief but is associated with a high incidence of early hypothyroidism (70% in the first year). The early risk for hypothyroidism is lower with low-dose regimens (15% in the first year), but they provide less control of the disease (50% of patients still hyperthyroid at 1 year). Long-term follow-up studies of patients given low-dose treatment indicate a steady increase in the cumulative incidence of hypothyroidism (75% at 11 years), suggesting that its early advantages fade with time. Regardless of the dose used, the risk for eventual hypothyroidism requires that patients be regularly reevaluated, typically at 6-month intervals.
